DICTIONARY OF CHEMISTR

VOL. I.

LONDON: PRINTED BY
SPOTTISWOODE AND CO., NEW-STREET SQUARE
AND PARLIAMENT STREET

A DICTIONARY

OF

CHEMISTRY

AND THE

ALLIED BRANCHES OF OTHER SCIENCES.

BY

HENRY WATTS, B.A., F.R.S., F.C.S.

EDITOR OF

'THE JOURNAL OF THE CHEMICAL SOCIETY.'

ASSISTED BY EMINENT CONTRIBUTORS.

IN FIVE VOLUMES.

VOL. I.

ABICHITE—CONGLOMERATE.

LONDON:
LONGMANS, GREEN, AND CO.
1868.

PREFACE.

THIS WORK was originally intended as a New Edition of Ure's *Dictionary of Chemistry and Mineralogy*; but the great changes made in chemical science since the publication of the last edition of that Dictionary (1831)—changes, not merely consisting in the addition of new discoveries, but involving a complete revolution in the mode of viewing and expressing chemical reactions—have rendered it almost impossible to adapt any matter written so long ago to the existing requirements of the science. The present must therefore be regarded as essentially a new work, in which only a few articles of Ure's *Dictionary* are retained, chiefly of a descriptive character. In compiling it, the Editor has freely availed himself of the stores of information in Gmelin's "Handbook," Gerhardt's "Chimie Organique," Rose's "Traité d'Analyse Chimique," Dana's "Mineralogy," Rammelsberg's "Mineralchemie," the "Handwörterbuch der Chemie," &c.; and has endeavoured, by careful consultation of original memoirs, to bring the treatment of each subject down to the present time. He has also been fortunate in obtaining the co-operation of several chemists of acknowledged ability and eminence, who have kindly contributed articles on subjects to which they have paid special attention:—a List of their names is given on the next leaf.

The work is essentially a Dictionary of Scientific Chemistry, and is intended as a Companion to the New Edition of Ure's *Dictionary of Arts, Manufactures, and Mines*, to which therefore reference is, for the most part, made for the details of manufacturing operations; but those branches of chemical manufacture which have come into existence, or have received important developements, since the publication of that work, are described in this Dictionary as fully as its limits will allow, and in all cases explanations are given of the principles on which manufacturing processes are conducted, and the chemical changes which they involve. Particular attention has also been given to the description of processes of Analysis, both qualitative and quantitative.

In order that the work may, as far as possible, truly represent the present state of scientific chemistry, it has been found absolutely necessary to make the modern or "unitary" scale of atomic weights the basis of the system of notation and mode of exposition adopted. Especial care has, however, been taken that the treatment of all Articles which are likely to be consulted, for the sake of practical information, by manufacturers, or others not exclusively occupied in chemical pursuits, shall be such as to make them readily intelligible to all who possess a general knowledge of chemistry, though they may not have followed closely the recent developements of the theoretical parts of the science. Hence, in all such Articles (as ACETIC ACID, ANTIMONY, COPPER, &c.) the formulæ are given according to the old notation (printed for distinction, in *Italics*), as well as according to that adopted in the rest of the work.

Temperatures are given on the *centigrade* scale, excepting when the contrary is expressly stated.

HENRY WATTS.

7 PROVOST ROAD, LONDON, N.W.
July 1863.

LIST OF CONTRIBUTORS.

EDMUND ATKINSON, Ph.D. F.C.S.
Professor of Chemistry at the Royal Military College, Sandhurst.

FRANCIS T. CONINGTON, M.A. F.C.S. (the late)
Fellow of Corpus Christi College, Oxford, and Examiner in Natural Science at that University; Author of a 'Handbook of Chemical Analysis.'

WILLIAM DITTMAR, Esq.
Principal Assistant in the Chemical Laboratory of the University of Edinburgh.

FREDERICK FIELD, F.R.S. F.R.S.E.
(lately) Professor of Chemistry at St. Mary's Hospital.

GEORGE C. FOSTER, B.A. F.C.S.
Professor of Physics at University College, London.

MICHAEL FOSTER, M.D.
Lecturer on Practical Physiology and Histology at University College, London.

EDWARD FRANKLAND, Ph.D. F.R.S.
Foreign Secretary of the Chemical Society; Professor of Chemistry at the Royal Institution of Great Britain, and at the Royal School of Mines.

FREDERICK GUTHRIE, Ph.D. F.C.S.
Professor of Chemistry at the Royal College, Mauritius.

M. L'ABBÉ A. HAMY,
Paris.

MICHAEL HANHART, Esq.
Lithographer.

A. W. HOFMANN, LL.D. F.R.S. V.P.C.S.
Professor of Chemistry at the University of Berlin.

WILLIAM S. JEVONS, M.A.
Cobden Professor of Political Economy at Owens College, Manchester; (lately) Gold Assayer in the Sydney Royal Mint.

CHARLES E. LONG, Esq. F.C.S. (the late)
Analytical Chemist.

WILLIAM ODLING, M.B. F.R.S.
Secretary to the Chemical Society, and Professor of Chemistry at St. Bartholomew's Hospital, Author of a 'Manual of Chemistry.'

BENJAMIN H. PAUL, Ph.D. F.C.S.
Consulting Chemist.

THOMAS RICHARDSON, Ph.D. F.R.S. &c. (the late)
Reader in Chemistry at the University of Durham.

HENRY E. ROSCOE, Ph.D. F.R.S. F.C.S.
Professor of Chemistry at Owens College, Manchester.

WILLIAM J. RUSSELL, Ph.D. F.C.S.
Of University College, London.

J. A. WANKLYN, F.R.S.E. F.C.S.
Professor of Chemistry at the London Institution.

C. GREVILLE WILLIAMS, F.R.S.
Author of a 'Handbook of Chemical Manipulation.'

ARTHUR WINCKLER WILLS, Esq.
Analytical and Manufacturing Chemist, Wolverhampton. (W. W.)

⁂ Articles communicated by the several contributors are signed with their initals; articles taken from URE's *Dictionary of Chemistry* (fourth edition, 1831) are signed with the letter U; those which have no signature are by the Editor.

DICTIONARY OF CHEMISTRY.

A

ABICHITE. (*Aphanesite, Strahlerz, Strahlenkupfer.*) A native arsenate of copper, found chiefly associated with other copper ores and veins in Cornwall, and in the Hartz. The crystals belong to the monoclinic or oblique prismatic system, but they seldom exhibit any definite shape, being aggregated in radiating groups, or disposed, as extremely minute individuals, in cavities of quartz. Sp. gr. 4·2 to 4·4. Hardness, 2·5 to 3. Translucent or opaque, with vitreous lustre. Colour, blackish green inclining to blue. Streak, bluish-green. Dana (Mineralogy, ii. p. 428) gives for this mineral the formula $3CuO.AsO^5 + 3CuO.HO$*, or $AsCu^3O^4 + Cu^2HO^2$, deduced from the analyses of Rammelsberg and Damour. L. Gmelin (Handb. v. 471) gives the formula $5CuO.AsO^5 + 5HO$, deduced from the analysis of Chenevix, who found 54 per cent. of protoxide of copper, 30 per cent. of anhydrous arsenic acid, and 16 per cent. of water.

ABIETIC ACID. $C^{20}H^{30}O$? When Strasburg or Canadian turpentine (obtained respectively from *Abies picea* and *Abies balsamea,*) is distilled with water; the residue exhausted with absolute alcohol; the solution evaporated to dryness; the residual resin boiled with twice its weight of solution of carbonate of potassium; the alkaline liquid poured off; and the residue, which is a mixture of abietin and abietate of potassium, treated with 30 times its weight of water, — abietin separates in the crystalline form, while abietate of potassium remains in solution. This solution may be decomposed by sulphuric or hydrochloric acid, and the precipitated abietic acid purified by digestion in hot aqueous ammonia. As thus obtained, it is a resinous mass which dissolves easily in alcohol, ether and volatile oils, forming acid solutions, from which it separates in the crystalline state. At 55° it becomes soft and translucent. Its barium-salt is said to contain 191 parts of the acid to 76·6 parts (1 at.) of baryta. The acid is perhaps identical with sylvic or pymaric acid. (Caillot, J. Pharm. xvi. 436; Gerh. iii. 656.)

ABIETIN. Prepared as above. It is a tasteless inodorous resin, insoluble in water, soluble in alcohol, especially at the boiling heat, also in ether, rock-oil, and strong acetic acid, and separates in the crystalline form from these solutions by evaporation. It melts when heated, and solidifies in a crystalline mass on cooling. It is not acted upon by caustic potash. (Caillot.)

ABRAZITE. (*Gismondin.*) A mineral of the zeolite family, containing, according to Marignac's analysis:

$$8(CaKO.SiO^2) + 4Al^4O^3.SiO^2 + 18H^2O; \qquad [Si=28;\ O=16].$$
$$\text{or } 2(CaO.KO).SiO^3 + 2(Al^2O^3.SiO^3) + 9HO; \qquad [Si=21;\ O=8].$$

It is found on Vesuvius, at Aci-Castello in Sicily, and at Capo di Bove, near Rome. It occurs united with Phillipsite in quadratic octahedrons, generally aggregated in

---

* The atomic weights adopted in this work are those of the unitary system (H = 1; O = 16; S = 32; C = 12). Frequently, however, the formulæ of compounds will likewise be given according to the dualistic system ($O = 8$, $S = 16$, $C = 6$); and for distinction, these latter formulæ will be printed in italics.

masses. Transparent or translucent, with greyish-white colour. Hardness = 4·5. Sp. gr. = 2·265. Gives off one-third of its water at 100°. Easily dissolves in acids and gelatinises. It was formerly supposed to be a variety of Phillipsite or lime-harmotome; but it differs from harmotome in composition as well as in crystalline form, the latter mineral crystallising in the dimetric system. (Dana, ii. 322.)

ABSINTHIN. $C^{16}H^{22}O^{5}$. The bitter principle of wormwood (*Artemisia absinthium*). It is prepared in the pure state, according to Luck, by exhausting the leaves of wormwood with alcohol, evaporating the extract to the consistence of a syrup, and agitating with ether. This ethereal solution is evaporated to dryness, and the residue treated with water containing a little ammonia, which dissolves the resin, and leaves the absinthin nearly pure. To complete the purification, it is digested with weak hydrochloric acid, washed with water, dissolved in alcohol, and treated with acetate of lead, as long as a precipitate is formed. After the removal of this precipitate by filtration, the excess of lead is precipitated by sulphuretted hydrogen, and the solution is evaporated. The absinthin then remains as a hard, confusedly crystalline mass, possessing an extremely bitter taste. It is but slightly soluble in water, very soluble in alcohol, and less so in ether. It possesses distinctly acid characters, and is dissolved by potash and ammonia. (Mein, Ann. Ch. Pharm. viii. 61; Luck, ibid. lxxviii. 87; Gerh. iv. 258.)

ABSORPTION OF GASES. See Gases.

ACACIN, or **ACACIA-GUM.** Known in commerce as *gum-arabic.* See Arabin and Gum.

ACADIOLITE. A variety of chabasite from New Caledonia, distinguished by its large amount of alkali. (Hayes, Sill. Am. J. [2] I. 122.)

ACAJOU. The stem of the Acajou or Cashew-nut tree, *Anacardium occidentale*, yields a yellow gummy substance, sparingly soluble in water, which is a mixture of ordinary gum and bassorin. The pericarp of the nuts of the same tree contains a large quantity of a red-brown resinous substance, which produces inflammation and blistering of the skin. It may be extracted by ether, and the ethereal solution when slowly evaporated, leaves a residue consisting of a network of small crystals of anacardic acid, soaked in an oily liquid called cardol, to which the resin owes its acrid properties (Städeler, Ann. Ch. Pharm. lxiii. 137). The name acajou is also applied to a gum and resin obtained from the stem of the mahogany-tree. The gum resembles that of the cherry-tree.

ACAROID RESIN. The resin of *Xanthorrhea hastilis*, a liliaceous tree growing in New Holland; also called resin of Botany Bay. It has a yellow colour, an agreeable odour, and is soluble in alcohol, ether, and caustic potash. Its potash-solution treated with hydrochloric acid deposits benzoic and cinnamic acids. Nitric acid converts it into picric acid, and so readily, that this resin appears to be the best raw material for obtaining picric acid. By distillation, the resin yields a light neutral oil, which appears to be a mixture of benzol and cinnamol, and a heavy acid oil, consisting of hydrate of phenyl, mixed with small quantities of benzoic and cinnamic acids. (Stenhouse, Ann. Ch. Pharm. lvii. 84.)

ACECHLORIDE OF PLATINUM. See Acetone, *Decompositions* (p. 29).

ACEDIAMINE. $C^{2}H^{6}N^{2}$. When hydrochlorate of acetamide is heated in a sealed tube to 180°—200°, and the product afterwards distilled, or when acetamide is distilled in a stream of dry hydrochloric acid gas, several volatile products pass over, and a residue is left consisting of hydrochlorate of acediamine, mixed with sal-ammoniac. (See Acetamide):

$$\underbrace{2C^{2}H^{5}NO}_{\text{Acetamide.}} + HCl = \underbrace{C^{2}H^{6}N^{2}.\ HCl}_{\substack{\text{Hydrochlorate}\\ \text{of acediamine.}}} + \underbrace{C^{2}H^{4}O^{2}}_{\text{Acetic acid.}}.$$

Alcohol extracts the hydrochlorate of acediamine from this residue, and deposits it by spontaneous evaporation in prismatic crystals, which may be completely freed from adhering sal-ammoniac by solution in a mixture of alcohol and ether, and evaporation in vacuo. The hydrochlorate decomposed by sulphate of silver, yields the *sulphate of acediamine* $(C^{2}H^{6}N^{2})^{2}.\ SO^{4}H^{2}$, which crystallises in colourless nacreous laminæ, easily soluble in water. The aqueous solution of the hydrochlorate mixed with dichloride of platinum yields the *chloroplatinate of acediamine*, $C^{2}H^{6}N^{2}.\ HCl.\ PtCl^{2}$, in rather large, hard, yellowish red prisms.

Acediamine is very unstable, and cannot be obtained in the free state. When the sulphate or hydrochlorate is heated with potash or baryta, ammonia is given off, and an acetate of the alkali is produced:

$$C^{2}H^{6}N^{2} + 2H^{2}O = C^{2}H^{4}O^{2} + 2NH^{3}.$$

Acediamine may be regarded as ammonia in which 1 at. H is replaced by the monatomic radical C^2H^4N (azethyl), its rational formula being then $N.H^2.C^2H^4N$ or as a double molecule of ammonia, N^2H^6, having 3 at. H replaced by the triatomic radical C^2H^3, making its formula $N^2.H^3.(C^2H^3)'''$ It bears the same relation to acetamide as ethylamine to alcohol:

$$C^2H^6O + NH^3 = C^2H^7N + H^2O: \text{ and } C^2H^3NO + NH^3 = C^2H^6N^2 + H^2O.$$

(Strecker, Ann. Pharm. ciii. 328.)

ACEPHOSGENIC ACID and **ACEPHOSSIC ACID.** Compounds produced by the action of phosphorus on acetone (see page 28).

ACETAL. $C^6H^{14}O^2$.—[Gm. ix. 38; Gerh. ii. 268.] A product of the oxidation of alcohol, first observed by Döbereiner, more fully examined by Liebig (Ann. Ch. Pharm. v. 25; xiv. 156), still further by Stas (Ann. Ch. Phys. [3] xix. 146), who first correctly determined its empirical formula, and finally by Wurtz (Compt. rend. xlviii. 478; Ann. Ch. Phys. [3] xlviii. 370; Ann. Ch. Pharm. cviii. 84). It is also obtained from aldehyde. (Wurtz and Frapolli, Ann. Ch. Pharm. cvii. 228.)

Preparation. I. From *Alcohol.* 1. By the imperfect oxidation of alcohol, under the influence of platinum-black. Pieces of pumice-stone previously washed and ignited are moistened with nearly absolute alcohol, and placed at the bottom of a large wide-necked flask, which is then filled up with capsules containing platinum-black, covered with a glass plate, and exposed to a temperature of 20°, till the whole of the alcohol is acidified. Alcohol of 60 per cent. is then poured into the flask, in quantity not quite sufficient to cover the pumice-stones, and the flask left to itself for two or three weeks in a room at a temperature of 20°, the glass plate being removed from time to time to admit fresh air. The thickish liquid is then drawn off, and the same process repeated with fresh alcohol, till several quarts of thickish acid liquid are obtained. This liquid is neutralised with carbonate of potassium, saturated with chloride of calcium and distilled, and the first fourth of the distillate is saturated with fused chloride of calcium, which separates from it a mixture of alcohol, acetic-ether, aldehyde, and acetal. The aldehyde is removed by distillation over the water-bath; the residue treated with strong potash to decompose the acetic ether; the alcohol removed by washing with water; and the remaining liquid, the acetal, dried over chloride of calcium and rectified. (Stas.)

2. By distilling alcohol with dilute sulphuric acid and peroxide of manganese. A mixture of 2 parts alcohol, 3 parts peroxide of manganese, 3 parts sulphuric acid, and 2 parts water (the proportions given by Liebig for the preparation of aldehyde), is subjected to distillation as soon as the frothing which first ensues has ceased; 3 parts of liquid are distilled off; the distillate is rectified; and the portion which goes over at 80° is collected apart from that which distils between 80° and 95°. The first portion is mixed with chloride of calcium and rectified, the distillate obtained below 60° chiefly consisting of aldehyde, while above 60° a product is obtained, which, when treated with a strong solution of chloride of calcium, yields an ethereal liquid. The portion of the former liquid which came over between 80° and 95°, is also rectified, and the first portion of the resulting distillate treated with strong solution of chloride of calcium, whereupon it likewise yields an ethereal liquid. These ethereal liquids, containing aldehyde, acetic ether, &c. and acetal are united, and shaken with caustic potash to resinise the aldehyde and decompose the acetic ether. The brown liquid which floats upon the potash-solution is separated and distilled; the distillate again mixed with chloride of calcium; the liquid thus separated is heated to 100° for twenty-four hours with twice its volume of caustic potash in a sealed tube; the lower stratum is rectified; the distillate again shaken with chloride of calcium; and the separated liquid is digested with pulverised chloride of calcium, and submitted to simple rectification. Pure acetal then distils over from 100° to 105°. (Wurtz.)

3. By the action of chlorine upon alcohol, acetal being indeed the principal product of that reaction, so long as no substitution-products are formed:

$$3C^2H^6O + 2Cl = C^6H^{14}O^2 + 2HCl + H^2O.$$

Chlorine is passed through 80 per cent. alcohol cooled to between 10° and 15°, till a portion becomes turbid on the addition of water, indicating the formation of substitution-products. One fourth of the strongly acid liquid is then distilled off; the distillate neutralised with chalk; one fourth again distilled off; and the distillate, consisting of alcohol, acetic ether, aldehyde and acetal, treated as above to separate the acetal. (Stas.)

According to Lieben (Ann. Ch. Phys. [3] lii. 313), the chief products of the action of chlorine on alcohol of 80 per cent. are monochloracetal and dichloracetal. (p. 5.)

II. From *Aldehyde.* 1. By treating aldehyde with pentabromide of phosphorus, whereby it is converted into *bromide of ethylidene* $C^2H^4Br^2$ (a compound isomeric with bromide of ethylene), and acting on this compound with ethylate of sodium.

$$C^2H^4Br^2 + 2C^2H^5NaO = 2NaBr + 2C^6H^{14}O^2.$$

This mode of preparation is, however, very troublesome, on account of the difficulty of obtaining the bromide of ethylidene. Chloride of ethylidene $C^2H^4Cl^2$, (produced by the action of pentachloride of phosphorus on aldehyde) does not appear to yield acetal when treated with ethylate of sodium.

2. By passing hydrochloric acid gas into a mixture of 1 vol. aldehyde and 2 vols. absolute alcohol immersed in a freezing mixture, whereby the compound C^4H^9ClO is obtained in the form of an ethereal liquid floating on aqueous hydrochloric acid,—and treating this compound with ethylate of sodium:

$$\begin{aligned} & C^2H^4O + C^2H^6O + HCl = C^4H^9ClO + H^2O \\ \text{and}\quad & C^4H^9ClO + C^2H^5NaO = NaCl + C^6H^{14}O^2 \end{aligned}$$

(Wurtz and Frapolli, Compt. rend. xlvii. 418; Ann. Ch. Pharm. cviii. 223.)

Properties.—Pure acetal is a colourless liquid, less mobile than ether, having a peculiar agreeable odour and a refreshing taste, with an after-taste like that of hazel nuts. Sp. gr. 0·821 at 22·4. Boils at about 105° C., with the barometer at 0·768 met. Vapour density = 4·141.

It dissolves in eighteen times its volume of water at ordinary temperatures, the solubility increasing as the temperature rises. From the aqueous solution it is separated by chloride of calcium and other soluble salts. Ether and alcohol dissolve it in all proportions.

Decompositions.—1. Acetal is not altered by mere exposure to the air, but in contact with platinum-black it is quickly converted, first into aldehyde, and then into acetic acid:

$$\underbrace{C^6H^{14}O^2}_{\text{Acetal.}} + 2O = \underbrace{3C^2H^4O}_{\text{Aldehyde.}} + H^2O.$$

It is likewise oxidised by nitric and by chromic acid. 2. Caustic alkalies do not decompose it, if the air is excluded. 3. Chlorine abstracts hydrogen from it and forms substitution-products. 4. Strong sulphuric acid dissolves and then decomposes it, the mixture turning black. 5. Hydrochloric acid likewise dissolves and blackens it, forming choride of ethyl. 6. Pentachloride of phosphorus acts strongly upon it, forming a large quantity of chloride of ethyl, together with other products. 7. Heated in a sealed tube with several times its weight of glacial acetic acid, it yields acetic ether, more than 1 atom of that compound being formed from 1 atom of acetal.

These reactions tend to show that acetal is an ethyl-compound. Stas regarded it as a compound of 1 at. aldehyde with 1 at. ether:

$$C^2H^4O + C^4H^{10}O = C^6H^{14}O^2;$$

and Wurtz, in his earlier researches on glycol (Compt. rend. xliii. 478), regarded it as glycol $\left.\begin{matrix} C^2H^4 \\ H^2 \end{matrix}\right\} O^2$, in which 2 at. hydrogen are replaced by ethyl $\left.\begin{matrix} C^2H^4 \\ (C^2H^5)^2 \end{matrix}\right\} O^2$. This view of its constitution was corroborated by the result of distilling a mixture of alcohol and wood-spirit with sulphuric acid and peroxide of manganese, whereby a distillate was obtained consisting of *dimethylate of ethylene* $\left.\begin{matrix} C^2H^4 \\ (CH^3)^2 \end{matrix}\right\} O^2$, and methylethylate of ethylene $\left.\begin{matrix} C^2H^4 \\ CH^3.C^2H^5 \end{matrix}\right\} O^2$. Subsequent researches have however shown that acetal is not identical, but only isomeric with diethyl-glycol, or diethylate of ethylene $C^2H^4.(C^2H^5)^2.O^2$. For, when glycol $C^2H^4.H^2.O^2$ is treated with sodium, 1 at. hydrogen is eliminated, and the compound $C^2H^4.NaH.O^2$ is obtained. This compound treated with iodide of ethyl yields *ethylate of ethylene* $C^2H^4.C^2H^5.H.O^2$, whence, by the action of potassium, the compound $C^2H^4.C^2H^5.K.O^2$ is produced; and, lastly, this compound treated with iodide of ethyl yields *diethylate of ethylene* $C^2H^4.(C^2H^5)^2.O^2$. Now this liquid has a specific gravity of 0·7993 at 0° C., and boils at 123·5 C., whereas acetal has a sp. gr. of 0·821 at 22°·4, and boils at 105°, that is to say, 18°·5 lower. Recent experiments by Beilstein (Ann. Ch. Pharm. cxii. 240) seem to indicate that the rational formula of acetal is $C^4H^9O.C^2H^5.O$.

Chloracetals (A. Lieben, Ann. Ch. Phys. [3] lvi. 313). Three of these compounds have been obtained; viz. *mono-*, *di-*, and *tri-chloracetal.* The two former are produced by the action of chlorine on alcohol of ordinary strength (80 per cent.) When the chlorine has been passed through for some time, and the heavy oil which separates on addition of water is washed several times with aqueous chloride of calcium, and submitted to fractional distillation, it begins to boil at 80°, and the boiling point gradually rises to 200°, not, however, remaining stationary at any intermediate point. The portion which distils below 120° consists of aldehyde and compound ethers; that which distils above 120° (which is the larger portion) contains monochloracetal and dichloracetal. On again submitting it to fractional distillation, the greater part goes over between 170° and 185°; this portion consists chiefly of dichloracetal, which may be obtained pure by subsequent rectification. To separate the monochloracetal, the portion of the second distillate boiling below 170°, and the portion of the first distillate which passed over above 120°, are heated for several days with aqueous potash, whereby a watery liquid is obtained, containing chloride and formate of potassium, and an oily liquid consisting chiefly of monochloracetal mixed with dichloracetal; these compounds are finally separated by fractional distillation.

According to Lieben, the product of the action of chlorine on alcohol of ordinary strength does not contain acetal. This is contrary to the statement of Stas, who, in fact, prepared acetal by this very process. Probably the relative quantities of acetal, monochloracetal, and dichloracetal obtained depend on the duration of the action of the chlorine (compare page 3).

Monochloracetal, $C^6H^{13}ClO^2$, is a colourless liquid, having an ethereal aromatic odour, and boiling at about 155°. Vapour-density, by experiment 5·38; by calculation (2 vols.) 5·29. It is perfectly neutral, insoluble in water, soluble in alcohol. It is not attacked by aqueous potash, and does not precipitate nitrate of silver.

Dichloracetal, $C^6H^{12}Cl^2O^2$, is a colourless neutral aromatic liquid of sp. gr. 1·1383 at 14°. Boils at about 180°. Vapour-density, by experiment 6·45; by calculation (2 vols.) 6·435. (Lieben.)

Trichloracetal, $C^6H^{11}Cl^3O^2$, is produced, together with dichloracetal, by the action of chlorine on highly concentrated but not absolute alcohol. (Dumas, Lieben.)

ACETAMIDE. $C^2H^5NO = N.H^2.C^2H^3O$. Produced:

1. By heating acetate of ethyl with strong aqueous ammonia to about 120°:

$$\underbrace{C^2H^3O.C^2H^5.O}_{\text{Acetate of ethyl.}} + NH^3 = \underbrace{NH^2.C^2H^3O}_{\text{Acetamide.}} + \underbrace{C^2H^5.H.O}_{\text{Alcohol.}}$$

2. By the action of ammonia on acetic anhydride:

$$\underbrace{(C^2H^3O)^2O}_{\text{Acetic anhydride.}} + NH^3 = \underbrace{NH^2.C^2H^3O}_{\text{Acetamide.}} + \underbrace{C^2H^3O.H.O}_{\text{Acetic acid.}}$$

3. By distilling acetate of ammonium ($C^2H^4O^2.NH^3 = C^2H^5NO + H^2O$). A large quantity of ammonia is given off at first, then at 160° an acid distillate, consisting chiefly of acid acetate of ammonium; above 160°, a distillate containing acetamide which crystallises in the condensing tube; and above 190° nearly pure acetamide. By saturating glacial acetic acid with dry ammoniacal gas, and then distilling, $\frac{1}{4}$ of the acetic acid may be converted into acetamide. (Kundig, Ann. Ch. Pharm. cv. 277.)

Acetamide is a white crystalline solid, which melts at 78° and boils at 221° or 222°. It deliquesces when exposed to the air, and dissolves readily in water. Heated either with acids or with alkalis, it takes up water, and is converted into acetic acid and ammonia.—Distilled with phosphoric anhydride, it gives up water and is converted into acetonitrile or cyanide of methyl C^2H^3N.—Heated in a stream of dry hydrochloric acid gas, it yields a liquid and a crystalline distillate, and a brownish non-volatile residue. The liquid portion of the distillate consists of strong acetic acid, together with small quantities of chloride of acetyl, and perhaps acetonitrile. The crystalline distillate is a mixture of hydrochlorate of acetamide, and a compound of acetamide and diacetamide $C^2H^5NO.C^4H^7NO^2$; the latter compound may be extracted by ether, in which the hydrochlorate of acetamide is insoluble. The non-volatile residue consists of hydrochlorate of acediamine mixed with sal-ammoniac. The decomposition is represented by the following equations:

$$2C^2H^5NO + HCl = \underbrace{C^4H^7NO^2}_{\text{Diacetamide.}} + NH^4Cl$$

$$2C^2H^5NO + HCl = \underbrace{C^2H^6N^2.HCl}_{\text{Hydrochlorate of acediamine.}} + \underbrace{C^2H^4O^2}_{\text{Acetic acid.}}$$

$$C^2H^5NO + 2HCl = \underbrace{C^2H^3OCl}_{\text{Chloride of acetyl.}} + NH^4Cl;\ C^2H^5NO - H^2O = \underbrace{C^2H^3N.}_{\text{Acetonitrile.}}$$

Acetamide acts both as a base and as an acid, combining with hydrochloric and with nitric acid, and likewise forming salts in which 1 atom of its hydrogen is replaced by a metal.

Hydrochlorate of Acetamide, $(C^2H^5NO)^2.HCl$ is prepared :—

1. By mixing acetamide fused at a gentle heat with oxychloride of phosphorus, dissolving the resulting crystalline mass in absolute alcohol, and leaving the solution to cool, or better, mixing it with ether; hydrochlorate of acetamide is then obtained in colourless crystalline needles. The crystalline mass first produced, appears to be a compound of acetamide and oxychloride of phosphorus, and this, on addition of alcohol, yields phosphate of ethyl and hydrochloric acid, which unites with the acetamide:

$$2C^2H^5NO + POCl^3 + 3(C^2H^5.H.O) = (C^2H^5NO)^2.HCl + P(C^2H^5)^3O^4 + 2HCl.$$

2. By directing a stream of dry hydrochloric acid gas on a solution of acetamide in alcohol and ether cooled from without, washing the resulting crystalline mass with anhydrous ether, and dissolving it in warm alcohol. The solution on cooling, or more quickly on addition of ether, deposits the hydrochlorate in crystals. This mode of preparation is preferable to the former. The compound forms long spear-shaped crystals, having an acid taste and reaction, easily soluble in water and alcohol, but insoluble in ether. Heated in a sealed tube to between 180° and 200°, it decomposes, yielding the same compounds that are obtained by heating acetamide in dry hydrochloric acid gas. (Strecker, Ann. Ch. Pharm. ciii. 321.)

Nitrate of Acetamide, $C^2H^5NO.NO^3H$, is obtained by dissolving acetamide in cold strong nitric acid. It forms colourless acid crystals, which melt at a moderate heat, and detonate at a higher temperature, leaving scarcely any residue.

CHLORACETAMIDES. — *Monochloracetamide*, $C^2H^4Cl.NO = N.H^2.C^2H^2ClO$, is obtained:

1. By the action of ammonia on monochloracetate of ethyl:

$$C^2H^2ClO.C^2H^5.O + NH^3 = N.H^2.C^2H^2ClO + C^2H^6O.$$

2. By bringing perfectly dry ammoniacal gas in contact with chloride of monochloracetyl:

$$C^2H^2ClO.Cl + 2NH^3 = N.H^2.C^2H^2ClO + NH^4Cl.$$

The product is a white amorphous mass, from which absolute alcohol extracts the amide, and deposits it in large shining laminæ. The amide dissolves in 10 parts of water and 10½ parts of alcohol at 24°, but is very sparingly soluble in ether. It is decomposed by potash, yielding chloride and acetate of potassium. (E. Willm. Ann. Ch. Phys. [3] xlix. 99.)

Trichloracetamide. $C^2H^2Cl^3NO = N.H^2.C^2Cl^3O$. This compound is produced by the action of gaseous or aqueous ammonia:

1. On chloride of trichloracetyl:

$$C^2Cl^3O.Cl + 2NH^3 = N.H^2.C^2Cl^3O + NH^4Cl.$$

2. On trichloracetate of ethyl:

$$C^2Cl^3O.C^2H^5.O + NH^3 = N.H^2.C^2Cl^3O + C^2H^6O.$$

3. On chloraldehyde, C^2Cl^4O, or the polymeric compound, perchloracetic ether, $C^4Cl^8O^2$:

$$C^2Cl^4O + 2\,NH^3 = C^2H^2Cl^3NO + NH^4Cl.$$

Also by the action of ammonia on the perchlorinated ethylic ethers of formic, carbonic, oxalic, and succinic acids, all these compounds yielding chloraldehyde when heated. The best product is obtained from perchloracetic ether. The mass is treated with cold water to dissolve the sal-ammoniac, and the residual trichloracetamide is crystallised from ether. It then forms snow-white crystalline laminæ. It dissolves also in boiling water and in alcohol, and crystallises from the aqueous solution in tabular crystals belonging to the rhombic system. It has a sweetish taste; melts at 135°, begins to turn brown at 200°, and boils at about 240°. It gives off ammonia when heated with potash. Ammonia dissolves it after a while, and the solution yields, by evaporation, beautiful prisms of trichloracetate of ammonium. Anhydrous phosphoric acid converts it into chloracetonitrile or cyanide of trichloromethyl: $C^2H^2Cl^3NO - H^2O = C^2Cl^3N$. (Cloez, Ann. Ch. Phys. [3] xvii. 305; Malaguti, ibid. xvi. 5; Cahours, ibid. xix. 352; Gerhardt, Compt. chim. 1848, 277; Traité, i. 760; Gm. ix. 270.)

Tetrachloracetamide, $C^2HCl^4NO = N.H.Cl.C^2Cl^3O$; sometimes called chloracetamic acid, is formed by exposing trichloracetamide, slightly moistened with water, to the action of chorine in sunshine. It then sublimes in needles, which may be purified by crystallisation from ether. It is permanent in the air, melts when heated, and partly sublimes undecomposed. It is nearly inodorous, but has a harsh disagreeable taste. Insoluble in water, but dissolves pretty readily in alcohol and wood-spirit, and very easily in ether. It dissolves without decomposition in cold aqueous alkalis, forming crystallisable salts. When boiled with potash, it gives off ammonia, and leaves chloride and carbonate of potassium:

$$C^2HCl^4NO + 3H^2O = NH^3 + 4HCl + 2\,CO^2.$$

(Cloez, Ann. Ch. Phys. [3] xvii. 305.)

Bromacetamides and *Iodacetamides* are likewise known.

Diacetamide, $C^4H^7NO^2 = NH(C^2H^3O)^2$. The ethereal solution of the compound of acetamide and diacetamide obtained by the action of hydrochloric acid gas on acetamide, deposits, when hydrochloric acid gas is passed through it, spicular crystals of hydrochlorate of acetamide, and the liquid filtered therefrom yields by evaporation over sulphuric acid, crystals of diacetamide, easily soluble in water, alcohol, and ether. The crystals when boiled with acids are resolved into acetic acid and ammonia, but not so readily as acetamide. The alcoholic solution boiled with dichloride of platinum deposits chloroplatinate of ammonium. (Strecker.)

Ethylacetamide. See Ethylamine.

Mercuracetamide, C^2H^4HgNO. An aqueous solution of acetamide saturated with mercuric oxide deposits by evaporation in vacuo, colourless crystalline crusts sparingly soluble in alcohol. *Silver-acetamide*, C^2H^4AgNO, is obtained in a similar manner in crystalline scales.

Phenylacetamide, or Acetanilide, see Phenylamine.

ACETENE. Synonyme of Ethylene and Olefiant Gas.

ACETIC ACID. *Essigsaure, Acide Acétique.* $C^2H^4O^2 = \left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O$, or $C^2H^3O^2.H$. The hydrate or hydrated oxide of acetyl; it may be regarded as a molecule of water (H^2O), in which half the hydrogen is replaced by acetyl C^2H^3O. (It was formerly supposed to be derived from a radicle, C^4H^3, also called acetyl, which, in combination with 3 atoms of oxygen, formed anhydrous acetic acid $C^4H^3O^3$; and this in combination with an atom of water HO, formed hydrated acetic acid, $C^4H^3O^3.HO = C^4H^4O^4$] See Acetyl.

Sources.—Acetic acid exists, in nature, in the organic kingdom only, being found in the juices of many plants, especially of trees, and existing probably also in several of the animal secretions; but more commonly it results from the decomposition and oxidation of organic bodies.

Formation.—1. By the destructive distillation of organic substances, especially of wood.—2. By the action of oxidising agents, viz. atmospheric oxygen, chromic acid nitric acid, hypochlorous acid, &c., on alcohol and other organic bodies.—3. By the action of hydrate of potassium or hydrate of sodium at a high temperature on various organic bodies, *e.g.* succinic acid, oleic acid, malic acid, sugar, alcohol, &c.—4. By heating cyanide of methyl with aqueous caustic alkalis: $CH^3.CN + 2H^2O = C^2H^4O^2 + NH^3$.—5. By the action of carbonic anhydride on sodium-methyl; $CO^2 + CH^3Na = C^2H^3NaO^2$ (acetate of sodium).—6. By the reducing action of zinc or sodium-amalgam on chloracetic acid.

Preparation.—1. From *alcohol.* Alcohol is converted into acetic acid by various processes of oxidation; *e.g.* by the action of spongy platinum. If a tray of finely-divided spongy platinum be placed on a triangle over a porcelain dish containing a little alcohol gently warmed, and the whole covered with a bell-glass standing on a wedge, and open at the top so as to allow a gentle current of atmospheric air to pass through the apparatus, the oxidation of the alcohol proceeds rapidly, acetic acid condensing in abundance on the inside of the bell-jar.

By this process, however, much of the alcohol is converted into aldehyde, and lost by volatilisation. It would appear, in fact, that, in the formation of acetic acid by direct oxidation, aldehyde is always developed as an intermediate product, especially if the oxidising influence be not sufficiently rapid—

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + O = \underbrace{C^2H^4O}_{\text{Aldehyde.}} + H^2O;\ \text{and}\ \underbrace{C^2H^4O}_{\text{Aldehyde.}} + O = \underbrace{C^2H^4O^2}_{\text{Acetic acid.}}$$

The oxidation of alcohol by atmospheric oxygen is greatly promoted by the presence of ferments; and, in fact, in the ordinary processes for making vinegar, an alcoholic solution is exposed to the joint influence of air and a ferment. In France and Germany wine is usually employed, and in England malt.

Wine Vinegar (*Weinessig, Vinaigre*).—The following is the plan of making vinegar practised in Paris. The wine destined for vinegar is mixed in a large tun with a quantity of wine-lees, and the whole being transferred into cloth-sacks, placed within a large iron-bound vat, the liquid matter is squeezed through the sacks by superincumbent pressure. What passes through is put into large casks set upright and having a small aperture at the top. In these it is exposed to the heat of the sun in summer, or to that of a stove in winter. Fermentation supervenes in a few days. If the heat should then rise too high, it is lowered by cool air and the addition of fresh wine. In the skilful regulation of the fermentative temperature consists the art of making good wine-vinegar. In summer, the process is generally completed in a fortnight; in winter, double the time is requisite. The most favourable temperature is between 25° and 30° (77° and 86° F.). The vinegar is then run off into barrels containing several chips of birch wood. In about a fortnight it is found to be clarified, and is then fit for the market. It must be kept in close casks.

At the same time that the alcohol is thus acidified, the nitrogenous organic matters which have served as ferments have likewise assumed new forms, and settled at the bottom of the vessel in the form of a white gelatinous mass, known as "mother of vinegar." This substance, which has been described by Mulder as a fungoïd plant, under the name of *Mycoderma Vini*, is a nitrogenised body, which has the power of exciting the acetification of pure alcohol in the presence of atmospheric air, probably in consequence of its own tendency to change. By treating it with potash, the whole of the nitrogen is removed, pure cellulose alone remaining.

A slight motion is found to favour the formation of vinegar, and to endanger its decomposition after it is made. Chaptal ascribes to agitation the operation of thunder, though it is well known, that when the atmosphere is highly electrified, beer is apt to become suddenly sour, without the concussion of a thunder-storm. Vinegar does not keep well in cellars exposed to the vibrations occasioned by the rattling of carriages. The lees, which had been deposited by means of isinglass during repose, are thus jumbled into the liquor, and promote the fermentation.

Almost all the vinegar of the north of France being prepared at Orleans, the manufacture of that place has acquired such celebrity as to render the process worthy of a separate consideration.

The Orleans casks contain nearly 400 pints of wine. Those which have been already used are preferred. They are placed in three rows, one over another, the upper ones having an aperture of two inches diameter, kept always open. The wine for acetification is kept in adjoining casks containing beech shavings, to which the lees adhere. The wine thus clarified is drawn off to make vinegar. One hundred pints of good vinegar, boiling hot, are first poured into each cask, and left there for eight days; ten pints of wine are mixed in, every eight days, till the vessels are full; and the vinegar is allowed to remain in this state fifteen days, before it is exposed for sale. The manufacturers at Orleans prefer wine of a year old for making vinegar; but if the wine has lost its extractive matter by age, it does not readily undergo the acetous fermentation.

The *used* casks, called *mothers*, are never emptied more than half, but are successively filled again, to acetify new portions of wine. In order to judge if the *mother* works, the vinegar makers plunge a spatula into the liquid; and according to the quantity of froth which the spatula shows, they add more or less wine. In summer, the atmospheric heat is sufficient. In winter, stoves heated to about 76° Fahr. maintain the requisite temperature in the manufactory.

Quick method of Vinegar-making (*Schnellessigbereitung*). Since the efficient conversion of the alcohol into acetic acid essentially depends upon the completeness of the oxidation, the German chemists have proposed to promote this result by enlarging the surface of the liquid exposed to the air. This is effected by allowing the alcoholic liquor to trickle down in a fine shower from a colander through a large oaken tube (called the vinegar generator, or graduator), filled with beech chips, up which a current of air ascends through apertures in the sides. By the oxidation which goes on, the temperature of the liquid rises to 37° or 40° C. (100 or 104° Fahr.). The liquid requires to be passed three or four times through the cask before the acetification is complete, which takes place in twenty-four or thirty-six hours. Care should be taken to allow a sufficient supply of air.

In England the same result is often attained by causing the alcoholic liquor to be distributed by means of a Barker's mill or other contrivance, over the beech shavings in a tun, whilst a current of air is forced up through it by two floating gasometers which are made to rise and fall alternately by steam power.

Wine vinegar is of two kinds, white or red, according as it is prepared from white or red wine. It contains, besides acetic acid and water, sugar, colouring matter, gum, and salts, especially bitartrate of potassium. Its specific gravity varies from 1·014 to 1·022.

MALT VINEGAR.—This is prepared from malt or a mixture of malt and raw barley, which is mashed with water as in the ordinary operation of brewing; the wort is then submitted to the vinous fermentation and the liquor thus obtained is converted by oxidation into vinegar. This effected in two ways; either by the process of *fielding* or *stoving*.

When *fielding*, that is, exposure to the open air, is resorted to, the wort must be made in the spring months, and then left to finish during several months of the warm season. In consequence, therefore, of the length of time required, the latter, or *stoving* process, is more generally used. The wash is introduced into barrels standing endways, tied over with a coarse cloth, and placed close together in darkened chambers, artificially heated by a stove. The liquor remains in these barrels until the acetification is complete. This usually occupies several weeks or months. The product is next introduced into large tuns with false bottoms, on which *rape* (the residuary fruit from the making of British wines) is placed, and allowed slowly to filter through them. Below the false bottom and above the true one is placed a tap which allows the vinegar to flow into a back or cistern. From this cistern a pump raises the liquid to the top of the vessel, and thence it flows through the rape to be again returned. Or sometimes the rape tuns are worked by pairs, one of them being quite filled with vinegar from the barrels, the other only three parts, so that the acetification is excited more readily in the latter than the former, and every day a portion of the vinegar is conveyed from one to the other, till the whole is finished and fit for sale.

Malt vinegar has a yellowish red colour, an agreeable acid taste, which is due to acetic acid; but the aromatic odour which distinguishes both it, and also wine vinegar, from pyroligneous acid (to be afterwards described) is imparted to it by the presence of acetic and other ethers.

Vinegar of four different strengths is sold by the makers, distinguished as Nos. 18, 20, 22, and 24. The last, which is the strongest, and is called proof vinegar, contains 5 per cent. of real acetic acid; its specific gravity is 1·019. (Pereira.)

Vinegar is liable to undergo a putrefactive decomposition, which was believed by the makers to be prevented by the addition of sulphuric acid, and they are allowed by law to add one-thousandth part by weight of sulphuric acid. It is now known that this is unnecessary; nevertheless the practice is still continued.

Distilled Vinegar.—By submitting wine or malt vinegar to distillation it is deprived of its colouring and other non-volatile matters, a colourless limpid liquid being obtained which is known in commerce as distilled vinegar. The product is, however, always weaker than the vinegar from which it has been derived, because the boiling point of strong acetic acid is above that of water; it is also liable to be contaminated with a small quantity of alcohol and empyreumatic bodies.

2. From *Wood*. Wood Vinegar, or Pyroligneous Acid.—The greater part of the acetic acid now employed in the arts is obtained by the destructive distillation of wood. The wood is heated in large iron cylinders like gas retorts, connected with a series of condensing vessels, the uncondensable gases which are evolved in large quantity being conveyed by pipes into the fire and aiding to maintain the heat. The liquid which condenses in the receivers consists of water, tar, wood-spirit or methylic alcohol, acetate of methyl, and acetic acid. The watery liquid, after being separated from the tar, is redistilled, the wood-spirit passing over among the first portions of the distillate, and the acetic or pyroligneous acid afterwards. The acid thus obtained is coloured, and has a strong tarry flavour, which cannot be removed by redistillation. To purify this crude acid, it is converted into acetate of sodium, either by direct saturation with carbonate of sodium, or more economically by saturating it with carbonate of calcium, and decomposing the calcium-salt with sulphate of sodium; and the acetate of sodium is purified from tarry matter, first by gentle torrefaction, and afterwards by recrystallisation. It is then decomposed by strong sulphuric acid diluted with half its weight of water, whereupon the sulphate of sodium, being insoluble in acetic acid, separates in the crystalline form, and may be separated by simple decantation; and the acetic acid thus separated is purified from the last traces of sulphate of sodium by distillation.

The process just described yields a very pure acid, but it is too expensive, principally in consequence of the large quantity of fuel which it requires. A more economical process has been proposed by Völckel (Ann. Ch. Pharm. lxxxii. 49; Chem. Soc. Qu. J. v. 274). In this process the crude wood-vinegar is immediately saturated with lime, without previous rectification. Part of the tarry matter then separates in combination with the lime, while the rest remains in solution with the acetate of calcium. The liquid, after being clarified by repose, or by filtration, is evaporated down to half its bulk in an iron pot, and mixed with a quantity of hydrochloric acid, sufficient to give it a slight acid reaction. The greater part of the tarry matter then separates, and may be skimmed off from the surface. The hydrochloric acid also decomposes certain compounds of the lime with creosote and other volatile substances, which are then expelled by heat; 33 gallons of crude wood-vinegar require for purification from 4 to 5 lbs. of hydrochloric acid. The acetate of calcium thus purified is completely dried and distilled with hydrochloric acid, 100 parts of the dry salt requiring from 90 to 95 parts of hydrochloric acid of sp. gr. 1·15 (or 20° Bm.). The sp. gr. of the acetic acid thus obtained is about 1·06 (8° Bm.). If it contains hydrochloric acid, it may be purified by redistillation, with addition of a small quantity of carbonate of sodium, or better, 2 or 3 per cent. of bichromate of potassium, which, at the same time, destroys certain organic impurities that impart a peculiar odour to the acid.

The presence of hydrochloric or sulphuric acid in vinegar is easily detected by boiling the liquid for about twenty minutes with a small quantity of potato-starch, then leaving it to cool and adding a few drops of iodide of potassium. If the vinegar is pure, the blue colour of iodide of starch immediately makes its appearance, but not if sulphuric or hydrochloric acid is present, because these acids boiled with starch convert it into dextrin, which is not coloured blue by iodine (Payen). Sulphuric acid may also be detected by chloride of barium, and hydrochloric acid by nitrate of silver.

[For further details of the manufacture of acetic acid, see the new edition of *Ure's Dictionary of Arts, Manufactures and Mines*, vol. i. pp. 5 to 20.]

CRYSTALLISABLE OR GLACIAL ACETIC ACID.—This term is applied to the pure acid $C^2H^4O^2$, [or $C^4H^4O^4$] of sp. gr. 1·0635, because it is at ordinary temperatures a crystalline solid. The acid obtained by either of the processes above described consists of this compound more or less mixed with water. On distilling this dilute acid, a weaker acid passes over, and a stronger acid remains behind, because the boiling point of aqueous acetic acid increases with its concentration; and by repeated fractional distillation, an acid is at length obtained which crystallises at a low temperature. Crystallisable acetic acid is, however, more conveniently obtained by distilling certain acetates in the dry state with an equivalent quantity of concentrated sulphuric acid or disulphate of potassium; thus with acetate of potassium:

$$2C^2H^3KO^2 + SO^4H^2 = 2C^2H^4O^2 + SO^4K^2.$$

and:

$$C^2H^3KO^2 + SO^4HK = C^2H^4O^2 + SO^4K^2.$$

The proportions required are 98 pts. of dry acetate of potassium, or 82 acetate of sodium, or 79 acetate of calcium, or 163 acetate of lead, to 49 parts of monohydrated sulphuric acid, SO^4H^2, or 136 parts of disulphate of potassium, SO^4HK. Glacial acetic acid may also be conveniently obtained from diacetate of potassium, $C^2H^3KO^2.C^2H^4O^2$ by simple distillation. When neutral acetate of potassium is mixed with aqueous acetic acid, not too dilute, and distilled, part of the acetic acid unites with the neutral acetate, and a weaker acid passes over. But as the distillation goes on, the acid potassium-salt decomposes, the distillate becomes continually richer in acetic acid, and at length the pure crystallisable acid distils over. The temperature must not be allowed to exceed 300°; otherwise the acid suffers partial decomposition, and becomes coloured (Melsens, Compt. rend. xix. 611).—Crystallised acetate of copper also yields glacial acetic acid, when dried at a temperature between 160° and 180° and afterwards distilled at a higher temperature. Towards the end of the distillation the acid becomes mixed with acetone: that which passes over towards the middle must be redistilled to free it from copper mechanically carried over, probably in the form of cuprous acetate. The acid obtained by this process was formerly called *Spiritus Aeruginis* or *Spiritus Veneris*.

Properties.—Pure acetic acid solidifies at or below 15° C. in prismatic or tabular crystals. In closed vessels it remains liquid at 12°, and does not solidify till the vessel is opened and shaken. Its specific gravity in the solid state is 1·100 at 8·5 (Persoz). It melts at 16° (Lowitz), at or above 22°·5 (Mollerat), forming a thin colourless liquid of sp. gr. 1·063 (Mollerat); 1·065 at 13° (Persoz); 1·0635 at 15° (Mohr); 1·0622 (Sébille-Auger); 1·08005 reduced to 0° (Kopp, Pogg. Ann. lxxii. 1). It boils at 119° (Sébille-Auger); at 117°·3 (Kopp). The density of its vapour is different at different temperatures, compared with an equal bulk of air at the same temperature. At temperatures considerably above the boiling point, it follows the ordinary law of condensation to 2 volumes; thus at 300° and upwards the sp. gr. of the vapour is found by Cahours to be 2·00, which agrees almost exactly with the calculated density, supposing the molecule to occupy 2 volumes. For the atomic weight of acetic acid, compared with hydrogen as unity is 60 ($= 2C + 4H + 2O = 24 + 4 + 32$); and if this be the weight of 2 volumes of the vapour, it follows that the weight of 1 volume of vapour, or in other words, the specific gravity as compared with hydrogen, will be 30; and multiplying this number by 0·0693, the sp. gr. of hydrogen referred to air as unity, we obtain for the sp. gr. of acetic acid vapour referred to air as unity, the number 2·079.

But at temperatures near the boiling point, the density of the vapour is much greater, exhibiting a condensation to $\frac{3}{2}$-volume, or even less. The following table exhibits the density of the vapour at various temperatures as determined by Cahours (Compt. rend. xix. 771; xx. 51):

Temperature.	125°	130°	140°	150°	160°	170°	190°	200°	230°	250°	300°
Density.	3·20	3·12	2·90	2·75	2·48	2·42	2·30	2·22	2·17	2·09	2·08

The tension of the vapour is 7 mm. at 15°; 14·5 mm. at 22°, and 32 mm. at 32°. (Bineau, Ann. Ch. Phys. [3] xviii. 226.)

The acid has a pungent sour taste and odour, blisters the skin, and acts as an acrid poison. It does not redden litmus paper *per se*, but very strongly when mixed with water.

Decompositions.—1. The vapour of acetic acid is inflammable, and burns with a blue flame, producing water and carbonic acid. When it is passed through a red-hot tube, the greater part remains unaltered, but a portion is decomposed, yielding free carbon and combustible gases, together with acetone, napthalin, hydrate of phenyl and benzol. (Berthelot, Ann. Ch. Phys. [3] xxxiii. 295.)

2. A mixture of glacial acetic and strong *sulphuric acid* blackens when heated, giving off carbonic and sulphurous anhydrides. *Fuming sulphuric acid* mixes with glacial acetic acid without evolution of gas; but the mixture becomes hot, and if it be raised to a higher temperature, carbonic anhydride is given off, mixed with only a small quantity of sulphurous anhydride. *Sulphuric anhydride* dissolves in acetic acid without evolution of gas, and on heating the mixture, sulphacetic acid is produced.

3. Acetic acid is not sensibly attacked by *nitric acid.*

4. *Periodic acid* converts it into carbonic or formic acid, with formation of iodic acid and separation of iodine.

5. *Chlorine* in sunshine converts acetic acid into monochloracetic and trichloracetic acids, the quantity of the one or the other being greater, according as the acetic acid or the chlorine is in excess. See CHLORACETIC ACID.

6. Glacial acetic acid heated with *bromine* in a sealed tube forms bromacetic and dibromacetic acids. *Iodine* has no action on acetic acid even in sunshine.

7. With *pentachloride of phosphorus*, glacial acetic acid forms hydrochloric acid, chloride of acetyl and oxychloride of phosphorus:

$$C^2H^3O.H.O + PCl^3.Cl^2 = C^2H^3O.Cl + HCl + PO.Cl^3.$$

8. With *pentasulphide of phosphorus*, it forms thiacetic acid and phosphoric anhydride:

$$5(C^2H^3O.H.O) + P^2S^5 = P^2O^5 + 5(C^2H^3O.H.S).$$

The difference between the mode of action of the pentachloride and pentasulphide of phosphorus, the former giving rise to two distinct chlorine-compounds, $C^2H^3O.Cl$ and HCl, whereas the latter forms only one sulphur-compound, is very remarkable, and shows clearly the propriety of regarding chlorine as a monatomic, and sulphur as a diatomic radicle.

AQUEOUS ACETIC ACID.—Acetic acid mixes with water in all proportions, imparting to it its taste and smell. The density of the aqueous acid varies with its strength in a remarkable manner. When water is gradually added to glacial acetic acid, the density increases till a hydrate is formed containing 79 pts. of crystallised acid to 21 water, and having the composition $C^2H^4O^2.\ H^2O$. This hydrated acid has a density of 1·073 and boils at 104°. All further additions of water diminish the density of the acid.

The following table constructed by Mohr (Ann. Ch. Pharm. xxxi. 277) gives the quantity of crystallisable acetic acid in 100 pts. of the aqueous acid of different densities.

Perc.	Sp. Gr.	Perc.	Sp. Gr.	Perc.	Sp. Gr.	Perc.	Sp. Gr.	Perc.	Sp. Gr.

Mollerat, Ann. Chim. lxviii. 88, and **Ad. van Toorn** (J. pr. Chem. vi. 171) have also given tables of the specific gravities of acetic acid of different degrees of concentration.

It will be seen from the preceding table that the specific gravity of acetic acid varies but slowly, a difference of 1 per cent. corresponding to a difference of only ·001 in the density, and sometimes even less. For this reason, the determination of the strength of commercial acetic acid by the hydrometer or *acetometer*, as it is called when graduated for this purpose, is not much to be depended on. The presence of colouring matter, saline substances and other impurities, which frequently occur in vinegar, are of course an additional source of inaccuracy in this method of estimation. It is better, therefore, to determine the strength of the acid by ascertaining the quantity of a standard solution of caustic soda or ammonia, required to neutralise a given volume. (See ACIDIMETRY and ANALYSIS, VOLUMETRIC.) This method, when applied to acetic acid, is affected with a slight source of inaccuracy, arising from the fact that the normal or neutral acetates of the alkalis exhibit a slight alkaline reaction. The error thence arising is, however, of small amount, not exceeding $\frac{1}{10}$ per cent. for an acid containing 10 per cent. of crystallisable acetic acid, as shown by **Otto** (Ann. Ch. Pharm. cii. 69). Moreover, it may be completely obviated by using a solution of caustic soda, graduated for the purpose by means of a solution of pure acetic acid of known strength (ANALYSIS, VOLUMETRIC). **Greville Williams** (Pharm. J. Trans. xiii. 594) recommends for the volumetric estimation of acetic acid a graduated solution of lime in sugar-water.

Acetic acid mixes in all proportions with alcohol. It dissolves resins, gum-resins, camphor, and essential oils. Its use for culinary purposes is well known. Its odour is employed in medicine to relieve nervous head-ache, fainting fits, or sickness occasioned by crowded rooms. Pungent smelling salts consist of sulphate of potassium moistened with glacial acetic acid. Pyroligneous acid is largely used in calico-printing; the tar and empyreumatic substances present in it appear to be rather advantageous than otherwise for that purpose. Large quantities of acetic acid are also used for the preparation of the acetates of lead, copper, aluminium, &c. (See *Dictionary of Arts, Manufactures, and Mines.*)

Acetates.—Acetic acid is monobasic, the general formula of its normal salts being $C^2H^3O^2.M$ [or $C^4H^3O^4.M = C^4H^3O^3.MO$], the symbol M denoting a metal. It also forms basic salts, which may be regarded as compounds of the normal acetates with oxides. The normal acetates all dissolve in water, and most of them readily. The least soluble are the silver and mercury salts, so that solutions of other acetates added to mercurous nitrate or nitrate of silver, throw down white shining scales of mercurous acetate or silver-acetate; but generally speaking, acetates are not formed by precipitation: they are produced by the action of acetic acid on metallic oxides or carbonates; many carbonates, however, the barium and calcium salts, for example, are not decomposed by acetic acid in its most concentrated state, but only after addition of water.

All acetates are decomposed by heat, most of them yielding carbonic anhydride, acetone and an empyreumatic oil. Those which are easily decomposed, and likewise contain bases forming stable carbonates, are almost wholly resolved into acetone and a carbonate of the base; this is especially the case with acetate of barium:

$$2C^2H^3O^2Ba = C^3H^6O + CO^3Ba^2.$$

Those which, like the potassium and sodium salts, require a higher temperature to decompose them, yield more complex products, but always a certain quantity of acetone. Among the products are found certain homologues of acetone, viz. *methylacetone* $C^3H^5(CH^3)O$ and *ethylacetone* $C^3H^5(C^2H^5)O$, together with *dumasin* $C^6H^{10}O$. (**Fittig**, Ann. Ch. Pharm. cx. 17). Acetates containing weaker bases, give off part of the acetic acid undecomposed, the remaining portion being resolved into acetone and carbonic anhydride, or if the heat be strong, yielding empyreumatic oil and charcoal: the residue consists sometimes of oxide, sometimes, as in the case of copper and silver, of reduced metal; in this case part of the acetic acid is burnt by the oxygen abstracted from the metal. Acetates heated with a large excess of fixed caustic alkali, are resolved at a temperature below redness into marsh gas and alkaline carbonate, *e. g.*:

$$C^2H^3KO^2 + KHO = CH^4 + CO^3K^2.$$

Acetates distilled with sulphuric acid, give off the odour of acetic acid, and yield a distillate which dissolves oxide of lead, and acquires thereby an alkaline reaction. Distilled with sulphuric and alcohol, they yield acetate of ethyl, recognisable by its odour. The neutral acetates impart to solutions of ferric salts a reddish yellow or red-brown colour, according to the degree of dilution. Acetates heated to redness with arsenious acid give off the odour of cacodyl. The acetates of the alkali-metals, and probably others also, treated with oxychloride of phosphorus, yield chloride of acetyl, together with a tribasic phosphate:

$$3(C^2H^3O.Na.O) + PO.Cl^3 = 3C^2H^3OCl + PO^4Na^3.$$

ACETATES OF ALUMINIUM. — *a. Triacetate.* As aluminium is sesquiatomic (Al^2 being equivalent to H^6 or $Al^{\frac{2}{3}}$ to H) the normal salt should be a triacetate $C^2H^3O^2.Al^{\frac{2}{3}}$ or $(C^2H^3O^2)^6.Al^2$, [or $Al^2O^3.3C^4H^3O^3$, regarding it as a compound of alumina with anhydrous acetic acid]. This salt, however, exists only in solution, and is decomposed by evaporation. The solution is obtained by digesting recently precipitated trihydrate of aluminium in strong acetic acid, or by precipitating a solution of the trisulphate with acetate of lead:

$$(SO^4)^6Al^4 + 6C^2H^3O^2Pb = 3SO^4Pb^2 + 2(C^2H^3O^2)^6Al^2.$$

This salt is largely used as a mordant in dyeing and calico-printing, and is generally prepared for this purpose by precipitating alum with acetate of lead. The solution thus formed contains sulphate of potassium as well as acetate of aluminium.

β. Diacetate. When the solution of the triacetate obtained by decomposing trisulphate of aluminium with acetate of lead is evaporated at a low temperature, with sufficient rapidity, as by spreading the concentrated liquid very thinly on plates of glass or porcelain, exposing it to a temperature not exceeding 100° F. (37°·7 C.), and, as it runs together in drops, rubbing it constantly with a spatula, *diacetate of aluminium* remains in the form of a dry powder containing $\left.\begin{matrix}(C^2H^3O)^2\\Al^4\end{matrix}\right\}O^4 + 5H^2O$ [or, using the smaller atomic weights of carbon and oxygen, $2C^4H^3O^3.Al^2O^3 + 5HO$]. The diacetate thus obtained dissolves easily and completely in water, and the solution when heated deposits dihydrate of aluminium soluble in water. (See ALUMINIUM.) But when the solution, instead of being quickly evaporated, is left to itself in the cold for some days, it deposits a white saline crust, which is an *allotropic diacetate of aluminium insoluble in water.* Heat effects the same change more rapidly, and the insoluble diacetate then separates in the form of a granular powder. At the boiling temperature, the liquid is thus deprived in half an hour of the whole of its alumina, which goes down with ⅔ of the acetic acid, leaving ⅓ in the liquid. The insoluble diacetate digested in a large quantity of water is gradually changed into the soluble modification, part of which is, however, decomposed during the process into acetic acid and the soluble dihydrate. (Walter Crum, Chem. Soc. Qu. J. vi. 217.)

ACETATES OF AMMONIUM. — *a. Normal acetate.* $C^2H^3O^2.NH^4$. A white odourless salt, obtained by saturating glacial acetic acid with dry ammonia. It is very difficult to obtain it in the crystalline form: for its aqueous solution loses ammonia on evaporation, and is converted into the acid salt (β). It is readily soluble in water and alcohol. Its aqueous solution, known in the Pharmacopeia as *Spiritus Mindereri*, is prepared by saturating aqueous acetic acid with ammonia or carbonate of ammonium. This solution is transparent and colourless, with a peculiar odour and cooling pungent taste. When kept it is decomposed, and becomes alkaline, owing to the formation of carbonate of ammonium; by heat it is converted into a solution of the acid salt (β).

β. Acid Acetate, $C^2H^3O^2.NH^4.C^2H^4O^2$ [or $C^4H^3O^3.NH^4O + C^4H^3O^3.HO$]. Obtained as a white crystalline sublimate when dry powdered chloride of ammonium is heated with an equal weight of acetate of potassium or calcium, ammonia being given off simultaneously. A warm saturated solution of this salt, kept in a closed bottle deposits long needle-shaped crystals. This salt is also obtained in a radiated crystalline mass, by evaporating the aqueous solution of the normal salt (*a*). The crystals redden litmus and deliquesce rapidly in the air. They melt at 76°C. and sublime undecomposed at 121°. The composition of this salt is probably that expressed by the above formula.

ACETATE OF BARIUM, $C^2H^3O^2 Ba$.—Prepared by decomposing carbonate or sulphide of barium with acetic acid. The solution evaporated at a gentle heat yields flattened prisms containing $2C^2H^3O^2Ba + H^2O$, but when cooled to 0° C. it yields rhomboidal prisms, isomorphous with acetate of lead, and containing $2C^2H^3O^2Ba + 3H^2O$. The crystals dried at 0° yield the anhydrous salt in the form of a white powder, which, when strongly heated, is resolved into acetone and carbonate of barium.

ACETATE OF BISMUTH separates in micaceous laminæ from a warm mixture of nitrate of bismuth and acetate of potassium. Acetic acid mixed with a solution of nitrate of bismuth prevents the precipitation of a basic salt of that metal by water.

ACETATE OF CADMIUM.—Small prismatic crystals very soluble in water (Stromeyer). According to Meissner and John, it is not crystallisable, but forms a gelatinous mass.

ACETATE OF CALCIUM, $C^2H^3O^2Ca$, crystallises in prismatic needles, which effloresce in the air, and dissolve in water and in alcohol. The salt is decomposed by heat into acetone and carbonate of calcium. A solution of acetate and chloride of calcium in equivalent proportions yields by slow evaporation, large crystals containing $C^2H^3O^2Ca.ClCa + 5H^2O$.

ACETATE OF CERIUM.—Small needles sparingly soluble in alcohol.

Acetates of Chromium.—The *chromous salt*, $2C^2H^3O^2Cr + H^2O$ is, produced by pouring protochloride of chromium into a solution of acetate of potassium or sodium. It forms red transparent crystals, which when moist absorb oxygen very rapidly from the air, undergoing a true combustion. The *chromic* salt is obtained as a green crystalline crust, very soluble in water, by dissolving chromic hydrate in acetic acid: the solution scarcely reddens litmus.

Acetates of Cobalt.—The red liquid formed by dissolving carbonate of cobalt in acetic acid, yields by evaporation a red residue which turns blue when heated. It may be used as a sympathetic ink. The oxides Co^4O^3 and Co^3O^2 also dissolve in acetic acid without separation of oxygen, forming brown solutions. The solution of the sesquioxide sustains a boiling heat without decomposition.

Acetates of Copper.—*a. Cuprous Acetate*, $C^2H^3O^2Ccu$. [$Ccu = Cu^2 = 63{\cdot}2$]. This salt sublimes towards the end of the distillation of normal cupric acetate. According to Berzelius, it is contained in common green verdigris, and sublimes when that substance is distilled. It forms soft, loose, white flakes, which redden litmus and have a caustic astringent taste. Water decomposes it into normal cupric acetate and yellow cuprous hydrate.

b. Cupric Acetates.—(Berzelius, Pogg. Ann. ii. 233; Traité, iv. 173; Gm. viii. 323; Gerh. i. 728.) Four of these salts are known, viz.:—

Normal Cupric Acetate	$C^2H^3O^2Cu$		$= C^4H^3O^3 \,.\, CuO.$
Sesquibasic . . .	$(C^2H^3O^2Cu)^4$	$. Cu^2O$	$= (C^4H^3O^3)^2 \,.\, (CuO)^3.$
Dibasic . . .	$(C^2H^3O^2Cu)^2$	$. Cu^2O$	$= C^4H^3O^3 \,.\, (CuO)^2.$
Tribasic . . .	$C^2H^3O^2Cu$	$. Cu^2O$	$= C^4H^3O^3 \,.\, (CuO)^3.$

1. The normal salt $C^2H^3O^2Cu$, called also *Crystallised Verdigris, Verdet, Cristaux de Venus*, is produced by dissolving cupric oxide or common verdigris in acetic acid, or by precipitating a solution of normal acetate of lead with sulphate of copper: in either case, the liquid must be highly concentrated and then left in a cool place. It forms dark bluish-green prisms belonging to the monoclinic system, and containing $2C^2H^3O^2Cu + H^2O$. The ordinary combination is $\infty P \,.\, 0P \,.\, +P \,.\, +2P\infty$. Twin-crystals also occur. Ratio of the axes: $a : b : c = 0{\cdot}6473 \; 1 : 0{\cdot}5275$. Inclination of the axes = 63°. Inclination of the faces, $\infty P : \infty P$ in the plane of the orthodiagonal and the principal axis = 108°; $\infty P : 0P = 105° \, 30'$; $0P : +2P\infty = 119° \, 4'$. Cleavage parallel to $0P$ and ∞P. The salt is efflorescent, soluble in water, sparingly soluble in alcohol, and poisonous like all soluble copper-salts. The crystals after drying in vacuo at ordinary temperatures, suffer no further diminution in weight at 100°, but give off 9·6 per cent. of water between 110° and 140°, then nothing more below 240°; between 240° and 260° strong acetic acid, which when rectified yields 32 per cent. of the crystallisable acid; at 270° white fumes which condense into white flakes of cuprous acetate; and lastly a mixture of carbonic anhydride and a combustible gas. At 330° the decomposition is complete, and a reddish substance remains consisting chiefly of metallic copper. The solution boiled with sugar yields a red precipitate of cuprous oxide. Acetate of copper crystallised at a temperature near 8°, yields crystals containing $2C^2H^3O^2Cu + 5H^2O$.

2. The basic cupric acetates are contained in *common verdigris* (*vert-de-gris, Grünspan*), a substance obtained by exposing plates of copper to the air in contact with acetic acid, and much used as a pigment and as a mordant in dyeing wool black. There are two varieties of this substance, the blue and the green, the former consisting almost wholly of dibasic cupric acetate, the latter of the sesquibasic salt mixed with smaller quantities of the dibasic and tribasic acetates. The *dibasic salt* or *blue verdigris* is prepared at Montpellier and in other parts of the south of France, by exposing copper to the air in contact with fermenting wine-lees. The wine-lees are loosely packed in casks together with straw, till they pass into the state of acetous fermentation; and when that is ended, they are arranged in pots covered with straw, in alternate layers with rectangular plates of copper, which when used for the first time, are previously moistened with a cloth dipped in a solution of normal acetate of copper, and then dried. At the end of three weeks, the plates are taken out; placed in an upright position to dry; dipped six or eight times in water in the course of as many weeks; and again left to dry, during which operations the verdigris continually swells up. It is then scraped off, the plates again arranged alternately with sour wine-lees, and the same processes are repeated till the plates are quite corroded. The same compound is obtained by exposing copper plates to damp air in contact with normal acetate of copper made into a paste with water. It forms delicate, silky, blue, crystalline needles and scales, which yield a beautiful blue powder. They contain 6 at. water, which they give off at 60°, and are then converted into a green mixture of the monobasic and tribasic salt:—

$$(C^2H^3O^2Cu)^2.Cu^2O = C^2H^3O^2Cu + C^2H^3O^2Cu \,.\, Cu^2O.$$

By repeated exhaustion with water, it is resolved into the insoluble tribasic salt, and a solution of the normal and sesquibasic salts:

$$5(C^4H^6O^3.2Cu^2O) = 2(C^4H^6O^3.3Cu^2O) + 2C^4H^6O^3.3Cu^2O + C^4H^6O^3.Cu^2O.$$

The following table exhibits the composition of several kinds of blue verdigris as determined by Berzelius and by Phillips:

				Phillips.		
				French.	English.	
Calculation.			Berzelius.		Crystallised.	Compressed.
$2Cu^2O$	160	43·24	43·34	43·5	43·25	44·25
$C^4H^6O^3$	102	27·57	27·45	29·3	28·30	29·62
$6H^2O$	108	29·19	29·21	25·2	28·45	25·51
Impurities	..	..	..	2·0	..	0·62
	370	100·00	100·00	100·0	100·00	100·00

The *sesquibasic acetate* is obtained in a state of purity by adding ammonia in small portions to a boiling concentrated solution of the normal salt, till the precipitate is just redissolved, and leaving the solution to cool; or by treating common green verdigris with cold or tepid water, and leaving the filtrate to evaporate. It is then deposited in bluish scales containing $(C^2H^3O^2Cu)^4. Cu^2O + 6H^2O$. It gives off half its water at 60°, and becomes greenish.

Green Verdigris, according to Berzelius, is a mixture of this salt with small quantities of the dibasic and tribasic salts, sometimes also containing cuprous acetate and other impurities. It is manufactured at Grenoble by frequently sprinkling copper-plates with vinegar in a warm room; and in Sweden by disposing copper-plates in alternate layers with flannel cloths soaked in vinegar, till the green salt begins to form, then exposing them to the air and frequently moistening with water. The greenest kind contains according to Berzelius, 49·9 per cent. of cupric oxide, and 13·5 per cent. of water and impurities; the pure sesquibasic salt contains 43·5 per cent. Cu^2O.

The *tribasic acetate*, $C^2H^3O^2Cu.Cu^2O + H^2O$, is the most stable of all the acetates of copper. It is obtained by exhausting blue verdigris with water; also by boiling the aqueous solution of the normal salt, or by heating it with alcohol, or again by digesting the same solution with cupric hydrate. The last method yields the salt in the form of a green powder; as obtained by the other methods, it forms a bluish powder composed of fine needles or scales. It gives off its water at 160°, and decomposes at a higher temperature, yielding acetic acid. Boiling water decomposes and turns it brown. The brown substance thus formed was regarded by Berzelius as a peculiar basic acetate, containing $C^4H^6O^3. 48Cu^2O$; but it is more probably a mixture of the tribasic salt with excess of oxide.

Acetate of Copper and Calcium. $C^2H^3O^2Ca . C^2H^3O^2Cu + 4H^2O$.—Obtained by heating a mixture 1 atom of normal cupric acetate and 1 atom hydrate of calcium with 8 times its weight of water and sufficient acetic acid to dissolve the precipitated oxide of copper, and evaporating the green filtrate at a temperature between 25° and 27°. It forms large, blue, transparent, square prisms, often converted into octagonal prisms by truncation of the lateral edges. They effloresce slightly in the air; fall to powder at 75°, giving off acetic acid; and dissolve readily in water. Another cuprico-calcic acetate, $C^2H^3O^2Ca + (C^2H^3O^2Cu). Cu^2O + 2H^2O$, often exists in crystallised verdigris: its optical properties differ from those of the normal cupric acetate.

Aceto-arsenite of Copper. $C^2H^3O^2Cu.3AsO^2Cu$, or $C^4H^3O^3.CuO + 3(AsO^3.CuO)$.—*Schweinfurt green*, *Imperial green*, *Mitis green*, and when mixed with gypsum or heavy spar, *Neuwieder green*, *Mountain green*. Used as a pigment, and prepared on the large scale by mixing arsenious acid with cupric acetate and water. 5 parts of verdigris are made up to a thin paste, and added to a boiling solution of 4 parts or rather more of arsenious acid in 50 parts of water. The boiling must be well kept up, otherwise the precipitate assumes a yellow-green colour, from formation of arsenite of copper; in that case, acetic acid must be added, and the boiling continued a few minutes longer. The precipitate then becomes crystalline, and acquires the fine green colour peculiar to the aceto-arsenite. The salt is insoluble in water, and when boiled with water for a considerable time, becomes brownish and gives up acetic acid. Acids abstract the whole of the copper, and aqueous alkalis first separate blue cupric hydrate, which when boiled with the liquid, is converted into black cupric oxide, and afterwards into red cuprous oxide, an alkaline arsenate being formed at the same time.

ACETATES OF IRON.—*a. Ferrous Acetate.* When metallic iron or the protosulphide is dissolved in strong acetic acid, and the solution concentrated, small colourless silky needles are obtained, which dissolve easily in water, and rapidly absorb oxygen from the air.

β. *Ferric Acetate.*—Obtained by dissolving ferric hydrate in acetic acid, or by decomposing a solution of ferric sulphate with acetate of lead. It is uncrystallisable and very soluble in water, forming a red-brown solution; soluble also in alcohol. The aqueous solution, when kept in a state of ebullition for about 12 hours, undergoes a remarkable modification, acquiring a brick-red colour, and remaining clear when viewed by transmitted light, but appearing opaque and opalescent by reflected light. At the same time, it loses entirely the metallic taste of iron salts, and acquires that of vinegar; it forms a brown instead of a blue precipitate with ferrocyanide of potassium, and no longer exhibits the characteristic red colour with sulphocyanides. Traces of sulphuric or phosphoric acid, or of alkaline salts, precipitate the whole of the iron in the form of a red-brown precipitate, which, at ordinary temperatures, is perfectly insoluble in acids, even the most concentrated; hydrochloric and nitric acids throw down a red granular precipitate, which, when perfectly freed from the acid mother-liquor, dissolves easily and completely in water. (Péan de St. Gilles, Ann. Ch. Phys. [3] xlvi. 47.)

A mixture of the two acetates of iron, called *pyrolignite of iron* (*liqueur de ferraille, bouillon noir*), is prepared on the large scale by treating iron with wood-vinegar, in contact with the air. It is used as a mordant for black dyes; also for preserving wood.

Acetates of Lead.— The normal acetate $C^2H^3O^2Pb$, or $PbO.C^4H^3O^3$ (*Sugar of lead, saccharum Saturni, sel de Saturne, Bleizucker*) is prepared by dissolving oxide or carbonate of lead in acetic acid, wood-vinegar being used on the large scale, or by immersing plates of lead in vinegar in vessels exposed to the air. It crystallises in prisms containing $2C^2H^3O^2Pb + H^2O$, and belonging to the monoclinic system. Ordinary combination: $\infty P . 0P . \infty P \infty$, sometimes with the face $0P$ predominating, so as to give the crystals a tabular form. The length of the orthodiagonal is to that of the clino-diagonal, as 0·4197 to 1. Inclination of the axes = 70° 28′. Inclination of the faces: $\infty P : \infty P = 128°$; $\infty P : \infty P \infty = 116°$; $\infty P : 0P = 98° 30'$; $0P : \infty P \infty = 109° 32$. Cleavage parallel to $0P$ and $\infty P \infty$. The crystals are efflorescent, soluble in 0·59 parts of water at 15°·5 (60° F.), and in 8 parts of alcohol. The salt has a sweet, astringent taste, and is very poisonous. It melts at 75°·5; begins to give off water with a portion of its acid a little above 100°; and is completely dehydrated at 280°. Above that temperature it decomposes, giving off acetic acid, carbonic anhydride, and acetone, and leaving metallic lead very finely divided and highly combustible. The aqueous solution is partially decomposed by the carbonic acid of the air, carbonate of lead being precipitated, and a portion of acetic acid set free, which prevents further decomposition. The solution is not precipitated by ammonia in the cold, but yields crystals of oxide of lead when heated with a large excess of ammonia. Normal acetate of lead forms crystalline compounds with chloride of lead and with peroxide of lead.

(Berzelius, Ann. Chim. xciv. 292; Schindler, Brande's Archiv, xli. 129; Payen, Ann. Ch. Phys. [2] lxv. 238, and lxvi. 37; Wittstein, Buchner's Repert. lxxxiv. 170; Gm. viii. 310; Gerh. i. 736.)

Four *basic acetates* of lead have been described, viz.:

The sesquibasic acetate	.	$(C^2H^3O^2Pb)^4 . Pb^2O$	or $(C^4H^3O^3)^2 . (PbO)^3$.
The dibasic „	.	$(C^2H^3O^2Pb)^2 . Pb^2O$	or $C^4H^3O^3 . (PbO)^2$.
The tribasic „	.	$C^2H^3O^2Pb . Pb^2O$	or $C^4H^3O^3 . (PbO)^3$.
The sexbasic „	.	$(C^2H^3O^2Pb)^2 . (Pb^2O)^5$	or $C^4H^3O^3 . (PbO)^6$.

All of these however, except the tribasic salt, are of rather doubtful composition.

The *sesquibasic salt* is obtained by heating the normal salt till it melts, and subsequently solidifies in a white porous mass. By dissolving the residue in water and evaporating, the salt is then obtained in nacreous laminæ containing $2 [(C^2H^3O^2Pb)^4 . Pb^2O] + H^2O$. It is more soluble in water and alcohol than the normal acetate, and forms alkaline solutions. (Payen, Schindler.)

The *dibasic acetate* is deposited in the crystalline form when oxide of lead (massicot) is dissolved in the proper proportion in the normal acetate. The crystals contain 2 atoms water, half of which is given off at 70°, and the rest at 100°. (Schindler.)

The *tribasic acetate* is obtained in the crystalline form, when a solution of the normal salt saturated in the cold and mixed with $\frac{1}{5}$ of its volume of ammonia, is left to evaporate; also by digesting 7 parts of massicot in a solution of 6 parts of the crystallised normal acetate. It forms long silky needles, very soluble in water, but insoluble in alcohol. The aqueous solution becomes turbid on exposure to the air. According to Payen, the crystals contain $2(C^2H^3O^2Pb . Pb^2O) + H^2O$, but according to Berzelius, they are anhydrous.

The *sexbasic salt* is obtained by digesting the solution of either of the preceding salts with excess of oxide of lead. A crystalline precipitate is then formed, which dissolves sparingly in boiling water, and separates in silky needles containing $2[(C^2H^3O^2Pb)^2.(Pb^2O)^5] + 3H^2O$. (Berzelius.)

The liquid called *Goulard's lotion, lead-vinegar, acetum Saturni*, is a mixture of the aqueous solutions of these basic acetates of lead, chiefly the tribasic salt. It is prepared by digesting oxide of lead in acetic acid, or in a solution of the normal acetate. It is an alkaline liquid which is decomposed by the carbonic acid in the air. It precipitates a large number of vegetable substances, such as gum-resins, colouring matters, &c. and from its power of coagulating mucus, is much used as a lotion for wounds and sores.

Acetate of Lithium. $C^2H^3O^2Li + 2H^2O$.—Right rhomboïdal prisms, deliquescent in moist air, soluble in less than a third of their weight of water at 15°, and in 4·6 pts. of alcohol of sp. gr. 0·81 at 14°.

Acetate of Manganese.—Pale rose-coloured splinters or small prisms grouped together; soluble in 3 pts. of water.

Acetates of Mercury.—*Mercurous acetate*, $C^2H^3O^2,Hhg$, [$Hhg = Hg^2 = 200$], is obtained by precipitating mercurous nitrate with a soluble acetate. It forms anhydrous micaceous laminæ, sparingly soluble in water. Heat decomposes it into metallic mercury, carbonic anhydride, and acetic acid.

Mercuric Acetate, $C^2H^3O^2Hg$ [or $C^4H^3O^3.HgO$], is prepared by dissolving red oxide of mercury in warm acetic acid. It crystallises in brilliant micaceous laminæ, soluble in their own weight of water at 10°, and somewhat more soluble in boiling water. Alcohol and ether decompose it, separating mercuric oxide.

Acetate of Mercurammonium, $C^2H^3O^2.(NH^3Hg) + H^2O$, is obtained by agitating recently precipitated mercuric oxide with a solution of acetate of ammonium. It crystallises in rhomboïdal plates, very soluble in water, insoluble in alcohol. At 100° it gives off from 30 to 31 per cent. of its weight, and is converted into *acetate of tetramercurammonium*, $C^2H^3O^2(NHg^4)$.

Acetate of Nickel crystallises in apple-green prisms, slightly efflorescent, soluble in 6 pts. of cold water, insoluble in alcohol. The solution is decomposed by hydrosulphuric acid, which throws down sulphide of nickel.

Acetates of Potassium.—*Normal acetate.* $C^2H^3O^2K$ [or $C^4H^3O^3.KO$]. (*Terra foliata Tartari, Arcanum Tartari, Tartarus regeneratus, Blättererde, geblätterte Weinsteinerde*).

This salt exists in the juices of many plants. It is prepared by dissolving carbonate of potassium in acetic acid. When brown vinegar is used for the purpose, the carbonate of potassium should be added by small portions, so as to keep the solution constantly acid. The object of this precaution is to avoid the formation of coloured products by the contact of free alkali with the foreign matters in the vinegar. Pure acetate of potassium is a white salt, difficult to crystallise, very soluble in water and deliquescent, soluble also in alcohol, and precipitated by ether from the alcoholic solution. Carbonic acid gas, passed into a solution of the salt in absolute alcohol, throws down carbonate of potassium, and liberates acetate of ethyl. The salt melts below a red heat, forming a limpid oil, which solidifies in an extremely deliquescent mass on cooling. It requires a very high temperature to decompose it, and then gives off acetone, empyreumatic oil, and inflammable gases, and leaves a residue of carbonate of potassium mixed with charcoal. Heated with excess of hydrate of potassium, it yields carbonate of potassium and marsh gas:

$$C^2H^3O^2K + KHO = CH^4 + CO^3K^2.$$

Heated with arsenious anhydride, it yields cacodyl. (See Arsenides of Methyl.) Chlorine, passed into the aqueous solution of acetate of potassium, liberates carbonic anhydride, and forms a bleaching liquid, which however loses its decolorising power on exposure to the air. When an electric current is passed through a strong aqueous solution of acetate of potassium separated into two parts by a porous diaphragm, hydrogen alone is evolved at the negative pole; while, at the positive pole, there is evolved a gaseous mixture of methyl and carbonic anhydride, together with acetate of methyl and a small quantity of oxide of methyl. The principal decomposition is represented by the equation:

$$C^2H^4O^2 = CH^3 + CO^2 + H,$$

the acetate and oxide of methyl being secondary products. (Kolbe, Ann. Ch. Pharm. lxix. 257.)

Acid Acetate or *Diacetate of Potassium*, $C^2H^3O^2K.C^2H^4O^2$, [or $C^4H^3O^3.HO + C^4H^3O^3.KO$.]

When the normal acetate is evaporated with an excess of strong acetic acid, this acid salt is deposited in needles or laminæ, or by slow evaporation in long flattened prisms, apparently belonging to the rhombic system. It is very deliquescent, melts at 148°, and decomposes at 200°, giving off crystallisable acetic acid. On this property is founded an easy method of obtaining the crystallisable acid.

Diacetate of potassium is formed when the normal acetate is distilled with butyric or valerianic acid; but neither of these acids decomposes the salt thus produced. Hence, when butyric or valerianic acid is mixed with acetic acid, a separation more or less complete may be effected by half neutralising the liquid with potash, and distilling. If the acetic acid is in excess, diacetate of potassium alone remains behind, the whole of the valerianic or butyric acid passing over, together with the remainder of the acetic acid. If, on the contrary, the other acid is in excess, it passes over, unmixed with acetic acid, and the residue consists of diacetate of potassium mixed with butyrate or valerate. By repeating the process a certain number of times, either on the acid distillate or on the acid separated from the residue by distillation with sulphuric acid, complete separation may be effected. (Liebig, Ann. Ch. Pharm. lxxi. 355.)

Anhydrous Diacetate of Potassium, $2C^2H^3O^2K.C^4H^6O^3$ [$=KO.\ 2C^4H^3O^3$] is produced by dissolving melted acetate of potassium in acetic anhydride at the boiling heat, or by the action of potassium on acetic anhydride. Forms colourless needles very soluble in water, less deliquescent than normal acetate of potassium. It is decomposed by heat, giving off acetic anhydride. (Gerhardt, Ann. Ch. Phys. [3] xxxvii. 317.)

ACETATE OF SILVER, $C^2H^3O^2Ag$.—Obtained by precipitating nitrate of silver with acetate of sodium. Crystallises from boiling water in thin, flexible laminæ; soluble in 100 pts. of cold water.

ACETATE OF SODIUM, $C^2H^3O^2Na$ [or $C^4H^3O^3.NaO$.] *Terra foliata tartari crystallisabilis, Terre foliée minérale.*—Prepared either by dissolving carbonate of sodium in acetic acid, or by decomposing acetate of calcium with sulphate of sodium. Forms large transparent prisms belonging to the monoclinic system. Ordinary combination: $\infty P . [\infty P \infty] . 0P . -P$; more rarely with $\infty P \infty$, $+P$, $+2P\infty$. Ratio of the axes: $a : b : c = 0{\cdot}8348 : 1 : 0{\cdot}8407$. Angle of the axes $= 68° 16'$. Inclination of the faces: $\infty P : \infty P$ in the plane of the orthodiagonal and principal axis $= 95°{\cdot}30$; $-P : +P$, forming the obtuse edges of the pyramid $+P$ in the plane of the oblique diagonal and principal axis $= 117°{\cdot}32$; $\infty P : 0P = 75°{\cdot}35$. Cleavage parallel to $0P$ and ∞P. (Gerhardt, Traité i. 725.) The crystals contain 3 at. water. They effloresce slightly in dry air, completely at a moderate heat, and melt below 100°. They dissolve in 3·9 pts. of water at 6°, in 2·4 pts. at 37°, and in 1·7 pts. at 48° (Osann). According to Berzelius, a solution saturated at the boiling heat, contains 0·48 pts. water to 1 pt. of salt, and boils at 124°·4. The salt is less soluble in alcohol. It has a bitter, pungent, but not disagreeable taste.

ACETATE OF STRONTIUM crystallises like the barium-salt in two different forms, containing different quantities of water. The salt deposited at 15°, contains 4·23 p. c. water (? $4C^2H^3O^2Sr + H^2O$), and that which is deposited at low temperatures contains $C^2H^3O^2Sr + H^2O$. The latter forms prisms belonging to the monoclinic system, $\infty P : \infty P = 124° 54'$; $\infty P . \infty P\infty = 107° 33'$; $0P : P\infty = 153°{\cdot}12$. Cleavage indistinct, parallel to $\infty P\infty$.

ACETATE OF TIN.—Boiling acetic acid dissolves tin slowly, with evolution of hydrogen; the hydrated protoxide dissolves easily in the boiling acid, and the solution evaporated to a syrup and covered with alcohol yields small colourless crystals. Hydrated dioxide of tin also dissolves in acetic acid, and the solution yields a gummy mass when evaporated. Dichloride of tin forms a crystalline compound with glacial acetic acid.

ACETATE OF URANIUM.—*Uranous Acetate*, obtained by evaporating a solution of oxide in acetic acid, crystallises in green needles grouped in warty masses.

Uranic Acetate, or *Acetate of Uranyl*, $C^2H^3O^2(U^2O)$* [$= C^4H^3O^3.U^2O^3$], is obtained by heating uranic nitrate till it begins to evolve oxygen, dissolving the yellowish red mass, which still contains nitric acid, in warm concentrated acetic acid, and evaporating to the crystallising point; all the nitric acid then remains in the mother liquid. From a very concentrated, or from an acid solution slightly cooled, the salt separates in beautiful rhomboïdal prisms, $C^2H^3O^2(U^2O) + H^2O$, belonging to the monoclinic system; boiling water decomposes them with separation of uranic hydrate, but the solution yields the same crystals by evaporation. A more dilute solution cooled below 10° deposits square-based octahedrons containing $C^2H^3O^2(U^2O) + \frac{3}{2} H^2O$, or

---

* Uranyl, U^2O, is a monatomic radicle, supposed to exist in the uranic compounds. (See URANIUM.)

$2C^2H^3O^2(U^2O) + 3H^2O$. They give off $\frac{1}{3}$ of their water at 200°, and the rest at 275°, leaving the yellowish red anhydrous salt.

Uranic acetate combines with the acetates of the more basic metals, forming double acetates. The *ammonium*, *potassium*, and *sodium* salts are obtained by adding the solutions of the carbonates to a solution of uranic acetate, till a precipitate is formed consisting of a uranate of the alkali-metal, redissolving this precipitate in a slight excess of acetic acid, and cooling the solution till it crystallises. The other double salts of this group are obtained by boiling the carbonates with uranic acetate, till the whole of the uranic oxide is precipitated, redissolving the precipitate in acetic acid, and evaporating. The *lead* and *cadmium* salts consist of 1 at. of uranic acetate combined with 1 at. of the monobasic acetate, their formula being $C^2H^3PbO^2 . C^2H^3(U^2O)O^2 + 3H^2O$ and $C^2H^3CdO^2.C^2H^3(U^2O)O^2 + \frac{5}{2} H^2O$. All the rest contain 2 at. uranic acetate with 1 at. of the monobasic metal, their general formula being $C^2H^3MO^2. 2C^2H^3(U^2O)O^2 + nH^2O$. Most of these salts crystallise with facility, the potassium and silver salts in the quadratic system; the sodium salt forms regular tetrahedrons. The strontium and calcium salts are very soluble in water, and difficult to crystallise. The sodium salt is anhydrous; the rest contain water of crystallisation. (Wertheim, J. pr. Chem. xxix. 209; Weselsky, Chem. Gaz. 1858, 390.)

ACETATE OF YTTRIUM, $C^2H^3O^2Y + H^2O$.—Rhomboïdal prisms with trihedral summits. They are permanent in the air at ordinary temperatures; give off their water, and become opaque at 100°; dissolve in 9 pts. of cold water, and in a smaller quantity of boiling water; also in alcohol. (Berlin.)

ACETATE OF ZINC, $C^2H^3O^2Zn + \frac{3}{2}H^2O$, or $2C^2H^3O^2 Zn + 3H^2O$ [$= C^4H^3ZnO^4 + 3HO$].—Obtained by dissolving either the metal, the oxide, or the carbonate in acetic acid. Crystallises in nacreous efflorescent laminæ belonging to the monoclinic system (Kopp's Krystallographie, p. 310). Ordinary combination: $0P . \infty P . \infty P\infty . +P . +2P\infty$, the face $0P$ predominating. $a : b : c = 0{\cdot}4838 : 1 : 0{\cdot}87$. Inclination of axes = 46°30′. Inclination of faces, $\infty P : \infty P$ in the plane of orthodiagonal and principal axis = 112° 36′; $\infty P . 0P = 112° 28′$; $0P : \infty P\infty = 113° 30′$; $0P : P\infty = 80°$; $0P : +P = 75° 30′$. Cleavage parallel to $0P$. The salt dissolves very readily in water. At 100° it melts, gives off its water with a little acetic acid, then solidifies, and does not liquefy again till heated to 190° or 195°, at which temperature anhydrous acetate of zinc sublimes in nacreous scales. At higher temperatures, complete decomposition ensues. (Larocque, Recueil des Trav. de la Soc. Pharm. 1847–54.)

ACETIC ACID, SUBSTITUTION PRODUCTS OF.—The following acids (which will be more fully described hereafter), are derived from acetic acid by substitution:

Bromacetic acid	$\left.\begin{matrix}C^2H^2BrO\\H\end{matrix}\right\}O$
Dibromacetic acid	$\left.\begin{matrix}C^2HBr^2O\\H\end{matrix}\right\}O$
Chloracetic acid	$\left.\begin{matrix}C^2H^2ClO\\H\end{matrix}\right\}O$
Trichloracetic acid	$\left.\begin{matrix}C^2Cl^3O\\H\end{matrix}\right\}O$
Iodacetic acid	$\left.\begin{matrix}C^2H^2IO\\H\end{matrix}\right\}O$
Diniod-acetic acid	$\left.\begin{matrix}C^2HI^2O\\H\end{matrix}\right\}O$
Thiacetic acid	$\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}S$

The brominated and chlorinated acids are produced by the direct action of bromine and chlorine on acetic acid; the iodated acids by the action of iodide of potassium on bromacetate and dibromacetate of ethyl; and thiacetic acid by treating glacial acetic acid with pentasulphide of phosphorus (p. 11). All these acids are monatomic, like acetic acid itself, correspond to it in nearly all their reactions, and are formed upon the same type.

ACETIC ANHYDRIDE. $C^4H^6O^3 = (C^2H^3O)^2O$. *Anhydrous Acetic acid; Oxide of Acetyl; Acetate of Acetyl.*—(Gerhardt, Traité, i. 711.)

This compound is obtained: 1. By the action of oxychloride of phosphorus, $POCl^3$, on acetate of potassium. The acetate deprived of water by fusion, is introduced into a tubulated retort, and the oxychloride of phosphorus admitted through the tubulus, drop by drop. A violent action takes place, the mixture becoming very hot without the application of external heat, and a liquid distils over, which is the chloride of acetyl, while tribasic phosphate of potassium remains in the retort:

$$3C^2H^3KO^2 + POCl^3 = PO^4K^3 + 3(C^2H^3O.Cl).$$

If now this liquid be poured back again three or four times into the retort, so that it may remain for some time in contact with the acetate of potassium, that salt being also in excess and pretty strongly heated, a further action takes place between the acetate of potassium and the compound $C^2H^3O.Cl$, the result of which is the formation of acetic anhydride: thus,

$$C^2H^3KO^2 + C^2H^3O.Cl = KCl + C^4H^6O^3.$$

The acetic anhydride enters into combination with the acetate of potassium, and a considerable degree of heat is required to destroy this compound and cause the anhydride to distil over. The distillate is more or less contaminated with acetic acid and chloride of acetyl; but on redistilling the crude product, these impurities pass over at the commencement, before the temperature rises to 137°·5, after which the pure anhydride distils over.—2. By the action of terchloride of phosphorus on acetate of potassium. When the liquid chloride is added drop by drop to the acetate of potassium (about 1 pt. PCl^3 to more than 2 pts. of the acetate), the action begins without application of heat, and chloride of acetyl, amounting in quantity to about half the chloride of phosphorus used, distils over mixed with a small quantity of chloride of phosphorus. On heating the residue after this action has ceased, acetic anhydride distils over free from chloride, and in quantity equal to about a third of the chloride of phosphorus used. The product contains a small quantity of a phosphorus-compound, which causes it to impart a brownish colour to nitrate of silver; but it may be freed from this impurity by a second distillation with acetate of potassium. — 3. By the action of chloride of benzoyl, $C^7H^5O.Cl$, on fused acetate of potassium. The first products of the action are chloride of potassium and acetate of benzoyl, $C^9H^8O^3$:

$$C^7H^5O.\,Cl + C^2H^3KO^2 = KCl + \left.\begin{matrix}C^7H^5O\\C^2H^3O\end{matrix}\right\}O.$$

But if the acetate of potassium is in excess, and the mixture is heated somewhat above the temperature at which the original substances act upon each other, a further action takes place, and a colourless liquid distils over, which is acetic anhydride, while benzoic anhydride remains in the retort in combination with benzoate of potassium. These new products are formed by double decomposition between 2 atoms of the benzoic acetate:

$$2\left\{\begin{matrix}C^7H^5O\\C^2H^3O\end{matrix}\right\}O = \left.\begin{matrix}C^7H^5O\\C^7H^5O\end{matrix}\right\}O + \left.\begin{matrix}C^2H^3O\\C^2H^3O\end{matrix}\right\}O$$

4. By the action of chloride of acetyl, C^2H^3OCl, on dry benzoate of sodium. The reaction, which takes place without the aid of heat, is precisely similar to the preceding.

Acetic anhydride is a colourless, very mobile, strongly refracting liquid, having a powerful odour, similar to that of the hydrated acid, but stronger, and recalling at the same time that of the flowers of the white-thorn. Sp. gr. 1·073 at 20°·5, which is nearly that of the hydrated acid, $C^2H^4O^2 + H^2O$, at its greatest density. Boiling point 137°·5 under a pressure of 750 mm. Vapour density = 3·47 (by calculation 3·531 for a condensation to 2 volumes).

Fuming sulphuric acid becomes heated by contact with acetic anhydride, carbonic anhydride being given off and a conjugated acid produced, which forms a gummy salt with lead. *Potassium* acts violently on acetic anhydride, evolving a gas which does not take fire if the potassium be introduced by small portions at a time. The liquid, after a while, solidifies into a mass of needles, consisting of a compound of acetic anhydride with acetate of potassium (p. 33). An oily substance is also produced, having a very pleasant ethereal odour. Finely divided *zinc* acts upon acetic anhydride in a similar manner, but less energetically, and only when heated in the water bath; hydrogen gas is then given off, and a soluble salt formed, which is deposited in microscopic crystals on the surface of the metal, and greatly retards the action. On saturating the excess of acetic acid in the residue with carbonate of sodium, the ethereal odour above mentioned is perceived. The hydrogen evolved, if collected immediately, has the same odour, burns with a bluish flame, and the product of the combustion renders lime-water turbid; but after passing through potassium, it is inodorous, and when burnt yields nothing but pure vapour of water.

Acetic anhydride does not combine immediately with *water*, but when poured into that liquid, falls to the bottom in oily drops which dissolve after a while, if the liquid is heated or agitated. It absorbs water from the air, and must therefore be kept in well closed vessels.

Acetic anhydride combines with *aldehydes.* With ordinary aldehyde, it forms a liquid compound, $C^4H^6O^3.\ C^2H^4O$ (Geuther), and a similar compound with valeral. $C^4H^6O^3.\ C^5H^{10}O$ (Guthrie and Kolbe); also with bitter almond oil (Geuther).

ACETOBENZOIC, OR BENZOACETIC ANHYDRIDE, $C^9H^8O^3 = \left.\begin{matrix}C^2H^3O\\C^7H^5O\end{matrix}\right\}O$. *Acetate of Benzoyl, Benzoate of Acetyl.*—Obtained by the action of chloride of acetyl on benzoate of sodium. Heavy oil smelling like Spanish wine. Neutral to litmus. Boils at 120° C. and is resolved into acetic and benzoic anhydrides (p. 35). Resolved into acetic and benzoic acids by boiling with water, and more quickly with alkalis.

ACETO-CINNAMIC ANHYDRIDE, $C^2H^3O.C^9H^7O.O$. *Acetate of Cinnamyl, &c.*—A very instable product obtained by the action of chloride of acetyl on cinnamate of sodium. Oil heavier than water, something like the preceding compound.

ACETO-CUMINIC ANHYDRIDE, $C^2H^3O\ .\ C^{10}H^{11}O\ .\ O$. *Acetate of Cumyl.*—Resembles the preceding compounds. In the moist state it quickly turns acid, and yields beautiful laminæ of cuminic acid, the odour of acetic acid becoming perceptible at the same time.

ACETO-SALICYLIC ANHYDRIDE, $C^2H^3O\ .\ C^7H^5O^2.O$. *Acetate of Salicyl, &c.*—Salicylate of sodium is strongly attacked by chloride of acetyl, even at ordinary temperatures, the mixture liquefying at first, but becoming perfectly hard in a few seconds. The product dissolves with effervescence in carbonate of sodium, the anhydride being converted into acetate and salicylate of sodium. (Gerhardt, Traité, iii. 319.)

ACETIC ETHERS. These compounds are the acetates of the alcohol-radicles, and may be divided into the following groups:

1. Monatomic Acetic Ethers.

ACETATE OF ALLYL, $C^2H^3O.C^3H^5$.—Prepared by treating acetate of silver with iodide of allyl, and rectifying once or twice over acetate of silver. It is a colourless liquid, lighter than water, having a pungent, aromatic odour, and boiling between 98° and 100°. Boiling potash decomposes it into acetate of potassium and allyl-alcohol. (Cahours and Hofmann, Chem. Soc. Qu. J. x. 322.)

ACETATE OF AMYL, OR ACETATE OF PENTYL, $C^2H^3O^2.C^5H^{11}$.—This compound is slowly produced when amylic alcohol is left in contact with acetic acid, and may be conveniently prepared by distilling 2 pts. of acetate of potassium, or 3 pts. of dehydrated acetate of lead, with 1 pt. of strong sulphuric acid, and 1 pt. of amylic alcohol, agitating the distillate with milk of lime, then dehydrating over chloride of calcium, and rectifying. It is a transparent, colourless liquid, of sp. gr. 0·8572 at 21°, and boiling at 133·3°, under a pressure of 27″ 8‴, with a platinum wire immersed in it. Vapour-density 4·458. Odour ethereal and aromatic, like that of acetate of ethyl. It is insoluble in water, but dissolves in *alcohol*, *ether*, and *fusel oil*. It is decomposed very slowly by aqueous potash, but quickly by alcoholic potash, yielding amylic alcohol and acetate of potassium. Chlorine passed through it at 100°, converts it into *di-chlorinated acetate of amyl*, $C^7H^{12}Cl^2O^2$, and this, by the action of chlorine in sunshine, is converted into a higher chlorine-compound.

ACETATE OF BENZYL, $C^2H^3O^2.C^7H^7$.—Produced by treating 2 vol. benzyl-alcohol with a mixture of 1 vol. sulphuric acid and 4 or 5 vol. acetic acid, or by boiling chloride of benzyl with alcoholic acetate of potassium. Colourless oil, heavier than water, and having a very agreeable odour, like that of pears. Boils at 210° C. Boiled with potash-ley, it yields acetate of potassium and benzylic alcohol. (Cannizzaro, Ann. Ch. Pharm. lxxxviii. 130.)

ACETATE OF ETHYL. *Acetic ether, Ethylic Acetate, Essigäther, Essignaphtha, Essigsaures Æthyloxyd, Ether acétique.* $C^4H^8O^2 = C^2H^3O^2.C^2H^5$. or $C^4H^3O^3.C^4H^5O$. (Lauragais, Journ. d. Sçavans, 1759, 324; Thénard, Mém. d'Arcueil, i. 153; Dumas and Boullay, J. Pharm. xiv. 113; Liebig, Ann. Ch. Pharm. v. 34; xxx. 144; Gm. viii. 493; Gerh. i. 743).—Discovered by Lauragais in 1759. It is formed by heating alcohol with acetic acid, or with an acetate and strong sulphuric acid, or by distilling ethyl-sulphate of calcium or potassium with glacial acetic acid. The best mode of preparing it is to distil a mixture of 3 pts. of acetate of potassium, 3 pts. of absolute alcohol, and 2 pts. of sulphuric acid; or 10 pts. of acetate of sodium, 6 pts. of alcohol, and 15 pts. of sulphuric acid; or 16 pts. of dry acetate of lead, 4½ pts. of alcohol, and 6 pts. of sulphuric acid. The acid is first mixed with the alcohol, and the liquid poured upon the salt reduced to fine powder. The mixture is then distilled to dryness, the heat being moderate at first, but increased towards the end of the process. The product is purified by digesting it with chloride of calcium and rectifying the decanted liquid.

Acetate of ethyl is a colourless liquid, having a pleasant ethereal odour. Sp. gr. 0·91046 at 0° (Kopp); 0·932 at 20° (Gössmann). Boils at 74°·3, when the barometer stands at 760 mm. (Kopp). Vapour-density 3·06 (Boullay and Dumas). It dissolves in 11 or 12 pts. of water, at ordinary temperatures (Mohr, Arch. Pharm. [2] lxv. 1), in all proportions of alcohol and ether. It burns with a yellowish flame, giving off the odour of acetic acid, and leaving that acid in the liquid state. It is permanent when dry, but in the moist state gradually decomposes into alcohol and acetic acid. The same decomposition takes place more quickly under the influence of alkalis. Heated with strong sulphuric acid, it is resolved into oxide of ethyl and acetic acid. Hydrochloric acid converts it into acetic acid and chloride of ethyl.

Action of Chlorine on *Acetate of Ethyl.* (Malaguti, Ann. Ch. Phys. [2] xx. 367; ibid. [3] xvi. 2, 58; Leblanc, ibid. [3] 197; Cloez, ibid. [3] xvii. 304.,—When acetate of ethyl is introduced into a bottle filled with dry chlorine gas, in the proportion of 1 atom acetate of ethyl to 8 atoms chlorine, and the action allowed to go on, first in the shade and afterwards with continually greater exposure to sunshine, a number of chlorinated compounds are formed in which 2, 3, 4, 5, 6, 7, and 8 atoms of hydrogen in the acetate of ethyl are successively replaced by an equal number of chlorine-atoms. It is however not always possible to obtain the particular compound required, the compounds $C^4H^6Cl^2O^2$, $C^4HCl^7O^2$, and $C^4Cl^8O^2$, being the only ones that can be produced with certainty. Other products are also formed, among which are acetic acid, trichloracetic acid, and sesquichloride of carbon. If the acetate of ethyl is at once exposed to sunshine in contact with chlorine, an explosion takes place, attended with deposition of charcoal.

Dichlorinated Acetate of Ethyl, $C^4H^6Cl^2O^2$, is the product obtained when the acetate of ethyl is kept cool and in the shade during the action of the chlorine. On distilling the product to separate the more volatile portions, till the boiling point rises to 110°, washing the brownish residue with water, and drying it over lime and sulphuric acid, the compound is obtained as a transparent colourless oil, of sp. gr. 1·301 at 12°. It smells somewhat like acetic acid, has a peppery taste, and produces irritation in the throat. It is slowly decomposed by water, yielding hydrochloric and acetic acids. $C^4H^6Cl^2O^2 + 2H^2O = 2C^2H^4O^2 + 2HCl$; slowly also by aqueous potash, but quickly by alcoholic potash, yielding acetate and chloride of potassium. (Malaguti.)

Trichlorinated Acetate of Ethyl, $C^4H^5Cl^3O^2$, was obtained by exposing the dichlorinated compound for some time to the action of chlorine in a bottle, covered at the upper part with black paper, so that the light fell only on the lower part of the liquid. It resembles the preceding compound, but cannot be distilled without alteration. It is isomeric with trichloracetate of ethyl, $C^2Cl^3O^2.C^2H^5$. See TRICHLORACETIC ACID. (Leblanc.)

Tetrachlorinated Acetate of Ethyl, $C^4H^4Cl^4O^2$, was obtained by exposing the dichlorinated compound to the sun in autumn, in bottles filled with dry chlorine. After rectification, washing, and drying, it forms an oil of sp. gr. 1·485 at 25°. It is decomposed by potash, yielding chloride, acetate, and trichloracetate of potassium (Leblanc). The *five-chlorine compound,* $C^4H^3Cl^5O^2$, was obtained in the same manner as the preceding, excepting that the gas above the liquid was protected from the action of the solar rays; the *six-chlorine compound* $C^4H^2Cl^6C^2$, by exposing the last compound to the sun for two days, in a bottle filled with dry chlorine. Sp. gr. 1·698 at 23·5. The *seven-chlorine compound,* $C^4HCl^7C^2$, was produced by exposing the dichlorinated compound in bottles filled with dry chlorine, to the sun for some months in winter. It forms rather soft crystals, insoluble in water, sparingly soluble in cold alcohol of ordinary strength, very soluble in ether. They melt below 100°, but do not appear to be volatile without decomposition. An oily liquid isomeric with this compound, and having a sp. gr. of 1·692 at 24·5°, is obtained by exposing trichloracetate of ethyl to chlorine in the shade, as long as any action goes on. (Leblanc.)

Perchlorinated Acetate of Ethyl, $C^4Cl^8O^2$, is prepared by exposing di- or tri-chlorinated acetate of ethyl to the brightest summer sunshine, and at the same time heating it to 110°; even then the substitution takes place very slowly (Leblanc). The product is distilled in an atmosphere of carbonic acid, to remove free chlorine. It is a colourless oil, which remains liquid at a few degrees below 0°, and has a strong pungent odour like that of chloral. Sp. gr. 1·79 at 25°. Boils, with partial decomposition, at 245° (Leblanc). When its vapour is passed through a tube filled with fragments of glass, and heated to 400°, it is partly converted into the isomeric compound chloraldehyde, C^2Cl^4O (Malaguti). In contact with water or moist air, it is gradually decomposed, yielding trichloracetic and hydrochloric acids. A similar decomposition is instantly produced by strong aqueous potash (Leblanc):

$$C^4Cl^8O^2 + 2H^2O = 2C^2HCl^3O^2 + 2HCl.$$

Ammonia, either gaseous or dissolved in water, acts strongly on the compound, producing sal-ammoniac and trichloracetamide (Malaguti):

$$C^4Cl^8O^2 + 2NH^3 = 2HCl + 2C^2H^2Cl^3NO$$

With absolute alcohol, the compound becomes strongly heated, and is completely converted into hydrochloric acid and trichloracetate of ethyl (Malaguti):

$$C^4Cl^8O^2 + 2C^2H^6O = 2HCl + 2C^4H^5Cl^3O^2.$$

When exposed for a long time to the action of chlorine, it yields crystals of sesquichloride of carbon. (Leblanc.)

Perchloracetic ether may be regarded as a *trichloracetate of pentachlorethyl*, $C^2Cl^3O^2.C^2Cl^5$; and in like manner, all the preceding compounds which contain more than 3 atoms of chlorine, may be viewed as trichloracetates of ethyl-radicles, in which the H is more or less replaced by Cl: *e.g.* pentachloracetic ether, $C^4H^3Cl^5O^2 = C^2Cl^3O^2.C^2H^3Cl^2$. Some of them appear however to be susceptible of isomeric modifications.

ACETATE OF METHYL, $C^3H^6O^2 = C^2H^3O . CH^3$. *Methylic Acetate, Essigsaurer Holzäther.* (Dumas and Péligot (1835), Ann. Ch. Phys. lviii. 46.—Weidmann and Schweizer, Pogg. xliii. 593.—H. Kopp, Ann. Ch. Pharm. lv. 181.—Gm. viii. 484; Gerh. i. 741.)—This compound occurs in crude wood-vinegar (Weidmann and Schweizer). The liquid called *Æther lignosus* or *Spiritus pyroaceticus* appears to be impure acetate of methyl.

Preparation.—1. Two pts. of wood-spirit are distilled with 1 pt. of glacial acetic acid and 1 pt. sulphuric acid; the distillate is shaken up with chloride of calcium, the acetate of methyl then rising to the top; and this product is freed from sulphurous acid by agitation with quicklime, and from wood-spirit by 24 hours' contact with chloride of calcium, which takes up the latter substance (Dumas and Peligot). —2. When 1 part of wood-spirit is distilled with 1 pt. acetate of potassium and 2 pts. of sulphuric acid, acetate of methyl passes over first, then sulphurous acid, acetic acid, methylic oxide, and a small quantity of methylic sulphate. The first receiver must therefore be removed as soon as sulphurous acid begins to escape; its contents shaken up with water; and the separated ether rectified over chloride of calcium and quicklime (Weidmann and Schweizer).—3. A mixture of 3 pts. wood-spirit, 14½ pts. dehydrated acetate of lead, and 5 pts. sulphuric acid is distilled; the distillate is shaken up with milk of lime; and the stratum of methylic acetate which rises to the surface is dehydrated by repeated treatment with chloride of calcium, then decanted from the lower liquid, and rectified. (H. Kopp.)

Acetate of methyl is a colourless liquid, having a very agreeable odour, like that of acetate of ethyl, sp. gr. 9·0085 at 21°; 0·9562 at 0° (Kopp). Boiling point, 56·3° under a pressure of 760 mm. (Kopp, Pogg. Ann. lxii. 1); 55° under a pressure of 762 mm. (Andrews, Chem. Soc. Qu. J. i. 27). Vapour-density 2·563 (Dumas and Péligot), by calculation 2·564. Index of refraction 1·3576. (Delffs, Pogg. Ann. lxxxi. 470.)

Acetate of methyl dissolves in water, and mixes in all proportions with alcohol and ether. The aqueous solution suffers but little decomposition by boiling. Solutions of caustic alkalis convert the compound into wood-spirit and an alkaline acetate. When poured on pulverised soda-lime, it is decomposed with violence, yielding a mixture of acetate and formate of sodium, and giving off hydrogen. In contact with strong sulphuric acid, it becomes heated, gives off acetic acid, and forms methylsulphuric acid. With chlorine it forms a number of substitution-products.

Dichlorinated Acetate of Methyl, $C^3H^4Cl^2O^2$, is formed by passing dry chlorine gas through acetate of methyl, assisting the action by a gentle heat towards the end. It is purified like the corresponding ethyl-compound. It is a colourless neutral liquid, having a pungent odour; its taste is sweet at first, but afterwards alliaceous and burning. Sp. gr. 1·25. Boils between 145° and 148°, but begins to decompose and give off fumes at 138°. It burns with a yellow flame, edged with green at the bottom. It is decomposed slowly by water, quickly by aqueous potash, and violently by alcoholic potash, yielding formic, acetic, and hydrochloric acids:

$$C^3H^4Cl^2O^2 + 2H^2O = CH^2O^2 + C^2H^4O^2 + 2HCl.$$

This compound is isomeric if not identical with dichlorinated formate of ethyl. (Malaguti, Ann. Ch. Phys. [2] lxx. 379.)

Trichlorinated Acetate of Methyl, $C^3H^3Cl^3O^2$, is obtained by passing chlorine very slowly into acetate of methyl, as long as any decomposition takes place, and purifying the product by repeated fractional distillation. It is a colourless oily liquid, heavier than water, boiling at 145°, and distilling without decomposition. It is decomposed by caustic potash, yielding chloride and formate of potassium, and *chloromethylase*, CHCl:

$$C^3H^3Cl^3O^2 + 2K^2O = 2KCl + 2CHKO^2 + CHCl.$$

It is isomeric but not identical with trichloracetate of methyl, $C\,Cl^3O^2.\,CH^3$, produced by distilling wood-spirit with trichloracetic acid and a small quantity of sulphuric acid. (Laurent, Ann. Ch. Phys. [2] lxxiii. 25.)

Perchlorinated Acetate of Methyl, $C^3Cl^6O^2$. (Cloez, Ann. Ch. Phys. [3] xvii. 297, 311.)—This compound, which appears to be identical with perchlorinated formate of ethyl, is produced by exposing acetate of methyl to the action of chlorine in sunshine, as long as the gas continues to be absorbed. It is a colourless liquid, having a suffocating odour and a disagreeable taste, which soon becomes intolerably acid, from decomposition. Sp. gr. 1·705 at 18°. Boils at about 200°, with partial decomposition. It is quickly decomposed by water and by moist air, yielding hydrochloric, carbonic, and terchloracetic acids:

$$C^3Cl^6O^2 + 2H^2O = 3HCl + CO^2 + C^2HCl^3O^2.$$

Similarly by the fixed alkalis in solution. With aqueous ammonia, it forms trichloracetamide, together with chloride and carbonate of ammonium:

$$C^3Cl^6O^2 + 6NH^3 + 2H^2O = N.H^2.C^2Cl^3O + 3NH^4Cl + CO^3\,(NH^4)^2$$

With alcohol it forms hydrochloric acid, trichloracetate of ethyl, and monochlorinated formiate of methyl:

$$C^2Cl^6O^2 + 2C^2H^6O = 2HCl + C^2Cl^3O^2.C^2H^5 + C^2H^3ClO^2.$$

Similarly with wood-spirit it yields trichloracetate of methyl, and monochlorinated formate of methyl.

The vapour passed through a red-hot porcelain tube is decomposed into chloraldehyde and chloro-carbonic oxide (phosgene) gas:

$$C^3Cl^6O^2 = C^2Cl^4O + COCl^2.$$

Acetate of Octyl, $C^2H^3O^2.\,C^8H^{17}$.—Prepared by passing hydrochloric acid gas through a mixture of acetic acid and octylic (caprylic) alcohol; or, better by distilling a mixture of octylic alcohol, acetate of sodium, and sulphuric acid. It is a liquid of very agreeable odour, insoluble in water, boiling at 190°. (Bouis, Compt. rend. xxxviii. 937.)

Acetate of Phenyl, $C^2H^3O.C^6H^5$.—Produced by the action of chloride of acetyl on acetate of phenyl: also by boiling an alcoholic solution of phosphate of phenyl with acetate of potassium. After all the alcohol has evaporated, the temperature of the mixture rises rapidly, and acetate of phenyl distils over in the form of an oily liquid. It is heavier than water, and slightly soluble in that liquid. Boils at 190°. Boiling potash decomposes it, yielding acetate of potassium and hydrate of phenyl. (Scrugham, Chem. Soc. Qu. J. vii. 241.)

Acetate of Tetryl, or Acetate of Butyl, $C^2H^3O^2.\,C^4H^9$.—Obtained by heating iodide of tetryl with a slight excess of very dry acetate of silver in a sealed flask at 100°:—also by distilling in an oil-bath equivalent quantities of acetate of potassium (recently fused) and tetryl-sulphate of potassium:

$$C^2H^3O^2.K + SO^4.K.C^4H^9 = C^2H^3O^2.C^4H^9 + SO^4.K^2$$

Acetate of Trityl, or Acetate of Propyl, $C^2H^3O^2.C^3H^7$.—Obtained by distilling propylic alcohol with a mixture of acetic and sulphuric acid. Resembles acetate of ethyl. Boils at 90°. (Berthelot.)

It is a colourless liquid of agreeable odour. Sp. gr. 0·8845 at 16° C. Boils at 114°. Vapour-density 4·073 (calculation, 4·017). Boiling potash converts it into acetate of potassium and tetrylic alcohol.

2. Diatomic Acetic Ethers. (*Glycolic Ethers.*)—These compounds are derived from the diatomic alcohols or glycols by the substitution of 1 or 2 at. acetyl ($C^2H^3O = Ac$), for 1 or 2 at hydrogen. They are related to the glycols in the same manner as the monatomic acetic ethers just described are related to the monatomic alcohols. The following have been obtained:—

Monoacetate of Ethylene	$\left.\begin{matrix}(C^2H^4)''\\ Ac.H\end{matrix}\right\}O^2$	Diacetate of Butylene	$\left.\begin{matrix}(C^4H^8)''\\ Ac^2\end{matrix}\right\}O^2$
Diacetate of Ethylene	$\left.\begin{matrix}(C^2H^4)''\\ Ac^2\end{matrix}\right\}O^2$	Diacetate of Amylene	$\left.\begin{matrix}(C^5H^{10})''\\ Ac^2\end{matrix}\right\}O^2$
Diacetate of Propylene	$\left.\begin{matrix}(C^3H^6)''\\ Ac^2\end{matrix}\right\}O^2$	Diacetate of Benzylene	$\left.\begin{matrix}(C^7H^6)''\\ Ac^2\end{matrix}\right\}O^2$

The diacetates are produced by the action of acetate of silver on the chlorides, bromides, or iodides of the several diatomic alcohol-radicles: *e.g.*

$$\underbrace{C^2H^4Br^2}_{\text{Bromide of ethylene.}} + \underbrace{\left.\begin{matrix}(C^2H^3O)^2\\ Ag^2\end{matrix}\right\}O^2}_{\text{2 at. acetate of silver.}} = 2AgBr + \underbrace{\left.\begin{matrix}C^2H^4\\ (C^2H^3O)^2\end{matrix}\right\}O^2}_{\text{Diacetate of ethylene.}}$$

Monoacetate of ethylene is obtained by heating acetate of potassium with an alcoholic solution of bromide or chloride of ethylene, or by heating in a sealed tube a mixture of 1 at. hydrate of ethylene and 1 at. acetic anhydride:

$$\left.\begin{matrix}(C^2H^4)''\\ H^2\end{matrix}\right\}O^2 + (C^2H^3O)^2.O = \left.\begin{matrix}(C^2H^4)''\\ C^2H^3O.H\end{matrix}\right\}O^2 + \left.\begin{matrix}C^2H^3O\\ H\end{matrix}\right\}O$$

All these compounds when distilled with potash are converted into the corresponding diatomic alcohols. They will be more fully described in connection with these several alcohols.

3. Triatomic Acetic Ethers; Acetins. (Berthelot, Ann. Ch. Phys. [3] xli. 277; Gm. ix. 496; Gerh. iii. 950; Berthelot and De Luca, Ann. Ch. Phys. [3] liii. 433).—Compounds obtained by the union of 1 at. glycerin, $C^3H^8O^3$, with 1, 2, or 3 at. acetic acid $C^2H^4O^2$, with elimination of an equal number of atoms of water. They may be regarded as glycerin, $C^3H^5O^3.H^3$, in which 1, 2, or 3 at. hydrogen are replaced by acetyl.

Monoacetin, $C^5H^{10}O^4 = C^3H^5O^3.H^2.C^2H^3O$, is produced by heating a mixture of glycerin and glacial acetic acid to 100° for 24 hours. Slight traces are also formed by mere contact of the liquids at ordinary temperatures. It is a neutral liquid, having a slightly ethereal odour. Sp. gr. 1·20. Mixed with half its bulk of water, it forms a clear liquid, which becomes turbid on the addition of two or more volumes of water; but the acetin does not separate from it, and the emulsion continues opalescent even after the addition of a large quantity of water. Treated with alcohol and hydrochloric acid, it forms glycerin and acetate of ethyl. It mixes with ether.

Diacetin, also called *Acetidin*, $C^7H^{12}O^5 = C^3H^5O^3.H.(C^2H^3O)^2 = C^3H^8O^3 + 2C^2H^4O^2 - 2H^2O$, is obtained by heating glacial acetic acid with excess of glycerin to 200° for 3 hours; by heating the same two liquids together at 275°; by heating glycerin to 200° with acetic acid diluted with an equal bulk of water; and by heating to 200° a mixture of 1 pt. of glycerin with 4 or 5 pts. of acetic acid. It is a neutral odoriferous liquid having a sharp taste; sp. gr. about 1·85. Boils at 280°, and distils without alteration. Assumes a viscid consistency at $-40°$. It becomes slightly acid by prolonged contact with air. 100 pts. of it saponified with baryta, yield 52·4 pts. of glycerin and a quantity of acetate of barium corresponding to 66·4 pts. of acetic acid; calculation requires 52·3 glycerin and 68·2 acetic acid. With alcohol and hydrochloric acid it yields glycerin and acetate of ethyl. It dissolves in ether and in benzol.

Triacetin, $C^9H^{14}O^6 = C^3H^5O^3.(C^2H^3O)^3 = C^3H^8O^3 + 3C^2H^4O^2 - 3\,H^2O$. — Obtained by heating diacetin to 250° for 3 hours with 15 to 20 times its weight of glacial acetic acid. Resembles the preceding compound. Sp. gr. 1·174 at 8°. Volatilises without residue. 100 pts. saponified with baryta yielded 80·6 pts. acetic acid, and 43·1 glycerin; by calculation it should be 82·6 acetic acid and 42·2 glycerin. It is insoluble in water, but soluble in dilute alcohol.

A compound of acetic acid and glycerin, probably triacetin, appears to exist in cod-liver oil (De Jongh, Berz. Jahresber. 1843), and in considerable quantity in the oil obtained from the seeds of *Euonymus europæus* (Schweizer, J. pr. Chem. liii. 437). Acetic acid was also observed by Chevreul among the product of the saponification of fats.

Acetochlorhydrin, $C^5H^9ClO^3 = C^3H^8O^3 + C^2H^4O^2 + HCl - 2H^2O$, is obtained by passing hydrochloric acid gas to saturation into a mixture of acetic acid and glycerin heated to 100°, and saturating the liquid with carbonate of sodium, after leaving it at rest for several days. This process yields the compound mixed with dichlorhydrin. It is also obtained, together with the following compound, by the action of chloride of acetyl on glycerin. It is a neutral oil, smelling like acetate of ethyl and volatilising at about 250°.

Acetodichlorhydrin, $C^5H^8Cl^2O^2 = C^3H^8O^3 + C^2H^4O^2 + 2HCl - 3H^2O$, is obtained by adding chloride of acetyl to glycerin externally cooled, as long as any action takes place, distilling the product, and purifying the distillate obtained between 180° and 160°, by agitation with water and then with an alkali, drying with chloride of calcium and quicklime, and fractional rectification. It is a transparent neutral oil having a refreshing ethereal odour, sparingly soluble in water and distilling at 205° without decomposition. (Berthelot and De Luca.)

Diacetochlorhydrin, $C^7H^{11}ClO^4 = C^3H^8O^3 + 2C^2H^4O^2 + HCl - 3H^2O$, is obtained by the action of chloride of acetyl on a mixture of equal volumes of glycerin and glacial acetic acid. It is a neutral liquid which volatilises at 245°. (Berthelot and De Luca.)

Similar compounds are produced by the action of bromide of acetyl on glycerin. By treating glycerin with a mixture of chloride and bromide of acetyl in equal numbers of atoms, *acetochlorbromhydrin*, $C^5H^8ClBrO^2 = C^3H^8O^3 + C^2H^4O^2 + HCl + HBr - 3\,H^2O$, is obtained as a neutral colourless liquid, smelling like acetate of ethyl and bromide of ethylene, boiling at 208°, and distilling without decomposition. It is somewhat coloured by exposure to light. (Berthelot and De Luca.)

The formulæ of all these compounds may be derived from that of a triple molecule of water $\begin{matrix}HHO\\HHO.\\HHO\end{matrix}$ By replacing 3 at. hydrogen in this formula by the triatomic radicle, *glyceryl* C^3H^5, we obtain glycerin $\begin{array}{ll}H & O\\ H(C^3H^5) & O.\\ H & O\end{array}$ Replacing 1, 2 or 3 at. H in this formula by acetyl ($C^2H^3O = Ac$), we obtain monoacetin, &c.; and, lastly, the replacement of one or two molecules of peroxide of hydrogen (HO), by chlorine in the formulæ of monoacetin and diacetin gives the acetochlorhydrins. Thus:

Monacetin	$\begin{array}{ll}H & O\\ Ac(C^3H^5)''' & O\\ H & O\end{array}$	Acetochlorbromhydrin .	$\begin{array}{ll} & Br\\ Ac(C^3H^5)''' & O\\ & Cl\end{array}$
Acetochlorhydrin . .	$\begin{array}{ll}H & O\\ Ac(C^3H^5)''' & O\\ & Cl\end{array}$	Diacetochlorhydrin . .	$\begin{array}{ll}Ac & O\\ Ac(C^3H^5)''' & O\\ & Cl\end{array}$
Acetodichlorhydrin . .	$\begin{array}{ll} & Cl\\ Ac(C^3H^5)''' & O\\ & Cl\end{array}$	Triacetin	$Ac^3(C^3H^5)'''O^3$.

ACETITE. A compound formed from acetic acid and mannite in the same manner as acetin from acetic acid and glycerin. (Berthelot, Compt. rend. xxxviii. 668.)

ACETOMETER. A hydrometer graduated for determining the strength of commercial acetic acid according to its density. (See ACETIC ACID.)

ACETONE. $C^3H^6O = C^2H^3O.CH^3$ [or $C^6H^6O^2$]. *Pyroacetic spirit*, *Essiggeist*, *Brenzessiggeist* (Gm. ix. 1; xiii. 462; Gerh. i. 700; iii. 943; iv. 906).—This compound has long been known as a product of the destructive distillation of acetates (p. 28). It is also produced by passing the vapour of acetic acid through a red-hot tube; by heating gum, sugar, tartaric acid, citric acid and other vegetable substances in contact with lime; and by heating citric acid with permaganate of potassium, or with a mixture of binoxide of manganese and dilute sulphuric acid. (Péan de St. Gilles, Compt. rend. xlvii. 555.)

$$\underbrace{C^6H^8O^7}_{\text{Citric acid.}} + O = C^3H^6O + 3CO^2 + H^2O.$$

It is prepared: 1. By distilling acetate of barium or acetate of calcium at a moderate heat, the metal then remaining in the form of carbonate:

$$2C^2H^3BaO^2 = C^3H^6O + CO^3Ba^2.$$

Acetate of barium when dry and pure, yields a perfectly colourless neutral distillate, in fact pure acetone. The calcium-salt requires a higher temperature to decompose it, and the distillate is in consequence contaminated with an empyreumatic oil, called *dumasin*, $C^{10}H^{16}O$.—2. By distilling in an iron retort or quicksilver bottle, a mixture of 2 pts. of acetate of lead and 1 pt. of pounded quicklime, rectifying the product several times over chloride of calcium, and finally distilling over the water-bath.

Acetone is a limpid, very mobile liquid, of sp. gr. 0·792 at 18° (Liebig), 0·814 at 0° (H. Kopp). It does not solidify at −15°. Boils at 56° (Dumas), at 56·3° (Kopp) under a pressure of 760 mm. Evaporates quickly, producing a considerable degree of cold. Vapour-density 2·0025 (Dumas). It has an agreeable odour, and a biting taste like that of peppermint. It is very inflammable, and burns with a white flame, without smoke.

Acetone mixes in all proportions with water, alcohol, ether, and many compound ethers. It does not dissolve potash or chloride of calcium. It dissolves many camphors, fats and resins.

Acetone forms definite compounds with the *alkaline bisulphites*. The potassium salt, $C^3H^6O + SO^3(KH)$, and the sodium-salt, $C^3H^6O + SO^3(NaH)$ crystallise in nacreous scales (Limpricht). The *ammonium-salt*, $C^3H^6O + SO^3(NH^4H,)$ is deposited on mixing an alcoholic solution of bisulphite of ammonium with acetone, in laminæ resembling cholesterin, which quickly aggregate into a heavy crystalline powder. (Städeler.)

Acetone was regarded by Kane as an alcohol, $C^3H^5.H.O$, containing the radicle C^3H^5, which he called *mesityl*. According to this view, however, the oxidation of acetone should yield products containing C^3, just as the oxidation of common alcohol, C^2H^6O yields aldehyde and acetic acid containing C^2; but no such products are obtained. A more probable view of the composition of acetone is that of Chancel, who regards it as aldehyde coupled with methylene, $C^2H^4O.CH^2$, or, which comes to the same thing, that of Gerhardt and Williamson, who regard it as aldehyde in which the basic hydrogen is replaced by methyl; $\left.\begin{matrix}C^2H^3O\\ CH^3\end{matrix}\right\}$. This view is quite in accordance with the decomposition of acetates into acetone and carbonates. For acetyl may be regarded as a compound of methyl with carbonic oxide; $[C^2H^3O = CH^3.CO.]$; and it is easy to conceive that 2 atoms of acetate of barium $\left.\begin{matrix}CH^3.CO\\ Ba\end{matrix}\right\}O$, may decompose in such a manner that the CO of the one may unite with the two atoms of barium and the two external atoms of oxygen, to form carbonate of barium, while the methyl remains in combination with the other atom of acetyl, forming acetone:

$$\underbrace{2\left(\left.\begin{matrix}CH^3.CO\\ Ba\end{matrix}\right\}O\right)}_{\text{Acetate of barium.}} = \underbrace{\left.\begin{matrix}CO\\ Ba^2\end{matrix}\right\}O^2}_{\text{Carbonate of barium.}} + \underbrace{\left.\begin{matrix}CH^3.CO\\ CH^3\end{matrix}\right\}}_{\text{Acetone.}}$$

The same view is strengthened by the fact (discovered by Williamson) that when a mixture of acetate and valerate of barium is heated, an acetone is formed containing acetyl coupled with tetryl (C^4H^9), or valyl (C^5H^9O) with methyl: thus

$$\left.\begin{matrix}CH^3.CO\\ Ba\end{matrix}\right\}O + \left.\begin{matrix}C^4H^9.CO\\ Ba\end{matrix}\right\}O = \left.\begin{matrix}CO\\ Ba^2\end{matrix}\right\}O^2 + \left.\begin{matrix}C^2H^3O\\ C^4H^9\end{matrix}\right\}$$

Decompositions of Acetone.—1. Acetone passed in the state of vapour through a red-hot tube, deposits charcoal and is converted into a peculiar oil called *dumasin*, which generally passes over together with acetone in the distillation of acetates.

2. Acetone is decomposed by *chlorine*, a portion of its hydrogen being replaced by that element; but it is not possible in this manner to replace the whole of the hydrogen by chlorine; even a mixture of chlorate of potassium and hydrochloric acid does not appear to be capable of replacing more than two of the hydrogen atoms by chlorine. The higher chlorinated acetones, may however be obtained by the action of chlorine, or the mixture just mentioned, on other organic bodies. (See CHLORACETONES, p. 29.)

Chlorine, in presence of alkalis, converts acetone into chloroform:

$$C^3H^6O + 12\,Cl + H^2O = 2CHCl^3 + CO^2 + 6\,HCl.$$

Bromine, in presence of alkalis, acts in a similar manner, producing bromoform: but iodine forms only a dark pitchy mass.

4. *Hydrochloric acid gas* is absorbed in large quantity by acetone, and according to Kane, yields chloride of mesityl (or chloropropylene) C^3H^5Cl. *Hydriodic acid gas* passed into acetone forms, according to Kane, iodide of mesityl, C^3H^5I, which distils over with the hydriodic acid; iodide of pteleyl C^3H^3I (or rather tri-iodomesitylene, $C^9H^9I^3$), which remains suspended in the residual liquid, in the form of yellow scales; and mesityl-hypophosphorous acid, $C^3H^6O.PHO$, which separates in silky needles as the liquid cools. Friedel (Compt. rend. xlv. 1013) stated that a solution of hydrochloric acid gas in acetone yielded, when heated to 100°, acetic acid and chloride of methyl ($2C^3H^6O + 4HCl = C^2H^4O^2 + 4CH^3Cl$), and similarly with hydriodic acid; but he has since admitted that these results were obtained with impure acetone containing wood-spirit.

5. With *pentachloride of phosphorus*, acetone yields chloropropylene, C^3H^5Cl, boiling at about 30° and *methylchloracetol*, a compound isomeric with chloride of propylene, $C^3H^6Cl^2$. This body treated with silver-salts, ammonia, ethylate of sodium, or alcoholic potash, is resolved into hydrochloric acid and chloropropylene, identical with the body obtained by the action of alcoholic potash on $C^3H^6Cl^2$. Hence it appears that acetone is related to the propylene series. (Friedel, Ann. Ch. Pharm. cxii. 236.)

6. Strong *nitric acid* acts violently on acetone, giving off copious red fumes, and forming mesitic aldehyde, C^3H^4O, and nitrite of pteleyl, $C^3H^3NO^2$. [or rather trinitromesitylene, $C^9H^9(NO^2)^3$], together with oxalic and cyanuric acid (Kane). By dropping acetone into fuming nitric acid contained in a flask externally cooled, and adding water as soon as the action ceases, a heavy oil is obtained, which explodes with violence when heated, giving off red fumes. (Fittig, Ann. Ch. Pharm. cx. 45.)

7. Acetone mixed with strong *sulphuric acid* becomes heated, and, according to the quantity of acid present and the rise of temperature which takes place, forms either

oxide of mesityl, $C^6H^{10}O$, or mesitylene, C^9H^{12}, together with mesitylsulphuric acid, $SO^4.C^3H^5.H$, and sulphurous acid. (According to Kane, the composition of mesitylsulphuric acid is $C^6H^5O.HO.SO^3$, and there is formed at the same time another acid called *permesitylsulphuric* acid, $C^6H^5O^2.\ 2\,SO^4H$).

8. Glacial *phosphoric* acid forms with acetone a dark brown mass, partly consisting of mesitylphosphoric acid. (Kane.)

9. A solution of *phosphorus* in acetone turns acid when kept for some weeks, and more quickly when heated, even in perfectly air-tight vessels. According to Zeise, the change consists in the formation of three peculiar acids, to which he gives the names, *phosphacetic, acephosgenic* and *acephoric* acids; but their nature and composition have not been clearly made out. Products of like nature are obtained with *sulphur*. *Sulphide of phosphorus* forms with acetone a peculiar acid, and an oil which has a powerful odour but no acid reaction. (Zeise.)

10. A solution of *ammonia* in acetone yields, by spontaneous evaporation, a colourless syrupy residue, which gradually changes into an alkaline liquid, consisting of *acetonine*, $C^9H^{18}N^2$, an organic base, which bears to acetone the same relation that amarine bears to bitter-almond oil:

$$3C^3H^6O + 2\,NH^3 = C^9H^{18}N^2 + 3H^2O.$$

The non-basic compound first formed is perhaps isomeric with acetonine. (Städeler, Chem. Gaz. 1853, 241.)

11. By the action of *ammonia* and *sulphur* on acetone, Zeise obtained a number of products, which however do not present any definite characters. (Gm. ix. 11.)

12. By the simultaneous action of *ammonia* and *hydrosulphuric acid*, acetone is converted into *thiacetonine*, a sulphuretted base consisting probably of $C^9H^9NS^2$. It crystallises in shining yellowish rhombohedrons, having an alkaline reaction, sparingly soluble in water, but dissolving with facility in alcohol, ether, acetone, and dilute acids. (Städeler.)

13. When 1 volume of acetone is mixed with 1 vol. *disulphide of carbon* and 2 vols. aqueous *ammonia*, laminated crystals, resembling ice, form in the liquid after a few days; but these gradually disappear, and are succeeded by large yellow crystals, which are insoluble in water, sparingly soluble in ether, but dissolve, with decomposition, in warm alcohol and in boiling hydrochloric acid (Hlasiwetz, J. pr. Chem. li. 355). Hlasiwetz assigns to these crystals the improbable formula $C^{30}H^{32}N^6S^9$. Städeler, on the other hand, regards them as the hydrosulphate of an organic base, *carbothiacetonine*, $C^{10}H^{18}N^2S^2$, and represents their formation by the equation,

$$3\,C^3H^6O + 2NH^3 + CS^2 = C^{10}H^{18}N^2S^2 + 3H^2O.$$

The formula $C^{10}H^{18}N^2S^2.H^2S$ agrees pretty nearly with the analytical numbers obtained by Hlasiwetz. A cold alcoholic solution of the crystals forms with dichloride of platinum a brownish yellow, amorphous precipitate consisting of $C^{10}H^{18}N^2S^2.PtCl^2.PtS$, and with mercuric chloride a white precipitate, which, according to Städeler, is merely Hg^2Cl^2S mixed with a small quantity of hydrochlorate of carbothiacetonine.

14. Acetone heated with a mixture of *hydrocyanic* and *hydrochloric acid*, is converted into *acetonic acid*, $C^4H^8O^3$ (Städeler):

$$C^3H^6O + CNH + 2\,H^2O = C^4H^8O^3 + NH^3.$$

15. Acetone distilled with *dichromate of potassium* and *sulphuric acid*, gives off acetic and carbonic acids, but no formic acid:

$$C^3H^6O + 4O = C^2H^4O^2 + CO^2 + H^2O.$$

16. Caustic alkalis, such as *hydrate of potassium* and *quick lime*, exert a dehydrating action on acetone, several products being formed, according to the proportion of water abstracted. Löwig and Weidmann, by subjecting acetone to the action of hydrate of potassium, obtained a dark brown mass, consisting chiefly of *xylite-oil*, $C^{12}H^{18}O$, which boiled at 200°, together with a resin which they call *xylite-resin*. Völckel, by leaving acetone for some time in contact with quick lime, also obtained an oil boiling above 200°, which he regarded as xylite-oil. But, according to Fittig (Ann. Ch. Pharm. cx. 32), the products obtained by the action of quick lime in closed vessels, are oxide of mesityl, $C^6H^{10}O^2$, boiling at 131°, and a liquid isomeric or identical with *phorone*, $C^9H^{14}O$. It must also be noticed that Schweizer and Weidmann (J. pr. Chem. xxiii. 14) obtained xylite-oil, and likewise xylite-naphtha, $C^{12}H^{22}O^3$, by the action of potash and of strong sulphuric acid on a compound produced from crude wood-spirit, which those chemists called *xylite*, assigning to it the improbable formula $C^6H^6O^{2\frac{1}{2}}$, but which was probably nothing but somewhat impure acetone. On the whole it appears that the action of alkalis on acetone is similar to that of sulphuric acid (p. 52), consisting in an abstraction of the elements of water. The products

obtained by the action of these dehydrating agents on acetone may be arranged as follows, according to their boiling-points:

		Boiling-point.
Xylite-naphtha . .	$C^{12}H^{22}O^{3} = 4\,C^{3}H^{6}O - H^{2}O$.	. 110° to 120°
Oxide of Mesityl .	$C^{6}H^{10}O = 2\,C^{3}H^{6}O - H^{2}O$.	. „ 131°
Mesitylene . .	$C^{9}H^{12} = 3\,C^{3}H^{6}O - 3H^{2}O$.	. 155° „ 160°
Phorone? . .	$C^{9}H^{14}O = 3\,C^{3}H^{6}O - 2H^{2}O$.	. 210° „ 220°
Xylite-oil . .	$C^{12}H^{18}O = 4\,C^{3}H^{6}O - 3H^{2}O$.	. above 200°

Vapour of acetone passed over heated hydrate of potassium or potash-lime is resolved into marsh-gas and carbonic anhydride:

$$C^{3}H^{6}O + 2\,KHO = CO^{3}K^{2} + 2\,CH^{4};$$

or if the heat is not very strong, the chief products are acetic acid, formic acid and hydrogen:

$$C^{3}H^{6}O + 2\,KHO + H^{2}O = C^{2}H^{3}KO^{2} + CHKO^{2} + 6\,H.$$

17. *Sodium* is violently attacked by anhydrous acetone, but without evolution of hydrogen, and hydrate of sodium is separated in white flakes. The liquid gradually assumes a pasty consistence, and the sodium becomes coated with oxide, so that it no longer acts perceptibly on the acetone. On distilling the mass, undecomposed acetone passes over first, and afterwards a watery liquid collects in the receiver, covered with a yellowish oil. On pouring the distillate into a basin, so that the undecomposed acetone may evaporate, the watery layer solidifies in a white crystalline mass, from which the oil may be separated by pressure between paper. The crystals consist of *hydrate of pinacone*, $C^{6}H^{12}O + 7\,H^{2}O$, and the oily liquid is *phorone*, $C^{9}H^{14}O$. The pinacone is produced by the abstraction of 1 at. oxygen from a double molecule of acetone:

$$2\,C^{3}H^{6}O + 2\,Na = Na^{2}O + C^{6}H^{12}O;$$

and the anhydrous pinacone thus formed appears to take water from another portion of the acetone, converting it into phorone:

$$3\,C^{3}H^{6}O - 2\,H^{2}O = C^{9}H^{14}O.$$

By heating the crystals of hydrated pinacone in a narrow glass tube, a viscid liquid is obtained, which absorbs water rapidly from the air, and is reconverted into the crystalline hydrate. This liquid appears to be anhydrous pinacone; but it is difficult to expel all the water (Städeler, Ann. Ch. Pharm. cxi. 277). Fittig (ibid. cx. 23) assigns to the hydrated crystals, the formula $C^{3}H^{6}O + 3H^{2}O$, regarding them as the hydrate of *paracetone*, a compound isomeric with acetone, which he also states is obtained in anhydrous crystals, by the action of ammonia on acetone. Fittig's formulæ do not, however, agree with the results of analysis so well as Städeler's (see PINACONE); moreover it is very unlikely that sodium should act with violence on acetone, without abstracting a portion of its oxygen. The action of ammonia on acetone, produces, according to Städeler, not a crystalline compound, but a liquid organic base, acetonine (p. 32).

18. Dry *dichloride of platinum* dissolves in acetone with evolution of heat, and forms a brown solution, which, when evaporated, gives off hydrochloric acid, and leaves a resinous mass, containing among other products, a yellow crystalline substance called *acechloride of platinum* or *chloroplatinite of mesityl*, $C^{6}H^{10}O.Pt^{2}Cl^{2}$. (?) This compound may be obtained in larger quantity, by triturating dichloride of platinum with acetone to the consistence of a thick paste, leaving the mass in a close vessel till it liquefies and ultimately forms crystals, washing these crystals with acetone, and purifying them by crystallisation from boiling acetone. Acechloride of platinum thus obtained, is yellow, inodorous, sparingly soluble in water, alcohol and ether, more readily in aqueous chloride of potassium or sodium. Cold acetone dissolves $\frac{1}{80}$ of it; boiling acetone a little more. The aqueous solution reddens litmus. The compound is decomposed and dissolved by potash, forming a brown solution. When boiled with water, it deposits a black substance called *aceplatinous oxide*, probably $C^{2}Pt^{2}O$. The same substance is deposited on boiling the mother-liquor of acichloride of platinum. The acichloride yields by distillation a residue of carbide of platinum, PtC. (Zeise, Ann. Ch. Pharm. xxxiii. 29; Gm. ix. 31.)

SUBSTITUTION-PRODUCTS OF ACETONE. *Chloracetones.*—Each of the atoms of hydrogen in acetone may be replaced by chlorine, giving rise to six chlorinated acetones. The first of these compounds is obtained by the action of nascent chlorine on acetone; the second by that of chlorine or the oxides of chlorine on acetone; the third and fourth by the action of chlorine on crude wood-spirit, probably containing acetone; the fifth and sixth can only be obtained by the action of chlorine or the oxides of chlorine on other organic compounds.

Monochloracetone, C^3H^5ClO, is obtained by the action of a feeble electric current (from three Bunsen's cells) on a mixture of acetone and hydrochloric acid, the chlorine set free at the positive pole from the hydrochloric acid, acting on the acetone and taking the place of 1 at. hydrogen. It is an oily, colourless liquid, which, when separated from the watery solution and rectified, boils at 117°, has a sp. gr. of 1·14 at 14°, and vapour-density = 3·40. Its vapour acts strongly on the nose and eyes, producing a copious flow of tears. (Riche, Compt. rend. xlix. 176.)

Dichloracetone, $C^3H^4Cl^2O$ (Kane's *mesitic chloral*), is produced by passing dry chlorine into anhydrous acetone, or better, according to Städeler, by mixing acetone in a capacious flask with twice its volume of strong hydrochloric acid diluted with an equal bulk of water, and adding pulverized chlorate of potassium by small portions. It is an oily liquid of sp. gr. 1·331 (Kane); 1·236 at 90° (Fittig). Boils at 116·5° (Städeler); at 121°·5 (Fittig). Vapour-density 3·2. Its vapour smells like chloroform at first, but, after a few seconds, attacks the nose and eyes with violence. The liquid blisters the skin like cantharides, producing wounds which are difficult to heal (Liebig, Kane, Fittig.) It is insoluble in water, but mixes in all proportions with alcohol and ether.

Trichloracetone, $C^3H^3Cl^3O$, is obtained by the action of chlorine on wood-spirit. When chlorine gas is passed into ordinary (unpurified) wood-spirit, crystals are formed consisting of $C^5H^{10}Cl^2O^2$ (*chloromesitate of methylene*), but if the action of the chlorine be further continued, the crystals disappear, and an oily liquid is formed, which is terchlorinated acetone. It is heavier than water, has an extremely pungent odour, and cannot be distilled without decomposition. (Bouis.)

Tetrachloracetone, $C^3H^2Cl^4O$, is obtained by dissolving the crystals just mentioned in wood-spirit and passing chlorine through the solution. It is an oily very volatile and pungent liquid, which blisters the skin. When exposed to moist air, it forms crystals containing $C^3H^2Cl^4O + 4\,H^2O$, which melt at 35°, and dissolve in water, alcohol and ether, forming solutions which are not precipitated by nitrate of silver. The crystals distilled with phosphoric anhydride yield the original anhydrous compound. This and the preceding compound are doubtless formed from acetone contained in the wood-spirit. (Bouis, Ann. Ch. Phys. [3] xxi. 111.)

Pentachloracetone, C^3HCl^5O, is obtained by the action of a mixture of chlorate of potassium and hydrochloric acid on several organic compounds, viz. kinic, citric, gallic, pyrogallic, catechucic and salicylic acids, also kinone, muscular flesh, albumin, indigo and tyrosin. The best mode of preparing it is to add a considerable quantity of chlorate of potassium to a boiling solution of kinic acid, and then add strong hydrochloric acid in such portions that chlorine and chlorous acid may be continually evolved. The distillate is concentrated by rectification over chloride of calcium. It then, if tolerably pure, solidifies into a crystalline hydrate when covered with water at 4° or 5°. If no solidification takes place, the product is contaminated with other oils, and must be purified by agitating it with ice-cold water, and heating the decanted and clarified liquid to 60°; the greater part of the oily impurities then separate out. To purify it completely, it is converted into the crystalline hydrate as above mentioned, and the crystals are pressed between paper. The pure anhydrous compound may be obtained by melting the crystals in a glass tube, whereupon they separate into a watery and an oily liquid, the latter, which is undermost, being pure anhydrous pentachloracetone. It is a colourless rather mobile oil, having a burning aromatic taste, and an odour like that of chloral. Sp. gr. between 1·6 and 1·7. It remains liquid at −20° and boils at 190°. The hydrate, which crystallises in rhombic tables, contains 4 atoms of water. Water dissolves $\frac{1}{10}$ of its volume of anhydrous pentachloracetone, and on the other hand, this compound takes up a certain quantity of water without change of appearance; but it then becomes turbid at the heat of the hand, like hydrated conine. Pentachloracetone dissolves readily in alcohol and ether. The alcoholic solution mixed with alcoholic potash deposits chloride of potassium together with scaly crystals, probably consisting of *dichloracetate* of *potassium*, and the solution is found to contain formic acid:

$$C^3HCl^5O + H^2O = \underbrace{CHCl^3}_{\text{Chloroform.}} + \underbrace{C^2H^2Cl^2O^2}_{\text{Dichloracetic acid.}}$$

and:

$$CHCl^3 + 2\,H^2O = 3\,HCl + CH^2O^2.$$

(Städeler, Ann. Ch. Pharm. cxi. 277.)

Hexachloracetone, C^3Cl^6O (discovered by Plantamour, who assigned to it the formula ($C^8Cl^{10}O^3$), is obtained by the action of chlorine in sunshine on an aqueous solution of citric acid. It is an oily liquid of peculiar pungent odour, sp. gr. 1·75 at 10°, and boiling between 200° and 201°. It makes transient grease spots upon paper, gradually reddens litmus paper, and forms with water, at temperatures not above 6°, a crystalline hydrate, $C^3Cl^6O + H^2O$, which melts at a temperature above 15°, with separation of an oil.

Bromacetone, C^3H^5BrO, is produced similarly to monochloracetone, viz. by the action of a feeble electric current on a mixture of acetone and hydrobromic acid. It is colourless when first prepared, but turns brown in a few minutes, and is decomposed by distillation, the greater portion however passing over between 140° and 145°. Its vapour irritates the eyes so strongly that the spilling of a few drops renders the air of a room unendurable. (Riche.)

Iodacetone appears also to be formed in small quantity by the electrolysis of a mixture of acetone and hydriodic acid. (Riche.)

Methylacetone, $C^4H^8O = C^3H^5(CH^3)O$. — When crude commercial acetone, or, better, the brown liquid which floats on the top of it, is dehydrated with chloride of calcium and then subjected to fractional distillation, pure acetone passes over below 60° and the distillate which is obtained between 60° and 130°, yields, after about thirty fractionations, three distinct compounds, viz. methylacetone, boiling between 75° and 77°, ethylacetone, $C^5H^{10}O$, between 90°, and 95° and dumasin, $C^6H^{10}O$, between 120° and 125°. (Fittig, Ann. Ch. Pharm. cx. 18.)

Methylacetone is a colourless liquid of sp. gr. 0·838 at 19° C. having the odour of acetone, miscible in all proportions with water and alcohol. It combines with acid sulphite of sodium, forming a crystalline compound, $2C^4H^7NaSO^4 + 3H^2O$, which is very soluble in water.

Ethylacetone, $C^5H^{10}O = C^3H^5(C^2H^5)O$. — Transparent, colourless liquid, smelling faintly like acetone, sparingly soluble in water, but miscible in all proportions with alcohol, sp. gr. 0·842 at 19°. Boils between 90° and 95°. With acid sulphite of sodium it forms the compound $2C^5H^9NaSO^3 + 3H^2O$, which crystallises in colourless nacreous laminæ very soluble in water. (Fittig.)

ACETONES or KETONES. This term is applied to a class of compounds which, like that just described, are composed of an acid-radicle united with an alcohol-radicle. Nearly all the acetones at present known consist of the radicle of a fatty acid combined with one of the corresponding alcohol-radicles; their general formula being $C^mH^{2m+1}.C^nH^{2n-1}O$. where *m* may be either greater or less than *n*. When $m = 0$, the acetone becomes an aldehyde, $H.C^nH^{2n-1}O = C^nH^{2n}O$; the acetones may therefore be regarded as aldehydes in which 1 at. hydrogen is replaced by an alcohol-radicle.

Acetones are either *simple* or *compound*. In the simple acetones, $m = n - 1$, so that their general formula is $C^{n-1}H^{2n-1}.C^nH^{2n-1}O. = C^{2n-1}H^{4n-2}O$; thus, acetic acetone, for which $n = 2$, is $CH^3.C^2H^3O$. The simple acetones are produced by heating the barium or calcium salts of the fatty acids, 2 atoms of the salt being decomposed in such a manner that the acid radicle of one of them is resolved into the next lowest alcohol-radicle and carbonyl (CO), so that a carbonate of calcium or barium is formed at the same time:

$$\left.\begin{matrix} C^nH^{2n-1}O \\ Ca \end{matrix}\right\}O + \left.\begin{matrix} CO.C^{n-1}H^{2n-1} \\ Ca \end{matrix}\right\}O = \left.\begin{matrix} C^nH^{2n-1}O \\ C^{n-1}H^{2n-1} \end{matrix}\right\} + \left.\begin{matrix} CO \\ Ca^2 \end{matrix}\right\}O^2.$$

The formation of acetic acetone or methyl-acetyl (p. 26) by the decomposition of acetate of barium, is a particular example of this process. In like manner, *propione* or *ethyl-propionyl*, $C^2H^5.C^3H^5O$, *butyrone* or *trityl-butyryl*, $C^3H^7.C^4H^7O$, *valerone* or *tetryl-valyl*, $C^4H^9.C^5H^9O$, are produced by the decomposition of the propionates, butyrates valerates, &c.

These simple acetones were the only ones known, till Williamson in 1851 (Chem. Soc. Qu. J. iv. 238) showed that, by distilling a mixture of the barium or calcium salts of two different fatty acids, acetones may be obtained in which an acid radicle is associated with an alcohol-radicle which is not the next below it in the series [*m* greater or less than $n-1$]: these are the so-called compound or intermediate acetones. If the acids whose salts are distilled together contain *p* and *q* atoms of carbon, the decomposition may be represented by the equation:

$$\left.\begin{matrix} C^pH^{2p-1}O \\ Ca \end{matrix}\right\}O + \left.\begin{matrix} CO.C^{q-1}H^{2q-1} \\ Ca \end{matrix}\right\}O = \left.\begin{matrix} C^pH^{2p-1}O \\ C^{q-1}H^{2q-1} \end{matrix}\right\} + \left.\begin{matrix} CO \\ Ca^2 \end{matrix}\right\}O^2.$$

or, since it is indifferent which of the acid radicles we suppose to be decomposed, the formula of the acetone thus produced may also be $\left.\begin{matrix} C^qH^{2q-1}O \\ C^{p-1}H^{2p-1} \end{matrix}\right\}$. Thus a mixture of acetate and valerate of calcium yields by distillation either *methyl-valyl*, $CH^3.C^5H^9O$, or *tetryl-acetyl*, $C^4H^9.C^2H^3O$, either of these formulæ being equal to $C^6H^{12}O$. Possibly two isomeric compounds having these formulæ, may be produced together. If one of the mixed salts is a formate, $\left.\begin{matrix} CO.H \\ Ca \end{matrix}\right\}O$, the alcohol-radicle separated from it is reduced to an atom of hydrogen, and the acetone becomes an aldehyde. (See ALDEHYDES.)

The compound acetones are also produced, together with the simple acetones and other products, when a calcium or barium salt of a fatty acid is distilled alone. Thus the distillation of butyrate of calcium yields, besides butyrone and a small quantity of butyral, a considerable number of hydrocarbons (Berthelot, Compt. rend. xliii. 236); and among these, methyl and ethyl appear to occur, and give rise to the formation of *ethyl-butyryl*, $C^2H^5.C^4H^7O$, and *methyl-butyryl*, $CH^3.C^4H^7O$. (Friedel, Compt. rend, xlvii. 553.)

The following is a list of the acetones, or ketones, at present known, which are derived from the fatty acids:

Methyl-acetyl (Acetone)	$C^3H^6O = CH^3 . C^2H^3O$
Methyl-butyryl	$C^5H^{10}O = CH^3 . C^4H^7O$
Ethyl-propionyl (Propione) . . .	$C^5H^{10}O = C^2H^5 . C^3H^5O$
Ethyl-butyryl	$C^6H^{12}O = C^2H^5 . C^4H^7O$
Methyl-valyl	$C^6H^{12}O = C\ H^3 . C^5H^9O$
Trityl-butyryl (Butyrone)	$C^7H^{14}O = C^3H^7 . C^4H^7O$
Methyl-œnanthyl	$C^8H^{16}O = C\ H^3 . C^7H^{13}O$
Tetryl-valyl (Valerone)	$C^9H^{18}O = C^4H^9 . C^5H^9O$
Amyl-capronyl (Capronone) . . .	$C^{11}H^{22}O = C^5H^{11} . C^6H^{11}O$
Heptyl-capryl (Caprylone) . . .	$C^{15}H^{30}O = C^7H^{15} . C^8H^{15}O$
Octyl-pelargonyl (Pelargonone) . .	$C^{17}H^{34}O = C^8H^{17} . C^9H^{17}O$
Laurone	$C^{23}H^{46}O = C^{11}H^{23} . C^{12}H^{23}O$
Myristone	$C^{27}H^{54}C = C^{13}H^{27} . C^{14}H^{27}O$
Palmitone or Margarone	$C^{31}H^{62}O = C^{15}H^{31} . C^{16}H^{31}O$
Stearone	$C^{35}H^{70}O = C^{17}H^{35} . C^{18}H^{35}O$

Some of the compounds in this table are isomeric, *e. g.* propione and butyracetone. Among the higher terms of the series, the number of such isomeric compounds is doubtless very great, though but few of them have yet been obtained.

These bodies, with the exception of acetic acetone, have not been much studied. Their reactions, so far as they are known, resemble those of common acetone already described. The lower terms of the series unite with the acid sulphites of the alkali-metals, generally forming crystalline compounds. The best mode of purifying the acetones is to shake them up with a strong aqueous solution of acid sulphite of potassium or sodium, and distil the resulting solid compound with potash. The acetone then passes over pure.

But little is known respecting acetones belonging to other series of acids. Two have been formed containing the radicle benzoyl, viz. *benzophenone*, or *phenyl-benzoyl*, $C^{13}H^{10}O = C^6H^5.C^7H^5O$, the acetone of benzoic acid, obtained by heating benzoate of potassium; and *methyl-benzoyl*, $C^8H^8O = CH^3.C^7H^5O$, obtained by distilling together equivalent quantities of acetate and benzoate of calcium (Friedel). Benzophenone treated with nitric acid yields *nitrobenzophenone*, $C^{13}H^8(NO^2)^2O$.

The calcium-salt of camphoric acid, which is dibasic, yields by dry distillation an oily liquid called *phorone*, which has the constitution of an acetone:

$$\underbrace{\left.\begin{matrix}C^{10}H^{14}O^2\\ Ca^2\end{matrix}\right\}}_{\text{Camphorate of calcium.}} O^2 = \underbrace{C^9H^{14}O}_{\text{Phorone.}} + \underbrace{\left.\begin{matrix}CO\\ Ca^2\end{matrix}\right\}}_{\text{Carbonate of calcium.}} O^2;$$

and suberate of calcium, $C^8H^{12}O^4Ca^2$, yields in like manner *suberone*, $C^7H^{14}O$, mixed with other products. These are the only two acetones of dibasic acids yet discovered. (Gerhardt, Traité, iv. 640.)

ACETONINE. $C^9H^{18}N^2$.—Produced by the action of ammonia on acetone (p. 28), either when a solution of ammonia in acetone is left to evaporate spontaneously to a syrup, or when acetone saturated with ammonia is heated to 100° in a sealed tube. It is a colourless liquid, having a peculiar urinous odour, a burning taste and alkaline reaction, easily soluble in water, alcohol, and ether. It unites with acids, forming salts. The *oxalate* $C^9H^{18}N^2.C^2H^2O^4 + H^2O$ crystallises from a hot saturated alcoholic solution in delicate colourless prisms, which are soluble in water, insoluble in ether, give off half their water at 100°, the rest between 115° and 120°, and decompose at a higher temperature. The *chloroplatinate*, $C^9H^{18}N^2.HCl.PtCl^2$, forms lustrous, orange-coloured, four-sided prisms with oblique terminal faces. It is soluble in water, also in boiling alcohol containing hydrochloric acid; insoluble in ether. (Städeler, Ann. Ch. Pharm. cxi. 308.)

ACETONITRILE. C^2H^3N.—A compound obtained by treating acetate of ammonium or acetamide with phosphoric anhydride:

$$\underbrace{C^2H^3O^2.NH^4}_{\text{Acetate of ammonium.}} - 2H^2O = C^2H^3N;\ \text{and}\ \underbrace{C^2H^5NO}_{\text{Acetamide.}} - H^2O = C^2H^3N.$$

It is identical with cyanide of methyl, obtained by distilling cyanide of potassium with methylsulphate of potassium. (See CYANIDE OF METHYL.)

Chloracetonitrile, C^2Cl^3N, or cyanide of trichloromethyl, $CCl^3.CN$, is obtained by distilling trichloracetate of ammonium or trichloracetamide with phosphoric anhydride. It is a liquid boiling at 81°; of sp. gr. 1·4441. With boiling potash, it yields ammonia and trichloracetate of potassium. It is violently attacked by potassium.

ACETONYL. C^6H^{12}.—A hypothetical radicle supposed by Hlasiwetz to exist in the yellow crystals formed by the action of ammonia and bisulphide of carbon on acetone. Hlasiwetz assigns to these crystals the formula $C^{30}H^{52}N^6S^8$, and regards them as *sulphocyanate of acetonyl with sulphocarbonate of sulphacetonyl* = $2(C^6H^{12}.2CNS) + 2C^6H^{12}S.C^2H^4N^2S^2$. Städeler's view of the constitution of this compound (p. 52), is much more probable.

ACETOSYL. The name given by Gerhardt to the hypothetical radicle C^2H^3 or C^4H^3, originally called *acetyl*, and supposed by some chemists to exist in acetic acid and its derivatives. (See ACETYL and VINYL.)

ACETOXYL. Kolbe's name for the radicle C^2H^3O or $C^4H^3O^2$, usually called acetyl, which see.

ACETUREÏD. Syn. of Acetyl-urea.

ACETYL. C^2H^3O or $C^4H^3O^2$. *Acetoxyl, Othyl.*—A radicle not yet isolated, but supposed to exist in acetic acid and its derivatives, the rational formula of acetic acid being, on this hypothesis, $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O$, and that of acetic anhydride, $\left.\begin{matrix}C^2H^3O\\C^2H^3O\end{matrix}\right\}O$.

The reason for assuming the existence of this radicle in the acetic compounds is, that the formula to which it leads, affords the simplest representation of the most important reactions of acetic acid and the other bodies of the series. Thus, when acetic acid $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O$ is treated with a metallic oxide or hydrate, the basic atom of hydrogen is replaced by a metal, and an acetate of that metal $\left.\begin{matrix}C^2H^3O\\M\end{matrix}\right\}O$ is produced. On treating the same compound with pentasulphide of phosphorus, P^2S^5, the external atom of oxygen is replaced by sulphur, and thiacetic acid, $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}S$ is formed; and by the action of pentachloride of phosphorus, the group HO is replaced by Cl, and chloride of acetyl $C^2H^3O.Cl$ is produced. (See ACETIC ACID, and ACIDS, p. 44.)

Formerly, however, acetic acid, and the other members of the same group, were supposed to be derived from the radicle C^2H^3 or C^4H^3; and to this the name *acetyl* was originally applied. Thus, anhydrous acetic acid was regarded as a trioxide of this radicle, viz. $C^4H^3.O^3$, and the hydrated acid as a compound of this oxide with water, viz. $C^4H^3O^3.HO$. &c. To apply the same name to two different radicles would of course create confusion; hence the terms *acetoxyl* proposed by Kolbe, and *othyl* (abbreviation of oxygen-ethyl) by Williamson, for the radicle C^2H^3O. Most chemists, however, are of opinion, that the radicle supposed to exist in acetic acid and its derivatives, is most appropriately designated by the term *acetyl;* and accordingly, this term is now generally applied to the group C^2H^3O, while C^2H^3, which more properly belongs to another series of compounds derived from alcohol, ether and ethylene, and having a less intimate distant relation to acetic acid, is called by a different name. (See ACETOSYL and VINYL.)

Acetyl, C^2H^3O is regarded by Kolbe as a compound or conjugate radicle, containing methyl and carbonyl, viz. CH^3,CO; and in like manner, propionyl, C^3H^5O, is regarded as a compound of ethyl: $C^2H^5.CO$; butyryl, C^4H^7O, as a compound of trityl: $C^3H^7.CO$, &c. each radicle of a fatty acid being supposed to contain the next lowest alcohol-radicle associated with carbonyl. This view, which has been adopted by Gerhardt, in his "Traité de Chimie Organique" is based upon the fact that certain methyl-compounds may be obtained from acetic acid and its derivatives, and the contrary; similar transformations likewise taking place in the other terms of the series. Thus, a solution of acetate of potassium subjected to electrolysis, yields methyl and carbonic anhydride:

$$\underbrace{\left.\begin{matrix}CH^3.CO\\H\end{matrix}\right\}O}_{\text{Acetic acid.}} = \underbrace{CH^3}_{\text{Methyl.}} + CO^2 + H$$

Cyanide of methyl boiled with aqueous potash gives off ammonia and forms acetate of potassium:

$$\underbrace{CH^3.CN}_{\text{Cyanide of methyl}} + KHO + H^2O = \underbrace{\left.\begin{matrix}CH^3.CO\\K\end{matrix}\right\}}_{\text{Acetate of potassium.}}O + NH^3;$$

and acetate of ammonium $(CH^3.CO).NH^4.O$, treated with phosphoric anhydride, gives off $2H^2O$, and is reduced to cyanide of methyl, $CH^3.CN$. Marsh-gas, or hydride of methyl, $CH^3.H$, is produced by the decomposition of acetates (p. 12); and cacodyl $As(CH^3)^2$, by the decomposition of acetic acid. The formation of acetone or methyl-acetyl, $CH^3.C^2H^3O$, from acetates, and the corresponding transformations of propionates, valerates, &c. (p. 26), is another example of the same kind of decomposition. Again it has been shown by Wanklyn (Chem. Soc. Q. J. xi. 103), that sodium-ethyl subjected to the action of carbonic anhydride is converted into propionate of sodium:

$$\underbrace{C^2H^5.Na}_{\text{Sodium-ethyl.}} + CO^2 = \underbrace{(C^2H^5.CO).Na.O}_{\text{Propionate of sodium.}};$$

and in like manner, acetate of sodium may be prepared from sodium-methyl. Lastly, many organic compounds, such as sugar, starch, alcohol, and acetone, which are convertible into acetic acid by oxidation, may also, under the influence of chlorine, or bromine, be converted into bodies belonging to the methyl-series, viz. chloroform, $C(HCl^2).Cl$, and bromoform, $C(HBr^2).Br$. It must be observed, however, that the representation of acetic acid as a methyl-compound applies chiefly to a state of transition, just as the acid is being produced from or converted into a body belonging to a different series, and exhibiting different chemical relations; so long as we are concerned with the transformation of one acetyl-compound into another, such as that of acetic acid into chloride or bromide of acetyl, or of the chloride into acetic anhydride, the formula $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O$ is sufficient for the representation of all the changes which take place.

The hydrogen in acetyl may be partly or wholly replaced by other elements, viz. chlorine, bromine, &c.; and hence arise the conjugate or derivative radicles, *bromacetyl*, *chloracetyl*, &c., which, like acetyl itself, are hypothetical, not having yet been isolated. The following table exhibits a general view of the compounds of acetyl and of the radicles derived from it by substitution.

Bromide of Acetyl	$C^2H^3O.Br$	
Chloride	$C^2H^3O.Cl$	
Iodide	$C^2H^3O.I$	
Hydride	$C^2H^3O.H$	Aldehyde
Hydrate	$C^2H^3O.H.O$	Acetic acid
Oxide	$(C^2H^3O)^2.O$	Acetic anhydride
Peroxide	$C^2H^3O.O$	
Sulphydrate	$C^2H^3O.H.S$	Thiacetic acid
Sulphide	$(C^2H^3O)^2.S$	Thiacetic anhydride
Nitrides	$C^2H^3O.H^2.N$	Acetamide
	$(C^2H^3O)^2.H.N$	Diacetamide
	$C^2H^3O.C^2H^5.H.N$	Ethyl-acetamide
	&c.	&c.
Hydrate of Bromacetyl	$C^2H^2BrO.H.O$	Bromacetic acid
Nitride	$C^2H^2BrO.H^2.N$	Bromacetamide
Hydrate of Dibromacetyl	$C^2HBr^2O.H.O$	Dibromacetic acid
Nitride	$C^2HBr^2O.H^2.N$	Dibromacetamide
Hydride of Tribromacetyl	$C^2Br^3O.H$	Bromal
Hydrate of Chloracetyl	$C^2H^2ClO.H.O$	Chloracetic acid
Nitride	$C^2H^2ClO.H^2.N$	Chloracetamide
Chloride of Trichloracetyl	$C^2Cl^3O.Cl$	Chloraldehyde
Hydride	$C^2Cl^3O.H$	Chloral
Hydrate	$C^2Cl^3O.H.O$	Trichloracetic acid
Nitride	$C^2Cl^3O.H^2.N.$	Trichloracetamide
Phosphide	$C^2Cl^3O.H^2.P.$	Trichloracetyphide
Hydrate of Iodacetyl	$C^2H^2IO.H.O$	Iodacetic acid
Nitride	$C^2H^2IO.H^2.N$	Iodacetamide
Hydrate of Di-iodacetyl	$C^2HI^2O.H.O$	Di-iodacetic acid
Nitride	$C^2HI^2O.H^2.N.$	Di-iodacetamide
Hydride of Tri-iodacetyl	$C^2I^3O.H.$	Iodal

Bromide of Acetyl. $C^2H^3O.Br$.—Prepared by slowly adding glacial acetic acid to pentabromide of phosphorus in a tubulated retort, distilling, and rectifying:

$$C^2H^3O.H.O + PBr^3.Br^2 = C^2H^3O.Br + HBr + PBr^3O.$$

It is a colourless liquid, boiling at 81°. When exposed to the air, it fumes strongly and immediately turns yellow. It colours the skin yellow, and is said to impart to it the odour of phosphuretted hydrogen; but this must arise from impurity. Water decomposes it into acetic and hydrobromic acids. (**Ritter**, Ann. Ch. Pharm. xcv. 209.)

Chloride of Acetyl. $C^2H^3O.Cl$.—Produced by the action of oxychloride of phosphorus on acetate of potassium:

$$3(C^2H^3O.K.O) + POCl^3 = 3C^2H^3OCl + PO^4K^3;$$

or in the same manner as the preceding compound, by distilling glacial acetic acid with pentachloride of phosphorus:

$$C^2H^3O.H.O + PCl^3.Cl^2. = C^2H^3O.Cl + HCl + PCl^3O.$$

Gerhardt, who discovered this compound (Ann. Ch. Phys. [3] xxxvii. 294), prepared it by adding oxychloride of phosphorus, drop by drop, to fused acetate of potassium. A brisk action then takes place, and sufficient heat is produced to cause the chloride of acetyl to distil over into the receiver, which must be well cooled. The distillate may be freed from excess of oxychloride of phosphorus by re-distillation over acetate of potassium, then distilled by itself, and the liquid which passes over at 55° collected apart. The re-distillation over acetate of potassium is, however, attended with some loss, in consequence of the formation of acetic anhydride.

$$C^2H^3O.Cl + C^2H^3O.K.O = (C^2H^3O)^2O + KCl.$$

For this reason, Ritter recommends the preparation of chloride of acetyl by the action of pentachloride of phosphorus on glacial acetic acid, the product being thereby obtained in larger quantity and more easily purified.

Chloride of acetyl is a colourless, very mobile, strongly refracting liquid, of specific gravity 1·125 at 11°, 1·1305 at 0°, and 1·1072 at 16° (**Kopp**). Boils at 55°. Vapour-density, 2·87 (**Gerhardt**): by calculation (2 vol.) = 2·718. It fumes slightly in the air, and has a pungent odour like that of acetic and hydrochloric acid. The vapour attacks the eyes and respiratory organs very strongly.

Chloride of acetyl is decomposed with explosive violence by water, yielding acetic and hydrochloric acids:

$$C^2H^3OCl + H^2O = C^2H^4O^2 + HCl.$$

Ammonia acts strongly upon it, forming acetamide:

$$C^2H^3O.Cl + H^3N = C^2H^3O.H^2.N + HCl.$$

Similarly with phenylamine, it forms phenylacetamide $C^2H^3O.C^6H^5.H.N$. Distilled with acetate of potassium, it yields acetic anhydride:

$$C^2H^3O.K.O + C^2H^3O.Cl = (C^2H^3O)^2O + KCl;$$

and with benzoate of potassium it forms benzoate of acetyl or acetate of benzoyl:

$$C^7H^5O.K.O + C^2H^3O.Cl = C^2H^3O.C^7H^5O.O + KCl;$$

and similarly with the salts of other acids. With thiacetate of lead, it forms chloride of lead, and probably also thiacetic anhydride:

$$C^2H^3O.Pb.S + C^2H^3O.Cl = (C^2H^3O)^2S + PbCl.$$

When it is heated with zinc in a sealed tube, the metal is strongly attacked; and a black tarry subtance is formed, from which water dissolves chloride of zinc, and separates a liquid having an ethereal odour.

Hydride of Acetyl. See ALDEHYDE.

Iodide of Acetyl. $C^2H^3O.I$.—Obtained by the action of iodide of phosphorus on acetic anhydride (**Guthrie**, Phil. Mag. [4] xiv. 183), or on acetate of potassium; (**Cahours**, Compt. rend. xliv. 1253). After being shaken up with mercury and re-distilled, it forms a transparent colourless liquid, of sp. gr. 1·98 at 17°. It boils at 108° (**Guthrie**); between 104° and 105° (**Cahours**). It fumes strongly in the air, has a very pungent odour, and an intensely sour caustic taste.

Iodide of acetyl is partially decomposed by distillation. Water decomposes it with violence, forming hydriodic and acetic acids. It acts strongly upon alcohol, forming acetate of ethyl. It is decomposed by zinc and by sodium at ordinary temperatures, also by mercury in direct sunshine, iodide of mercury being formed, and little or no permanent gas being given off.

Peroxide of Acetyl. $C^2H^3O.O$. — Discovered by **Brodie** in 1858 (Proceedings of the Royal Society, ix. 361.) It is obtained by mixing acetic anhydride and peroxide of barium, in equivalent proportions, in anhydrous ether. The mixture must be effected very gradually, as it is attended with great evolution of heat. The products are acetate of barium and peroxide of acetyl, the latter remaining dissolved in the ether:

$$(C^2H^3O)^2.O + BaO = C^2H^3O.Ba.O + C^2H^3O.O.$$

The ethereal solution, after filtration from the acetate of barium, is carefully distilled at a low temperature, and the remaining liquid is washed three or four times with water till the wash-water ceases to be acid. The residue is peroxide of acetyl.

It is a viscid liquid, extremely pungent to the taste, the smallest portion placed upon the tongue burning like cayenne pepper. It is a powerful oxidising agent, and highly explosive: a drop heated on a watch-glass explodes with a loud report, shivering the glass to atoms. Baryta-water poured upon it is instantly converted into peroxide of barium, with formation of acetate of barium.

Acetyl-urea. (See UREAS (Compound) and CARBAMIDE.)

ACETYLENE. (See ADDENDA, p. 1111.)

ACETYLOUS ACID. ALDEHYDIC ACID. *Lampic acid, Etheric acid.* An acid supposed to be produced by the slow combustion of ether or of alcohol, and under certain circumstances by the oxidation of aldehyde. When ether is repeatedly distilled, or allowed to fall in successive drops on a solid body heated to about 129°, so that its vapour may come in contact with the air at a high temperature, a disagreeable pungent odour is produced, supposed to be that of aldehydic acid. The compound possessing this odour is formed in larger quantity, when a spiral of fine platinum wire, previously heated to redness, is suspended over a basin containing ether, and the whole covered with a bell-jar. The wire then continues to glow, the ether undergoing a slow combustion without flame, and an acid liquid is formed, which runs down the sides of the bell-jar, and may be collected in a vessel placed below. This liquid is colourless, has a very sour taste, and gives off a pungent vapour which excites tears, and causes great oppression when inhaled. The same compound is obtained, according to Liebig, by heating oxide of silver with aqueous aldehyde; part of the silver is then reduced, while the other portion remains in solution in the form of acetylite of silver, and by decomposing this silver-salt with sulphuretted hydrogen, the acid may be obtained in the free state. It is, however, very liable to decompose, as also are its salts. When the silver-salt is boiled with baryta-water, silver is reduced and acetate of barium remains in solution.

$$\underbrace{2C^2H^3AgO}_{\substack{\text{Aldehydate of}\\\text{silver.}}} + \underbrace{2BaHO}_{\substack{\text{Hydrate of}\\\text{barium.}}} = \underbrace{C^2H^3BaO}_{\substack{\text{Aldehydate}\\\text{of barium.}}} + \underbrace{C^2H^3BaO^2}_{\substack{\text{Acetate of}\\\text{barium.}}} + 2Ag + H^2O$$

Gerhardt (Traité i.) is of opinion that the so-called aldehydic or acetylous acid is merely a mixture of aldehyde and acetic acid, the aldehydate or acetylite of silver being in fact merely aldehyde in which 1 atom hydrogen is replaced by silver.

ACHILLEA MILLEFOLIUM (*Millefoil.*)—The ash of this plant has been analysed by Way and Ogston. 100 parts of the dry herb left 13·45 per cent. ashes containing in 100 parts 30·37 parts of potash, 13·40 lime, 3·01 magnesia, 0·21 sesquioxide of iron, 2·44 sulphuric anhydride, 9·92 silica, 9·36 carbonic anhydride, 7·13 phosphoric anhydride, 20·49 chloride of calcium, and 3·63 chloride of sodium.

ACHILLEIC ACID. An acid said to exist in millefoil (*Achillea Millefolium*). It crystallises in colourless prisms, soluble in 2 parts of water at 12°·5. With the alkalies it forms salts which are easily soluble in water, but sparingly in alcohol. The solutions are precipitated by neutral acetate of lead, whereas the free acid is precipitated by the basic acetate only. The potassium, sodium, and calcium salts are crystallisable: the ammonium and magnesium salts dry up to amorphous masses. The *quinine* salt is said to be obtained in fine crystals grouped in stars, when its aqueous solution is mixed with alcohol, then boiled and left to cool slowly (Zanon, Ann. Ch. Pharm. lviii. 31). Neither the acid nor its salts have been analysed. L. Gmelin, (Handbook, x. 207) suggested that this acid might be impure malic acid. According to Hlasiwetz (J. pr. Chem. lxii. 429) it is aconitic acid.

ACHILLEIN. A bitter substance of unknown composition, extracted by Zanon from millefoil. It forms a hard, yellowish brown extract, having a peculiar odour and bitter taste, easily soluble in water and in boiling alcohol, sparingly in cold alcohol and insoluble in ether; but on treating it with a few drops of any acid, it becomes easily soluble in ether; it dissolves also in ammonia. It is said to be useful as a remedy against fever.

ACHIRITE. (See DIOPTASE.)

ACHMITE. A mineral first distinguished by Ström. It has a brown-black or red-brown colour on the outside, blackish or dark greyish green on the fractured surfaces; in thin fragments it is translucent, and exhibits a yellowish-brown colour. Sp. gr. 3·43 to 3·53. Scratches glass. Melts to a black bead before the blowpipe. It crystallises in oblique four-sided prisms with truncated lateral edges and very sharp four-sided terminal faces, the edges of which correspond with the lateral edges of the oblique prism. It has four cleavages, two parallel to the sides of the oblique prism, and the other two less obvious parallel to the truncations of the acute lateral edges. According to the analyses of Berzelius and Rammelsberg, its composition is $NaO.SiO^3 + Fe^2O^3.\ 2SiO^3$ ($Si = 21{\cdot}5\ .\ 0 = 8$) or $2Na^2O.3SiO^2 + 2(Fe^4O^3,3SiO^2)$ ($Si = 28{\cdot}5\ .\ O = 16$.) It occurs, though rarely, embedded in granite at Eger, and in syenite, near Porsgund in Norway.

ACHROÏTE. A name given to the colourless variety of tourmalin.

ACHTARANDITE. A name given by Breithaupt to a doubtful mineral, hitherto found only in decomposed crystals (trigonal dodecahedrons) which occur in association with vesuvian from Vilui (viluite): they are perhaps derived from helvin.

ACIBROMIDES, ACICHLORIDES, &c. (See OXYBROMIDES, OXYCHLORIDES, &c. &c.)

ACICULITE. (*Acicular Bismuth, Needle ore,*) a native sulphide of bismuth, containing also sulphides of copper and lead. The formula assigned to it by Dana is $(3CuS + BiS^3) + 2(3PbS + BiS^3)$ showing it to be analogous to Bournonite, with which it is isomorphous.

It occurs embedded in white quartz, and accompanying gold, at Beresof, in Siberia.

ACIDIMETRY. The determination of the quantity of real acid in a sample of hydrated acid, is a problem of frequent occurrence, both for scientific and for technical purposes. As the specific gravity of a mixture of acid and water always increases with the proportion of acid present, and as, moreover, a certain specific gravity always corresponds to a certain strength, provided no foreign substances are present, it follows that if the specific gravity corresponding to each particular percentage of real acid has once been accurately determined and tabulated, the strength of any given sample of aqueous acid may always be determined by taking its specific gravity and referring to the tables. (See SULPHURIC, NITRIC, HYDROCHLORIC ACID, &c.) This method is in fact much used, the density being generally taken with the specific gravity bottle for scientific purposes, and with the hydrometer for commercial estimations. This method, however, necessarily supposes that the acid is pure; the presence of any foreign substance, such as nitrate of sodium in nitric acid, cream of tartar and extractive or colouring matter in vinegar, &c. would altogether destroy the accuracy of the result. Moreover, in some acids, the specific gravity varies so little for considerable difference of strength, that a very slight inaccuracy of observation entails a large error in the result. In acetic acid, for example (p. 11), an increase of strength amounting to 1 per cent. produces on the average, an increase of density not exceeding 0·0034. For these reasons it is essential, especially for technological purposes, to adopt some ready and exact method of determining the strength of an acid, independently of its specific gravity.

The strength of an acid may be estimated:

a. By *Volumetric analysis*, that is by ascertaining the measured quantity of a standard alkaline solution required to saturate a given volume of the acid. (See ANALYSIS, VOLUMETRIC.)

b. By *Weight analysis*. This mode of estimation might be conducted in various ways: for instance, by converting a given quantity of the hydrated acid into a neutral salt of potassium, sodium, barium, lead, silver, &c. either by saturation or precipitation, weighing the salt thus formed, and calculating the quantity of acid from its known composition. This method is indeed constantly adopted in scientific chemistry; but is for the most part too tedious for technical purposes. A quicker method is to decompose a known weight of the acid with an excess of acid carbonate of sodium or potassium, and estimate by weight the quantity of carbonic anhydride evolved. The quantity of real acid in the sample of hydrated acid is then easily calculated; for each atom of a monobasic acid, expels 1 atom of carbonic anhydride ($CO^2 = 44$,) and each atom of a dibasic acid expels two atoms of carbonic anhydride ($2CO^2 = 88$): this will be seen from the following equations:

For hydrochloric acid:

$$CO^3NaH + ClH = ClNa + CO^2 + H^2O.$$
$$CO^2 : ClH = 44 : 36{\cdot}5$$

For acetic acid:

$$CO^3NaH + C^2H^3O^2.H = C^2H^3O^2.Na + CO^2 + H^2O$$
$$CO^2 : C^2H^3O^2.H = 44 : 60$$

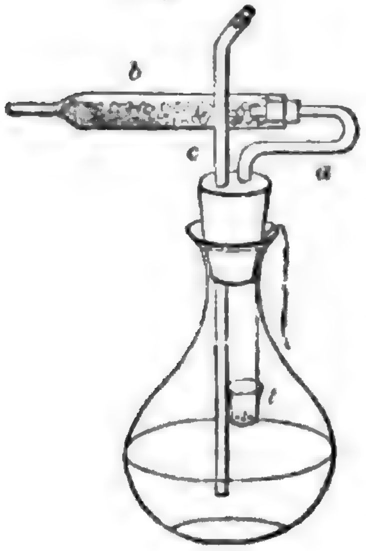
For sulphuric acid:

$$2CO^3NaH + SO^4H^2 = SO^4Na^2 + 2CO^2 + 2H^2O$$
$$2CO^2 : SO^4H^2 = 88 : 98 = 44 : 49$$

Suppose, for example, that 13·5 grm. of hydrated sulphuric acid thus treated with acid carbonate of sodium, eliminate 1·4 grains of carbonic anhydride. The quantity of real acid (SO^4H^2) in the 12·5 grm. is then $1·4 \times \frac{49}{44} = 1·47$ grm. and the quantity of real acid in 100 parts of the hydrated acid will be given by the equation: $x = 1·47 \times \frac{100}{13·5} = 10·89$.

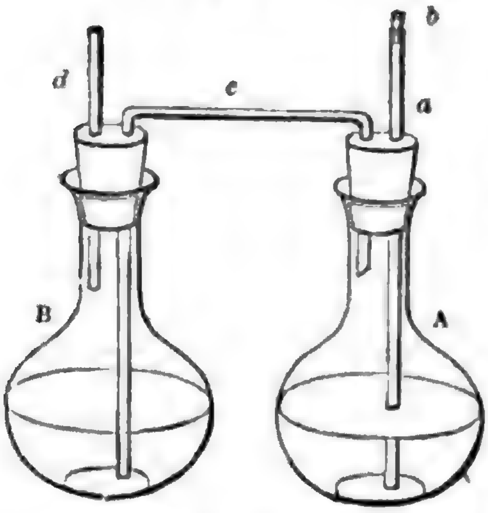
A convenient apparatus for these determinations is a small light glass flask (*fig.* 1) of about100 cubic centimetres (3 or 4 oz.) capacity, having a lipped edge, and fitted with a cork perforated with two holes. Into one of these apertures is fitted a bent tube *a*, carrying a drying tube *b*, filled with chloride of calcium, and into the other, a narrow tube *c*, reaching nearly to the surface of the liquid, and bent at an obtuse angle above the cork. A convenient quantity of the acid whose strength is to be determined, having been weighed out in the flask, a quantity of acid carbonate of sodium or potassium more than sufficient to neutralise the acid, is placed in a small test-tube about an inch long, and having its lip slightly turned over, so that it may be suspended by a thread. This tube is then let down into the flask by the thread, but not low enough to come in contact with the acid; the thread is fixed in its place by inserting the cork into the neck of the flask, and the whole apparatus is weighed. The orifice of the bent tube *c*, is then closed with a plug of cork or wax, the cork of the flask loosened sufficiently to allow the short tube *t*, containing the alkaline carbonate to drop into the acid, and the cork immediately tightened. The carbonate is now decomposed by the acid, and carbonic anhydride escapes through the drying tube, the chloride of calcium retaining any moisture that may be carried along with it. When the effervescence ceases, the flask must be warmed to ensure the complete removal of the carbonic acid from the liquid, and after it has cooled, the plug must be removed from the bent tube *c*, and air drawn through the apparatus by applying the mouth to the extremity of the chloride of calcium tube, in order to remove all the carbonic anhydride remaining in the flask, and replace it by air. The whole is then again weighed, and the loss of weight gives the quantity of carbonic anhydride which has escaped. At the completion of the experiment, a piece of blue litmus paper must be thrown into the liquid in the flask; if it remains blue, the determination may be considered exact; but if it is reddened, there is still free acid in the flask, showing that the quantity of carbonate introduced was not sufficient to decompose it. In that case, a second small tube containing alkaline carbonate must be introduced as before, the apparatus again weighed, and the whole process repeated. The second loss of weight added to the first, gives the total quantity of carbonic anhydride evolved.

Fig. 1.



Another form of apparatus for these estimations, devised by Will and Fresenius, is shown in *fig.* 2. A and B are two small flasks, having strong necks turned over in a lip. Each of them is closed with a tight-fitting cork pierced with two holes. Through the cork of A there passes a straight tube *a*, reaching nearly to the bottom of the flask; a tube *c*, bent twice at right angles, passes through both corks, terminating just below that of A, but reaching nearly to the bottom of the flask B; a straight tube *d* also passes through the cork of B, terminating just below it. The tube *a* is closed at the extremity *b* with a plug of wax. The acid to be estimated is weighed out in the flask A; the other flask B is filled to about one-third with strong sulphuric acid; and the whole apparatus is connected in the manner shown in the figure, the proper quantity of acid carbonate of sodium being introduced into A in a short test-tube, suspended by a thread in the manner described with the former apparatus. The whole apparatus is then weighed, the cork *a* loosened, so as to allow the tube containing the carbonate to fall into the acid, and the cork immediately secured. Carbonic anhydride is now evolved, and is obliged to pass through the sulphuric acid in B, whereby it is completely dried. As soon as gas ceases to escape, the flask A is immersed in water at about 50° or 60° C. till the fresh evolution of gas thereby occasioned ceases. The wax-plug is then loosened, to

Fig. 2.



prevent the sulphuric acid in B from being forced into A, in consequence of diminished pressure in that vessel; the apparatus is removed from the hot water; and air is sucked through the tube *d* as long as any taste of carbonic acid is perceived. Lastly, the apparatus, when quite cold, is re-weighed, and the loss of weight gives the quantity of carbonic anhydride evolved.

This apparatus is much heavier and more bulky than that before described, and does not appear to possess any advantage over it. Mohr points out, as a source of inaccuracy in its use, that the large surface of the two flasks, being heated during the experiment, is not likely, on cooling, to condense exactly the same quantity of moisture as was attached to it before.

It is of the utmost importance that the acid carbonate of sodium or potassium, used in these determinations, be quite pure and free from neutral carbonate. The acid carbonates give a white precipitate with chloride of mercury, and the neutral carbonates a red-brown precipitate; but this test will not indicate the admixture of a small quantity of neutral carbonate with the acid carbonate. A more certain test of purity is to weigh out two equal portions of the acid carbonate, ignite one in a platinum crucible, and determine the quantity of carbonic anhydride given off from the other by the action of the acid in the apparatus represented in *fig.* 2 (See ALKALIMETRY). The quantity of neutral carbonate of sodium remaining after the ignition should be to that of the carbonic anhydride evolved as 53 to 44; and that of the neutral carbonate of potassium to the carbonic anhydride as 69 : 44.

If the acid carbonate is not pure enough to give a white precipitate with chloride of mercury, it should be at once rejected. Commercial acid carbonate of sodium, which will stand that test, may be further purified by triturating it to a uniform powder, covering it with an equal weight of cold distilled water, leaving it for 24 hours, then washing it two or three times on a filter with a small quantity of cold water, leaving it to drain, and drying it by exposure to the air without heating. Acid carbonate of potassium may be purified by recrystallisation. (For further details on Acidimetry, see *Dictionary of Arts, Manufactures, and Mines*, new edition, vol. i. p. 23.)

ACIDS. Salts of hydrogen. The following properties are common to the most important acids,—

1. Solubility in water.
2. A sour taste. (In those acids which possess the most strongly marked characters, this property can be perceived only after dilution with a large quantity of water.)
3. The power of reddening most organic blue and violet colouring matters (for example, litmus), and of restoring the original colour of substances which have been altered by alkalis.
4. The power of decomposing most carbonates, causing effervescence.
5. The power of destroying, more or less completely, the characteristic properties of alkalis, at the same time losing their own distinguishing characters, and forming alkaline salts.

The last is the only one of these properties which can be considered essential to acids; indeed, comparatively few acids possess them all. Moreover, there are many substances which possess, in a greater or less degree, all these properties, but which are never included among acids; of these it will be sufficient to mention *alum* (sulphate of potassium and aluminium). Alum is soluble in water; its solution has a taste which, though not purely sour, approaches much more nearly to sourness than that of many acids (benzoic acid, for example); its solution also reddens litmus, causes brisk effervescence with alkaline carbonates, and neutralises completely the alkalinity of potash or soda, forming an alkaline sulphate.

In order to get a more exact idea of what it is which essentially constitutes acidity, it may be useful to consider briefly the opinions which have successively been held upon the subject by the chemists of past times.

In ordinary language, *acid* is equivalent to *sour;* and in both Greek and Latin, the idea of "sourness" was expressed by almost the same word as that used for "vinegar," the only acid known to the ancients (thus, *Gr.* *ὀξύς*, sour; *ὄξος*, vinegar: *Lat. acidus*, sour; *acetum*, vinegar). It does not, however, appear that very great importance was at any time attached to sourness as a characteristic of acids from a chemical point of view. The number of known acids was first increased by the labours of the Arabian chemists[*]; and the solvent power which many of them exert on substances which are insoluble in water, seems first to have caused them to be regarded as a special class of substances. Thus, **Geber** (middle of the eighth century), who was acquainted

---

[*] Almost all the historical statements contained in this article, for which no reference is given, are made on the authority of **Kopp**, "Geschichte der Chemie," 4 vols. 8vo. Brunswick, 1843-47.

with nitric acid and with an impure kind of sulphuric acid, speaks of these bodies under the common name of *aquæ dissolutivæ.* The idea of corrosiveness, or at least a kindred idea, which may perhaps be expressed with tolerable accuracy as that of *chemical activity*, seems to have been long connected by chemists with the idea of acidity. For example, **Van Helmont** (lived 1577 to 1644) attributed the active properties of quick-lime to a peculiar acid, which he supposed limestone to obtain from the fire during burning. **Stahl** (lived 1660 to 1734), who supposed the earths and alkalis to have the same qualitative composition (see Art. ALKALI), represented the alkalis as containing, in larger proportion than the earths, an acid principle to which they owed their greater chemical activity; and even as lately as 1764, a similar idea to that of Van Helmont was applied by **Meyer** to explain a large number of phenomena. This chemist endeavoured to explain the different properties of the caustic and carbonated alkalis and alkaline earths, by supposing the former to be combinations of the latter with a substance which he called *acidum pingue* (fatty acid), because, as he thought, fat-like properties could be perceived by the sense of touch in its combinations with alkalis (caustic alkalis). The idea that corrosiveness is the most important characteristic of acids, was also plainly uppermost in the mind of **Lemery**, when (1675) he attributed the properties of acids to a sharp-pointed form of their smallest particles.

That the properties of acids are, in some important respects, opposed to those of alkalis, was perceived at a comparatively early period. This opposition of properties was in fact the basis of the medical theory of the Iatro-chemists (from the first quarter of the 16th century to the middle of the 17th century). According to them, the constituents of the human body had, some of them an acid, the rest an alkaline nature; the undue preponderance, or want of acidity or of alkalinity was the cause of disease, the condition of perfect health being a particular relation between these two opposing qualities. **Otto Tachenius**, a chemist of this school, gave, in 1668, as the essential character of an acid, its power of combining with alkalis to form salts; and accordingly he included silica among acids. **Boyle** was well acquainted with the properties which are now considered most distinctive of acids. He characterised acids by the solvent power which they exert on various substances with various degrees of energy; by their power of precipitating sulphur and other substances from solution in alkali; by their power of changing the blue colour of many plants to red, and the red of many others to bright red, and of bringing back to their original colour those which have been changed by alkali; and lastly by their forming with alkalis so-called neutral salts, at the same time losing the properties just mentioned. This enumeration of the distinctive qualities of acids differs in no important respect from that given at the beginning of this article.

Various suppositions have been made, from time to time, in order to account for the properties possessed in common by the most strongly marked acids. In order to understand these, it must be borne in mind that the distinction which most chemists are now accustomed to make between acids and salts, dates only from the time of Lavoisier, that is, from the end of the last century; and that, till his time, acids, alkalis, and the substances now by preference called salts, were all included under the common term *salts*. But since the acids then known were comparatively few, and, as was natural, were those of which the acid properties are most evident, the apparent difference between acids and other salts was much greater then than it is now.

The first theory of the constitution of acids was proposed by **Becher** in his "Physica Subterranea," published in 1669. He attributed the common properties of acids to their containing a common principle of acidity (*acidum primigenium*), formed by the union of primitive earth * and water, and supposed that the distinguishing characters of each acid were due to the particular substance which it contained mixed with the primitive acid.

The ideas of **Lemery** regarding acids have already been referred to.

He was followed by **Stahl**, who, in 1723, revived and extended Becher's theory. The following may be taken as a summary of Stahl's views:—The essential properties of all saline substances are: to affect the sense of taste, or to have sapidity; to be soluble in water; and with regard to other chief properties, such as specific gravity and fixity, to be intermediate between water and pure earth. In some salts the saline properties are very marked, in others they are less prominent, and in some they are barely perceptible. Those substances which are most saline, acids and alkalis, have a great tendency to combine with bodies which have not saline properties, and to impart such properties to them. Hence we may conclude that some substances are in themselves essentially saline, while others exhibit saline properties merely because they contain a substance essentially saline as one of their constituents.

---

* According to Becher there were three primitive earths,—the vitrifiable, the combustible, and the mercurial,—which were the causes respectively of fusibility, of combustibility, and of volatility; thus corresponding to what the alchemists understood by salt, sulphur, and mercury.

We must regard as belonging to the former class those bodies which not only possess saline properties (taste, solubility, &c.) but which can impart these properties to other bodies by combining with them, and which, when separated from their combinations, recover their original qualities. Hence, all acids and alkalis, fixed and volatile, liquid and solid, must be considered as essentially saline. But, comparing these bodies among themselves, we find that even they possess saline properties in very various degrees. It appears, therefore, that there is only a very small number of actual primitive salts, or rather that there is only one such substance, which is a constituent of all other saline bodies, and is the cause of their saline properties. It is obvious that this substance must be sought among bodies which most distinctly and most invariably manifest saline properties, and which are, at the same time, most simple in their composition. Following this rule, we may at once exclude neutral salts, as being resolvable into more simple saline substances; again, alkalis are more subject to alteration and to loss of their saline properties than acids; they must, therefore, be excluded. Of acids, we may select mineral acids as the most energetic. Lastly, of all mineral acids, *vitriolic* (sulphuric) is the most active, has the greatest solvent powers, adheres most forcibly to the matter dissolved, is the most deliquescent, &c. &c. Accordingly, acids must be considered as the basis of all other saline bodies, and vitriolic acid as the basis of all acids. (Macquer's Dictionnaire de Chimie [1st. Edit. published anonymously, Paris, 1766] Articles "Acide" and "Sel;" Kopp, iii. 15; also Encyclopédie, ou Dictionnaire raisonné des Sciences, des Arts, et des Métiers, * * mis en ordre et publié par MM. Diderot et D'Alembert, t. xiv. [Neufchâtel, 1765] Article "Sel et Sels." The chemical part of this work was by Malouin).

Such were the ideas respecting acids and the cause of acidity, which, with unimportant variations, were held by almost all chemists until the rise of the antiphlogistic system of chemistry. (See COMBUSTION.) But before the downfall of the older system, chemists had begun to have more exact notions than formerly of what were elementary bodies, and to feel the necessity of considering as elements all bodies which they could not decompose. Hence, although Stahl regarded sulphuric acid as a secondary principle, formed by the union of the primitive principles of earth and water, and the other acids as compounds of sulphuric acid with various substances, many of the last upholders of the phlogistic theory regarded most of the inorganic acids as simple substances. For instance, phosphoric and sulphuric acids were supposed to be elements which, when combined with phlogiston, formed phosphorus and sulphur respectively. Sulphurous acid was one of the few inorganic acids which were regarded as compounds; it was supposed to be sulphuric acid combined with less phlogiston than was needed to convert it into sulphur; or, what was the same thing, to be sulphur deprived of part of its phlogiston.

But all previous ideas about acids were gradually superseded by those of Lavoisier. Having found, experimentally, that carbonic, nitric, phosphoric, sulphurous and sulphuric acids, all contained the then newly-discovered substance — oxygen (discovered August 1st, 1774), Lavoisier concluded that oxygen was a constituent of all acids,— that it was the acidifying principle. (Lavoisier, Traité élémentaire de Chimie (1st edit. 1789), i. 69 *et passim;* Kopp, i. 308; also iii. 17.)

He first proposed this theory of acids in 1778; and, although acids were known in which no oxygen could be detected, nearly all chemists continued for about thirty years to consider the assumption, that acidity was in every case due to the presence of oxygen, as a necessary part of the antiphlogistic doctrine. Berthollet, indeed, as early as 1789, pointed out that hydrosulphuric and prussic acids contained no oxygen; but it was not till about 1810, after Davy's and Gay-Lussac and Thénard's researches on muriatic and oxy-muriatic acids (hydrochloric acid and chlorine) that chemists generally began to admit the existence of acids free from oxygen. The conclusions drawn from these experiments were confirmed by Gay-Lussac's discovery of hydriodic acid in 1814, and by his examination of prussic acid in 1815. From this time, most chemists recognised two classes of acids — those containing oxygen (oxygen-acids), and those containing no oxygen (hydrogen acids). Attempts, however, were still made to discover a constituent common to all acids, to which their common properties could be ascribed. Thus, on the one hand, Berzelius continued till 1820 to assert the necessary existence of oxygen in all acids; while, on the other hand, some chemists maintained that all acids contained hydrogen as an essential constituent.

The latter opinion was advocated by Davy. His ideas about acids appear to have been essentially the following:—No one substance ought to be regarded as the acidifying principle; the chemical properties of acids, as well as of other bodies, depend not only on the nature of their constituents, but also on their corpuscular arrangement. The so-called *hydrated* acids are the only true acids, and have a constitution similar to that of their salts. Hydrated chloric acid is a ternary compound of chlorine oxygen, and hydrogen, analogous to chlorate of potassium, which is a ternary compound of chlorine, oxygen, and potassium. The whole of the oxygen may be removed from the acid, and it will remain acid; the whole of the oxygen may be removed from the neutral salt, and it will remain neutral. We have no proof that in either of these bodies the oxygen is divided between the chlorine and the other constituent, or that either of them contains so-called anhydrous chloric acid. Similarly, there is no proof that sulphates or nitrates contain anhydrous sulphuric or nitric acid. Hydrated sulphuric and hydrated nitric acids are the true acids, and are ternary compounds, like the sulphates and nitrates. (Davy, Journal of Science and the Arts, i. 285—288; also Gilbert's Annalen, liv. 377—381; Phil. Trans. 1815, 212, 213; 218, 219; also Kopp.)

In 1816 Dulong proposed the theory, since known as the binary or hydrogen-theory of acids. He endeavoured to show that all acids were similar in constitution to hydrochloric acid; that they were all compounds of hydrogen with a radicle which was in some cases simple (as in hydrochloric and hydriodic acids), in other cases compound (as in hydrocyanic, oxalic, sulphuric, and nitric acids). His view of the constitution of these acids may be expressed by the following formulæ:—

Hydrochloric acid	$H(Cl)$
Hydriodic	$H(I)$
Hydrocyanic	$H(CN)$ or $H(Cy)$
Oxalic	$H(C^2O^4)$
Sulphuric	$H(SO^4)$
Nitric	$H(NO^6)$

Salts, according to this theory, were represented as compounds of an acid-radicle with a metal instead of with hydrogen; thus:—

Hydrochloric acid	$H(Cl)$	Nitric acid	$H(NO^6)$
Chloride of potassium	$K(Cl)$	Nitrate of potassium	$K(NO^6)$

Dulong's theory resembled Davy's in so far as it restricted the term *acid** to substances containing hydrogen (hydrated acids), and assigned an analogous constitution to acids and their salts, but differed from Davy's theory in representing the atoms of every acid as arranged in a specific manner: namely, all the atoms except hydrogen as grouped together to form a compound radicle.

These views did not attract much attention till they were applied by Liebig, in 1837, to explain the constitution of several organic acids, and of the various modifications of phosphoric acid (Ann. Ch. Pharm. xxvi. 170; Ann. Ch. Phys. lxviii. 70.), and although they are explained and discussed in a large proportion of the Manuals of Chemistry published during the fifteen or twenty years following that date, they have never been generally adopted. Until a comparatively recent date, almost all chemists continued to regard oxygen-acids as a class of bodies essentially distinct from hydrogen-acids and from metallic salts. Confining the name of oxygen-acids to the substances now known as ANHYDRIDES, they regarded oxygen-salts as bodies formed by the direct union of acids with metallic oxides, and recognised no essential distinction between actual hydrated acids (acids in the sense of Davy and of Dulong) and mere solutions of the anhydrides in water.

An important extension in the then existing views respecting acids resulted from the discovery announced by Berzelius, in 1826 (Berzel. Jahresb. vi. pp. 184 *et seq.*), that certain metallic sulphides, such as those of arsenic and antimony, were capable of uniting with the alkaline sulphides so as to form well-defined salts perfectly analogous to those formed by the combination of the corresponding metallic oxides with the alkalis. From this time, the existence of three new classes of acids (and corresponding salts) was recognised, namely, acids in which the oxygen of ordinary acids was replaced by sulphur, or by the analogous elements, selenium and tellurium.

We owe the ideas of the nature of acids, now very generally entertained, chiefly to the advance of organic chemisty, which has brought to light a very large number, not only of new acids, but of new substances of all kinds, whose chemical relations cannot be adequately expressed upon the system formerly universally adopted, of regarding all

---

* Notwithstanding the more strict use, which was made by both Davy and Dulong, of the word acid, very many chemists still use it to express bodies belonging to two very different classes: *acids* and *anhydrides*. Thus the bodies HCl, HNO^3, H^2SO^4, N^2O^5, SO^3 are all of them frequently called acids, although the first three possess marked resemblances among themselves and equally marked differences from the other two. Again, the bodies H^2SO^4 and SO^3 are often called by the same name, sulphuric acid, although they cannot be obtained in any case by the same process, and although, when caused to act upon one and the same substance, they almost always give rise to products essentially unlike. This confusion between acids and anhydrides dates from the earliest knowledge of the latter class of bodies, and was caused by the fact that the anhydrides which were first discovered immediately produce acids when they come in contact with water. Thus, Lavoisier, by burning phosphorus in oxygen, obtained phosphoric anhydride, but since the solution of this substance in water contained phosphoric acid, he supposed the anhydride to be the acid, and regarded the real phosphoric acid as a combination of phosphoric acid and water. Similarly, sulphuric acid was looked upon as containing "dry sulphuric acid" (sulphuric anhydride) and water; and all other acids, even those of which the anhydrides were unknown, as nitric and hydrochloric acids, were, in like manner, regarded as compounds of a hypothetical anhydride (often called "real acid") with water.

compound bodies as formed by the union of two molecules possessing opposite electro-chemical characters, or of two groups, which, in their turn, have a similar binary constitution. Among the new theories which were the earliest to be thus introduced into the science, was the "Theory of Chemical Types," which represented chemical compounds as combinations of the elementary atoms held together by the attraction exerted by each atom upon all the rest, and capable of exchanging one or several atoms of one element for an equal number of atoms of another, so as to produce new substances, built up after the same plan or *type* as the original compounds, though one or more of their atoms was of a different nature. According to this view, acids and metallic salts were regarded as bodies of the same class: each acid and its corresponding salts were regarded as compounds formed upon the same type, and differing only from the fact of the acid containing hydrogen in the place of the metal contained in the salts. It will be seen that this manner of representing the mutual relation of acids and salts differed but little from that of Davy.

Another result of the progress of organic chemistry which helped to modify the older notions on these subjects, was the acquisition of more consistent ideas than had previously existed of the relative weights of different substances which are chemically comparable with each other. Thus it was discovered that an atom of water contained twice as much hydrogen as an atom of hydrochloric acid, and therefore, that the so-called monobasic acids, or acids containing the same quantity of hydrogen as hydrochloric acid, could not be compounds of water with anhydrous acids, as had been hitherto supposed. The discovery by Gerhardt in 1852 (Ann. Ch. Phys. xxxvii. 285) of the anhydrides corresponding to several monobasic acids, and the fact of their atomic weights being found to be double the atomic weights of the hypothetical anhydrides of the older theory, confirmed the same conclusion.

It is now clear that acids do not form a class apart, distinguished from other substances by something essentially different in their nature; they are, on the contrary, nothing more than a particular class of salts. The definition of acids as *salts of hydrogen*, first clearly enunciated by Gerhardt[*], and repeated at the head of this article, is an accurate statement of the relations which exist between acids and other chemical substances. This definition is, however, obviously insufficient, without a previous answer to the question — what is a salt? For this we must refer to the article SALT. In that article also the properties which acids possess in common with other salts, and which characterise them as belonging to that class, will be most suitably discussed. In the remainder of this article we shall consider the distinguishing properties of acids as such, and the mutual relations of the principal classes into which acids may be divided.

The mode in which acids most frequently react with other substances is by double decomposition, in which they exchange their hydrogen for metals, or for radicles possessing, to a certain extent, metallic functions. The following reactions are all of this kind: namely, their reactions —

1° With metals, —

$$Zn^2 + H^2SO^4 = H^2 + Zn^2SO^4.$$

2° With metallic oxides, sulphides, and salts generally, —

$$\begin{array}{llll}
KHO & + HCl & = H^2O & + KCl \\
KHS & + HCl & = H^2S & + KCl \\
Pb^2O & + 2HCl & = H^2O & + 2PbCl \\
Fe^2S & + H^2SO^4 & = H^2S & + Fe^2SO^4 \\
2NaCl & + H^2SO^4 & = 2HCl & + Na^2SO^4 \\
KNO^3 & + H^2SO^4 & = HNO^3 & + KHSO^4
\end{array}$$

3° With the hydrates of alcohol-radicles, —

$$\underbrace{C^2H^5.H.O}_{\text{Hydrate of ethyl.}} + HCl = H^2O + \underbrace{C^2H^5Cl}_{\text{Chloride of ethyl.}}$$

4° With various metallic compounds, —

$$\underbrace{C^2H^5Zn}_{\text{Zinc-ethyl.}} + HCl = \underbrace{C^2H^5.H}_{\text{Hydride of ethyl.}} + ZnCl.$$

$$\underbrace{KH^2N}_{\text{Potassamine.}} + HCl = H^3N + KCl:$$

---

[*] Précis de Chimie organique (Paris, 1844) i. 70; Introduction à l'étude de la Chimie par le Système Unitaire (Paris, 1848), 103. On the similar characters of acids, or hydrogen-salts, and of metallic salts in general, and on the important differences between them and the anhydrides, comp. Laurent, Méthode de Chimie, pp. 48—56, or Cavendish Society's translation, pp. 39 to 45.

With some substances acids unite directly: namely —

1° With ammonia and its analogues, —

$$\begin{aligned} NH^3 + HCl &= NH^4Cl \\ PH^3 + HI &= PH^4I \\ \underbrace{2NC^6H^7}_{\text{Aniline.}} + H^2SO^4 &= \underbrace{(NC^6H^7)^2.H^2SO^4}_{\text{Sulphate of aniline.}}. \end{aligned}$$

2° With some hydrocarbons, —

$$\underbrace{C^2H^4}_{\text{Ethylene.}} + H^2SO^4 = \underbrace{C^2H^6SO^4}_{\text{Sulphovinic acid.}}$$

$$\underbrace{C^3H^6}_{\text{Propylene.}} + HCl = \underbrace{C^3H^7Cl}_{\text{Chloride of trityl.}}$$

Reactions such as the above can be produced by all well characterised acids. The majority of acids can also produce other reactions of various kinds, some of which are characteristic of individual acids, while others are common to a considerable number, and therefore serve for their division into classes. The rational formulæ by which the various acids are commonly represented, indicate the nature of their leading reactions, and hence to the class to which they belong.

Oxygen-acids form by far the most numerous and important class of acids. We may take acetic acid as a special example, and show how the double decompositions which it is capable of undergoing, in common with the other acids of this class, lead to the choice of the rational formulæ by which oxygen-acids in general are usually represented.

1. When acetic acid is converted into an acetate by acting upon it with an oxide, metal, or any other substance, it loses hydrogen. This may be represented by writing one atom of hydrogen in its formula apart from the rest: $C^2H^4O^2 = C^2H^3O^2,H$.

2. By perchloride of phosphorus acetic acid is converted into chloride of acetyl, and loses one atom of oxygen and one atom of hydrogen. To express this, we must write the formula of acetic acid thus; $C^2H^3O.HO$.

3. By the action of pentasulphide of phosphorus, acetic acid loses half its oxygen, and becomes thiacetic acid, $5(C^2H^4O^2) + P^2S^5 = 5(C^2H^4OS) + P^2O^5$.

The rational formula derivable from this reaction is $C^2H^4O.O$.

Combining these three expressions, we come to divide the formula of acetic acid into three parts H, C^2H^3O and O, and to write it $\begin{matrix}C^2H^3O\\H\end{matrix}O$, or $H.C^2H^3O.O$, or in some similar way. This formula indicates beforehand all the most frequent double decompositions of which acetic acid is capable; viz. the separation of one atom of hydrogen, the other atoms remaining together (formation of acetates); the separation of one atom of hydrogen and one atom of oxygen, leaving the group C^2H^3O (formation of chloride of acetyl, of acetamide &c.); the separation of one atom of oxygen, leaving the remaining atoms combined (formation of thiacetic acid, &c.)

The large number of acids which resemble acetic acid as to their leading double decompositions, receive similar rational formulæ; that is to say, rational formulæ consisting of three parts: namely (1) one or more atoms of hydrogen, (2) one or more atoms of oxygen or sulphur, (3) a radicle, nearly always compound and containing oxygen, sulphur or a similar element. Thus, writing the rational formula of acetic acid $\begin{matrix}C^2H^3O\\H\end{matrix}O$, we write that of benzoic acid $\begin{matrix}C^7H^5O\\H\end{matrix}O$, of pyruvic acid $\begin{matrix}C^3H^3O^2\\H\end{matrix}O$, of oxalic acid $\begin{matrix}C^2O^2\\H^2\end{matrix}O^2$, of phosphoric acid $\begin{matrix}PO\\H^3\end{matrix}O^3$, of thiacetic acid $\begin{matrix}C^2H^3O\\H\end{matrix}S$, of sulphocarbonic acid $\begin{matrix}CS\\H^2\end{matrix}S^2$, of sulphocyanic acid $\begin{matrix}CN\\H\end{matrix}S$, of hypochlorous acid $\begin{matrix}Cl\\H\end{matrix}O$.

If in any of these formulæ we replace the radicle by its equivalent quantity of hydrogen (see EQUIVALENTS) and the sulphur (where it occurs) by its equivalent of oxygen, we obtain the formula of one, two, or three, atoms of water $\begin{matrix}H\\H\end{matrix}O$, $\begin{matrix}H^2\\H^2\end{matrix}O^2$, or $\begin{matrix}H^3\\H^3\end{matrix}O^3$. Moreover, the decompositions of which water is susceptible are essentially quite similar to those of acetic acid. Thus, when converted into a hydrate by the action of a metal or of an oxide, water loses one atom of hydrogen—$K + H^2O = H + HKO$, or $Ca^2O + H^2O = CaHO + HCaO$; oxychloride of phosphorus converts water into hydrochloric acid, removing from it one atom of hydrogen and one atom of oxygen.

$3H^2O + POCl^3 = 3HCl + PO^4H^3$; lastly, pentasulphide of phosphorus converts it into hydrosulphuric acid, removing from it one atom of oxygen: — $5H^2O + P^2S^5 = 5H^2S + P^2O^5$. It is in this sense that water is taken as the *type*, or standard of comparison for acetic acid and all other acids which undergo similar double decompositions.

Another class of acids are, in the same way, referred to the type hydrochloric acid, HCl. These acids are susceptible of only one kind of double decomposition: their atoms are separable into only two groups, hydrogen and a radicle. Hydrobromic acid HBr, hydriodic acid HI, hydrocyanic acid HCN, are of this class.

There is still a third class of acids which may be referred to the type ammonia, NH^3. Succinimide, $C^4H^5NO^2$, cyanic acid (carbimide), CONH, and sulphocyanic acid (sulphocarbimide), CSNH, are acids of this kind. Under the influence of metallic oxides, and hydrates they part with one atom of hydrogen, and take up in exchange an atom of metal:

$$\underbrace{2(C^4H^5NO^2)}_{\text{Succinimide.}} + Ag^2O = \underbrace{2(C^4H^4AgNO^2)}_{\text{Argento-succinimide.}} + H^2O.$$

$$\underbrace{CHNO}_{\text{Cyanic acid.}} + HKO = \underbrace{CKNO}_{\text{Cyanate of potassium.}} + H^2O.$$

When boiled with dilute acids, they break up into two groups, a carbonised radicle on the one hand (which combines with oxygen or with oxygen and hydrogen derived from the water of the dilute acid), and the group HN (which combines with two atoms of hydrogen) on the other hand.

$$\underbrace{CHNO}_{\text{Cyanic acid.}} + H^2O = \underbrace{CO.O}_{\text{Carbonic anhydride.}} + \underbrace{HN.H^2}_{\text{Ammonia}}.$$

$$\underbrace{C^4H^5NO^2}_{\text{Succinimide.}} + 2H^2O = \underbrace{C^4H^4O^2.H^2O^2}_{\text{Succinic acid.}} + HN.H^2$$

These reactions show that the rational formulæ of these acids must consist of three parts; an atom of nitrogen, an atom of hydrogen, and a radicle composed of the remaining atoms. Thus the formula of succinimide must be $N.H.C^4H^4O^2$ or $N\left\{\begin{matrix}C^4H^4O^2,\\ H\end{matrix}\right.$ that of cyanic acid N.H.CO, or $N\left\{\begin{matrix}CO\\ H\end{matrix}\right.$. The substance called by Gerhardt nitride of benzoyl, sulphophenyl and hydrogen ($C^{13}H^{11}SO^3N$) is another acid deriving from the type ammonia. Its decompositions have not yet been much studied, but its behaviour with metallic oxides and its formation from ammonia by the successive action of the chlorides of sulphophenyl and of benzoyl ($C^6H^5SO^2Cl$ and C^7H^5OCl) require that its rational formula should be composed of the four parts N, H, $C^6H^5SO^2$ and C^7H^5O. Since the constituent atoms of this acid are separable into four groups, it is evidently susceptible of undergoing even more numerous decompositions than either the acids deriving from the type H^2O, or those previously mentioned as deriving from the type NH^3, whose atoms are separable into only three groups.

In regard to their *chemical constitution*, we may thus divide acids into three principal classes, which have the same mutual relations of formation and decomposition as hydrochloric acid[*], water, and ammonia, and which may therefore be regarded as deriving from these bodies as types.

But, in the same sense as some of the acids which we have been considering, are formed from two, or from three atoms of the same type (from H^2Cl^2, H^4O^2, H^6O^3, &c.), there are certain others which are formed from two or more atoms of two (or perhaps three) different types; for example, sulphuric acid SO^4H^2, derives from the type $\left.\begin{matrix}H^2\\ H^2\end{matrix}\right\}O^2$, thus $\left.\begin{matrix}(SO^2)''\\ H^2\end{matrix}\right\}O^2$, while sulphamic acid, SO^3H^3N, and chlorhydrosulphuric acid, SO^3HCl, derive respectively from the double types $\left.\begin{matrix}H^3N\\ H^2O\end{matrix}\right\}$ and $\left.\begin{matrix}HCl\\ H^2O\end{matrix}\right\}$; thus $\left.\begin{matrix}(SO^2)''\ N\\ H^3O\end{matrix}\right\}$ = sulphamic acid; $\left.\begin{matrix}(SO^2)''\ Cl\\ H\ \ \ \ O\end{matrix}\right\}$ = chlorhydrosulphuric acid. Acids of this kind may be called, for the sake of distinction, *intermediate* acids. The so-called *amic acids* (see AMIC ACIDS) afford the most numerous and best known illustrations of this

---

[*] Since the reactions of the acids of the first class are also possessed by those of the second and third classes, it is plain that, if we have regard to these reactions only, all acids may be referred to the type *hydrochloric acid*. To this extent, but no further, the hydrogen-theory represents correctly the constitution of all acids.

class. Like sulphamic acid, they derive from the type $\left.\begin{matrix}H^2N\\H^2O\end{matrix}\right\}$. They can give rise to two kinds of double decomposition; that is, they can decompose either as hydrates (derivatives of water), or as amides (derivatives of ammonia), according to the nature of the body with which they react. In like manner, chlorhydrosulphuric acid and analogous substances can decompose either as hydrates or as chlorides (derivatives of hydrochloric acid).

Another way in which acids may be classified has reference to their *basicity*: they may be divided into *monobasic*, *dibasic*, and *tribasic** acids. Graham was the first to call attention to the existence of polybasic acids in his paper on arsenic and phosphoric acids (Phil. Trans. 1833, 253; Phil. Mag. iii. 451, 469). The distinctions which he established between monobasic and polybasic acids, had reference merely to the composition of their salts. In 1837 Liebig (Ann. Ch. Pharm. xxvi. 138; Ann. Ch. Phys. lxviii. 35) showed that tartaric, citric, meconic, and some other organic acids were polybasic, but he pointed out no new general characters of polybasic acids, nor any new way of distinguishing them from monobasic acids. Gerhardt (Précis de Chimie Organique (1844), i. 71—84) was the first to connect the basicity of acids with other facts than the composition of their metallic salts, and he and Laurent (Ann. Ch. Phys. [3] xviii. 266; Méthode de Chimie, 62—76, or Cavendish Society's Translation pp. 50—62) first placed the question on its present footing.

Mono-, di-, and tri-basic acids may be defined, in a few words, as containing respectively, *one*, *two*, and *three* atoms of hydrogen replaceable by other metals, or by compound groups of analogous function. This definition, taken by itself, is, however, obviously insufficient to decide the basicity of any particular acid, since, by properly multiplying or dividing its formula, we can represent it as possessing whatever basicity we please. Hence, before we can decide what the basicity of an acid is, we must know its atomic weight, and conversely, in order to fix the atomic weight of an acid we require to know its basicity: in other words, the determination of its basicity and the determination of its atomic weight are the same thing.

To decide either of these points, we must take into consideration the general behaviour of the acid with other bodies, and the nature of its derivatives. The following are the most important general differences shown by acids of different degrees of basicity:—

a. Each *monobasic* acid can form *but one* ether. This is neutral in its properties. Two volumes of its vapour contain only *one* volume of ethyl, or alcohol-residue. Monobasic acids do *not* form acid ethers.	*a.* Each *dibasic* acid can form *two* ethers; one of them neutral, the other acid. (Thus, sulphuric acid forms sulphate of ethyl and ethyl-sulphuric acid.) Two volumes of the vapour of the neutral ether contain *two* volumes of ethyl or alcohol-residue.	*a.* Each *tribasic* acid can form *three* ethers; one of them neutral, the other two acid. (*e.g.* phosphoric acid forms phosphate of ethyl and monethyl- and diethyl-phosphoric acids.) Two volumes of the vapour of the neutral ether contain *three* volumes of alcohol-residue.
b. Monobasic acids cannot form stable, well-defined acid salts, or salts with two or more metallic bases.	*b. Dibasic* acids can form, with each metallic base, a neutral salt and an acid salt, which last is exactly intermediate in composition betweeen the neutral salt and the free acid. They can also form well-defined double salts containing two metallic bases, as well as hybrid salts containing two or more metallic bases in indefinite proportions.	*b. Tribasic* acids can form *three* salts with the same metallic base, two of them acid, and one neutral. They can also form double, triple, and hybrid salts.
c. Monobasic acids cannot form double or multiple ethers, that is, ethers containing two or more kinds of alcohol-residue.	*c. Dibasic* acids can form double ethers, that is, ethers containing two kinds of alcohol-residue. (Example, double oxalate of ethyl and methyl.)	*a.*

---

* It is probable that tetrabasic acids also exist, but none have yet been much investigated: pyrophosphoric and silicic acids seem to be such.

The above distinctions apply to acids of all kinds, from whatever type they derive. The following apply only to acids which derive from the type *water* (oxacids).

d. Each *monobasic* oxacid can form a chloride, in two volumes of the vapour of which is contained only *one* volume of chlorine. Each such chloride can take up an atom of oxygen and an atom of hydrogen in exchange for an atom of chlorine to re-form the normal acid,—but there is no compound intermediate in composition between the chloride and the normal acid.	*d.* Each *dibasic* oxacid can form a chloride, in two volumes of the vapour of which are contained *two* volumes of chlorine. Dibasic oxacids can also form chlorides which contain, in two volumes of vapour, only *one* volume of chlorine, and are exactly intermediate in composition between the chlorides last-mentioned and the normal acids; that is, they can take up an atom of chlorine in exchange for an atom of oxygen and an atom of hydrogen, to form chlorides containing two volumes of chlorine in two volumes of vapour; or they can take up an atom of oxygen and an atom of hydrogen in exchange for an atom of chlorine, to re-form the normal acid. Thus, sulphuric acid, SO^4H^2, forms chloride of sulphuryl or chlorosulphuric aldehyde SO^2Cl^2, and the intermediate compound chlorhydrosulphuric acid, SO^3HCl.	*d.* Each *tribasic* oxacid can form a chloride in two volumes of the vapour of which are contained *three* volumes of chlorine.
e. Monobasic oxacids, by reacting with ammonia, or its derivatives, form neutral amides, in two volumes of the vapour of which is contained only *one* volume of nitrogen. There are no compounds intermediate between these amides and the corresponding acids.	*e. Dibasic* oxacids, by reacting with ammonia, or its derivatives, form neutral amides, in two volumes of the vapour of which are contained *two* volumes of nitrogen. Intermediate in composition between these amides and the corresponding acids are compounds, generally acid (amic acids), in two volumes of the vapour of which is contained but *one* volume of nitrogen. For, example, oxalic acid, $C^2O^4H^2$, forms neutral oxamide, $C^2O^2H^4N^2$, and the intermediate compound oxamic acid $C^2O^3H^3N$.	*e. Tribasic* oxacids, by reacting with ammonia, or its derivatives, form neutral amides, in two volumes of the vapour of which are contained *three* volumes of nitrogen. Intermediate in composition between each of these amides and the corresponding acid, there may exist two acid compounds, one monobasic and containing in two volumes of vapour *two* volumes of nitrogen: the other dibasic and containing in two volumes of vapour only *one* volume of nitrogen. For example, citric acid, $C^6H^8O^7$, forms with phenylamine (aniline) neutral citrophenylamide, $C^6H^8O^4Ph^3N^3$, ($Ph = C^6H^5 =$ phenyl), and the intermediate monobasic citrodiphenylamic acid, $C^6H^8O^5Ph^2N^2$; the dibasic citromonophenylamic acid, $C^6H^8O^6PhN$, has not yet been discovered.
f. Monobasic oxacids do not form acid compounds (so-called conjugate acids) by reacting with hydro-	*f. Dibasic* oxacids form acid compounds (conjugate acids) by reacting with hydrocarbons or other neu-	*f. Tribasic* oxacids form acid compounds by reacting with hydrocarbons or other neutral substances. For

carbons, or other neutral substances.	tral substances. For example, sulphuric acid reacts with benzene to form sulphobenzidic (phenylsulphurous) acid, and with glycerin to form sulphoglyceric acid.	example, phosphoric acid reacts with glycerin to form phosphoglyceric acid.

(Compare Odling, Chem. Soc. Qu. J. xi. 127.)

In addition to these, other properties of acids might be mentioned, which are connected more or less intimately with their basicity; but, notwithstanding the number of comparatively very well-defined characters which they severally possess, it is impossible to establish any absolute distinction between monobasic and dibasic, or between dibasic and tribasic acids. There are many acids, which, in relation to a particular set of reactions, have the properties of monobasic acids, but, in relation to another set of reactions, behave like dibasic acids; others, again, appear from one point of view to be dibasic, while from another point of view they seem to be tribasic. This will appear more distinctly by considering what degree of generality belongs to each of the differences we have pointed out between acids of different basicities.

a. Number of ethers. Perhaps the only exception to this law is afforded by phosphorous acid, which forms three ethers, one of them containing, in two volumes of vapour, three volumes of alcohol-residue, although, as regards its metallic salts, it is only dibasic.

b. Number of metallic salts. Acetic and formic acids, which possess in a special degree most of the characters of monobasic acids, form, each of them, two potassium- and two sodium-salts.

c. Multiple ethers. No exception to this law is known so far as regards mono- and di-basic acids. Tribasic acids ought by analogy to form ethers containing two or three kinds of alcohol residue; none such have yet been obtained, but there is no reason to suppose that they might not easily be formed.

d. Number of chlorides. Some acids, which according to *a*, *b*, and *c* would be classed as monobasic, form chlorides containing two volumes of chlorine, as well as intermediate chloracids. For instance, Wurtz's *chlorure d'acétyle chloré*, $C^2H^2Cl^2O$ (Ann. Ch. Phys. [3] xlix. 60) reacts with one atom of water to form chloracetic acid, $C^2H^3ClO^2$; and this, with a second atom of water, forms glycollic acid, $C^2H^4O^3$. These three bodies are therefore related in the same way as chloride of sulphuryl, chlorhydrosulphuric acid, and sulphuric acid. Again, lactic acid, $C^3H^6O^3$, a homologue of glycollic acid, is decomposed by pentachloride of phosphorus, giving chloride of lactyl, $C^3H^4Cl^2O$, which reacts with alcohol to form chloropropionate (chlorhydrolactate) of ethyl, $C^5H^9ClO^2$, (Wurtz, Ann. Ch. Pharm. cvii. 192); that is to say, the ether of an acid intermediate between chloride of lactyl and lactic acid. The intermediate acid itself is produced $C^3H^5ClO^2$, by the action of chloride of lactyl on water. (Ulrich, Chem. Soc. Qu. J. xii. 23; Ann. Ch. Pharm. cix. 268.) So far then as their chlorides are concerned, glycollic and lactic acids resemble dibasic and not monobasic acids. (See also observations on *e.*)

In the case of tribasic acids, no intermediate chloracids are known, such as would correspond to chlorhydrosulphuric acid and other derivatives of dibasic acids. It is probable that each tribasic acid can form two such compounds, that phosphoric acid (PH^3O^4), for example, can form chlorhydrophosphoric acid (PH^2ClO^3,) dibasic?) and dichlorhydrophosphoric acid[*] ($PHCl^2O^2$, monobasic?)

e. Number and nature of amides. Some monobasic acids form amides containing, in two volumes of vapour, two volumes of nitrogen. For instance, acetic acid forms *acediamine*, $C^2H^6N^2$, between which and acetic acid $C^2H^4O^2$, acetamide C^2H^5NO is exactly intermediate, (just as oxamic acid, $C^2H^3NO^3$, is intermediate between oxamide, $C^2H^4N^2O^2$, and oxalic acid, $C^2H^2O^4$); acetamide, however, is neutral, not acid, in its properties.

Certain other acids, generally considered monobasic, form amides containing one atom of nitrogen, which possess some of the properties of acids. Thus glycollic acid, $C^2H^4O^3$, forms glycocoll, $C^2H^5NO^2$, a substance capable of acting as an acid, and possessing the same relation of composition to glycollic acid, that oxamic acid does to oxalic acid, or acetamide to acetic acid. The so-called benzamic, toluamic, cuminamic, &c. acids, are substances of a similar constitution: they are to oxybenzoic, oxycuminic, &c. acids what glycocoll is to glycollic acid. In short, glycollic and similar acids, though in the strict sense *monobasic* are *diatomic;* that is, they form but one salt

---

[*] Chlorhydrosulphuric acid is formed when sulphuric anhydride is brought in contact with dry hydrochloric acid ($SO^3 + HCl = SHClO^3$). Similarly, a liquid, which probably contains one or both of the compounds mentioned in the text, is formed when phosphoric anhydride is exposed to dry hydrochloric acid ($P^2O^5 + 3HCl = PH^2ClO^3 + PHCl^2O^2$—?)

with each metallic base—are monobasic as regards their metallic salts,—but resemble dibasic acids so far as regards their other derivatives (chlorides and amides).

f. Formation of complex acids. The difference in respect of acidity between compounds formed by the reaction of monobasic and of polybasic acids on neutral substances, is a particular case of a general rule which was first announced by Gerhardt (Précis de Chim. Organ. i. (1844) 102; Compt. rend. Trav. Chim. 1845, 161) in the following form; $B = b' + b - 1$, where B denotes the basicity of the body resulting from the the reaction, b and b' the basicities of the reacting substances (the basicities of alkaline or neutral substances, and of mono-, di-, and tribasic acids being estimated respectively as 0, 1, 2, and 3). Strecker (Ann. Ch. Pharm. lxviii. 47) showed that the rule admitted of a somewhat more extended application in the form $B = b + b' - aq$, where aq denotes the number of atoms of water which separate in the reaction. Piria (Ann. Ch. Pharm. xcvi. 381), observing that, when more than two substances reacted upon each other, the number of atoms of water formed was usually one less than the number of reacting substances, expressed the rule of basicity in the following form, $B = b + b' + b'' + \dots - (n-1)$, ($n$ being the number of reacting substances). In all these expressions, one substance only is regarded as the essential product of the reaction, but, if we take into consideration the basicity of all the products (water, hydrochloric acid, &c. as well as more complex substances) and regard water as a monobasic * acid, we arrive at the following expression—*The sum of the basicities of the products of a reaction is equal to the sum of the basicities of the reacting bodies.*

Examples:—

$$\begin{array}{lccccccc} & HCl & + & KHO & = & KCl & + & H^2O \\ \text{Basicities} & 1 & + & 0 & = & 0 & + & 1 \end{array}$$

$$\begin{array}{lccccccc} & H^2SO^4 & + & KHO & = & KHSO^4 & + & H^2O \\ \text{Basicities} & 2 & + & 0 & = & 1 & + & 1 \end{array}$$

$$\begin{array}{lccccccccccc} & H^2SO^4 & + & KHO & + & KHO & = & K^2SO^4 & + & H^2O & + & H^2O \\ \text{Basicities} & 2 & + & 0 & + & 0 & = & 0 & + & 1 & + & 1 \end{array}$$

$$\begin{array}{lccccccc} & \overbrace{C^2H^4O^2}^{\text{Acetic acid.}} & + & \overbrace{C^2H^6O}^{\text{Alcohol.}} & = & \overbrace{C^4H^8O^2}^{\text{Acetate of ethyl.}} & + & H^2O \\ \text{Basicities} & 1 & + & 0 & = & 0 & + & 1 \end{array}$$

$$\begin{array}{lccccccc} & C^2H^4O^2 & + & NH^3 & = & \overbrace{C^2H^5NO}^{\text{Acetamide.}} & + & H^2O \\ \text{Basicities} & 1 & + & 0 & = & 0 & + & 1 \end{array}$$

$$\begin{array}{lccccccccccccccc} & C^2H^4O^2 & + & HCl & + & HBr & + & \overbrace{C^3H^8O^3}^{\text{Glycerin.}} & = & \overbrace{C^5H^8O^2ClBr}^{\text{Acetochlorhydrobromhydrin.}} & + & H^2O & + & H^2O & + & H^2O \\ \text{Basicities} & 1 & + & 1 & + & 1 & + & 0 & = & 0 & + & 1 & + & 1 & + & 1 \end{array}$$

$$\begin{array}{lccccccccccccccc} & \overbrace{PON^3H^6}^{\text{Phosphamide.}} & + & H^2O & + & H^2O & + & H^2O & = & H^3PO^4 & + & NH^3 & + & NH^3 & + & NH^3 \\ \text{Basicities} & 0 & + & 1 & + & 1 & + & 1 & = & 3 & + & 0 & + & 0 & + & 0 \end{array}$$

The application of the rule of basicity to substances which, like glycollic acid, are monatomic in some relations but diatomic in others, or, like phenylic alcohol (carbolic acid), are intermediate between neutral bodies and acids, often leads, as might be expected, to contradictory results. It must be looked upon, not as a law universally true, but as a rule applicable to the majority of cases, and always dependent on our definitions of acidity and basicity. (Comp. Kekulé, Ann. Ch. Pharm. cvi. 130.)

It has been pointed out by Beketoff (Bullet. de l'Académie de St. Pétersbourg, xii. 369) that this law, in any of the forms yet given to it, gives contradictory results when applied to the three following reactions, which nevertheless are strictly comparable with each other.

---

* If water be also considered as a *monacid base*, the *acidity* of bases (or the number of atoms of acid with which they react,—a property correlative with *basicity*,) is usually conformable to the following rule:—*The sum of the acidities of the products of a reaction is equal to the sum of the acidities of the reagents.* The representation of water as a monobasic acid and as a monacid base expresses the fact that it easily takes up 1 atom of an electro-positive, or of an electro-negative radicle in exchange for an atom of hydrogen, or, an electro-positive *and* an electro-negative radicle in exchange for the two atoms of hydrogen. The representation of water as a dibasic acid (or as a diacid base) expresses the possibility of replacing both atoms of hydrogen by the same radicle (formation of anhydrides). This replacement though not unfrequent, certainly takes place less readily than the replacement of 1 atom of hydrogen only, or than the replacement of the two by radicles of different electro-chemical qualities. Either view, however, is evidently entirely relative.

$$1.\ \overbrace{C^7H^6O^2}^{\text{Benzoic acid.}} + \overbrace{C^2H^6O}^{\text{Alcohol.}} = \overbrace{C^9H^{10}O^2}^{\text{Benzoate of ethyl.}} + H^2O$$

$$\text{Basicities}\quad 1 + 0 = 0 + 1$$

$$2.\ \overbrace{C^7H^6O^2}^{\text{Benzoic acid.}} + \overbrace{C^2H^4O^2}^{\text{Acetic acid.}} = \overbrace{C^9H^8O^3}^{\text{Aceto-benzoic anhydride.}} + H^2O$$

$$\text{Basicities}\quad 1 + 1 \quad 0 + 1$$

$$3.\ \overbrace{C^2H^6O}^{\text{Alcohol}} + \overbrace{C^4H^4O}^{\text{Methylic alcohol.}} = \overbrace{C^3H^8O}^{\text{Methyl-ethyl ether.}} + H^2O$$

$$\text{Basicities}\quad 0 + 0 \quad 0 + 1$$

According to the conventions which have been made above, the sum of the basicities of the products of the first reaction is equal to the sum of the basicities of the reagents, but in the second reaction it is less, and in the third it is greater. The obviously artificial character of the law of basicity, which is sufficiently shown by these instances, induced Beketoff to propose to compare the whole quantity of replaceable hydrogen in the reagents with that in the products, instead of merely comparing their basicities, or the number of atoms of hydrogen which are easily replaceable by basylous radicles. If the so-called typical formulæ (see FORMULÆ, RATIONAL) are employed in writing the above reactions, it at once becomes evident that in each case the whole quantity of replaceable hydrogen is two atoms, both in the products and in the reagents; and in all regular double decompositions, the whole number of atoms of replaceable hydrogen remains similarly unaltered (For an account of all that is important in Beketoff's paper, and for an extended criticism of the law of basicity, see Kekulé, Lehrbuch d. organisch. Chemie, pp. 210—219.)

A general classification of acids according to their composition cannot yet be given. There are but few elements which are known to form more than two or three distinct acids; and, although many remarkable relations can be pointed out among the acids formed by different elements, these relations are more important as indications of analogies among the elements, than as serving for the classification of the acids themselves.[*] There is, however, one element — carbon — which, in combination with hydrogen and oxygen, forms a very large number of acids, the best known of which, generally exhibit, when compared together, certain gradations of chemical composition and properties, in accordance with which they can be arranged in a number of *homologous series.* (See HOMOLOGY.) The most important of these series are the following: —

a. Monobasic acids represented by the general formula $C^nH^{2n}O^2$.

Formic	acid	CH^2O^2,	Caproic	acid	$C^6H^{12}O^2$,
Acetic	„	$C^2H^4O^2$,	Œnanthylic	„	$C^7H^{14}O^2$,
Propionic	„	$C^3H^6O^2$,	Caprylic	„	$C^8H^{16}O^2$,
Butyric	„	$C^4H^8O^2$,	Pelargonic	„	$C^9H^{18}O^2$,
Valeric	„	$C^5H^{10}O^2$,	Rutic or capric	„	$C^{10}H^{20}O^2$,

&c.

The acids of this series are found in various vegetable and animal products; several of them occur in combination with glycerin as the chief constituents of most natural solid and liquid fats. The first four have been found in mineral waters (Scheerer, Ann. Ch. Pharm. xcix. 257). They are produced artificially by a great variety of processes, the most important of which are the following:

1°. The oxidation of the alcohols $C^nH^{2n+2}O$

$$\underbrace{C^2H^6O}_{\text{Ethyl-alcohol.}} + O^2 = \underbrace{C^2H^4O^2}_{\text{Acetic acid.}} + H^2O.$$

2°. The decomposition of the so-called nitriles, or cyanides of alcohol-radicles, of the formula $C^nH^{2n-1}N$, by alkaline hydrates.

$$\underbrace{C^3H^5N}_{\text{Acetonitrile or cyanide of ethyl.}} + 2H^2O = \underbrace{C^3H^6O^2}_{\text{Propionic acid.}} + NH^3.$$

---

[*] For an able exposition of nearly all that can yet be said on this point, see Odling, Phil. Mag. xvlll. 368; also a lecture on "Acids and Salts," delivered by the same at the Royal Institution, 30th March, 1860, Chemical News, i. 220.

3°. The combination of the potassium- and sodium- compounds of the alcohol-radicles C^nH^{2n+1} with carbonic anydride.

$$\underbrace{C^2H^5Na}_{\text{Sodium-ethyl.}} + CO^2 = \underbrace{C^3H^5NaO^2}_{\text{Propionate of sodium.}}.$$

4°. The oxidation, destructive distillation, fermentation, or putrefactive decomposition of complex organic compounds.

When a fixed-alkaline, or alkaline-earthy salt of one of these acids is subjected to dry distillation, a carbonate and an acetone are generally produced. These products are formed by the decomposition of two atoms of the salt.

The dry distillation of a mixture of the fixed-alkaline, or alkaline-earthy, salts of *two* acids of this series gives rise, in like manner, to a carbonate and to an acetone intermediate in composition between the two acetones corresponding to the acids employed.

When one of the salts is a formate, a similar reaction takes place, but an aldehyde is then produced instead of an acetone.

In some cases the dry distillation of salts of these acids produces (besides acetones) aldehydes, or isomeric compounds (butyral, valeral) and hydrocarbons. (See ALDEHYDES, ACETONES.)

When distilled with excess of alkaline hydrate, they give hydrocarbons of the formula C^nH^{n2+2} (hydrides of alcohol-radicles) and alkaline carbonate.

$$\underbrace{C^2H^3KO^2}_{\text{Acet. potassium.}} + HKO = CK^2O^3 + \underbrace{CH^4}_{\text{Hydride of methyl.}}.$$

With pentachoride of phoshorus they produce chlorides of the formula $C^nH^{2n-1}OCl$; *e.g*:—

$$\underbrace{C^2H^4O^2}_{\text{Acetic acid}} + PCl^5 = \underbrace{C^2H^3OCl}_{\text{Chloride of acetyl.}} + POCl^3 + HCl$$

Their alkaline salts distilled with arsenious anhydride give compounds of arsenic with the alcohol-radicles. (See ARSENIC.)

Subjected to electrolysis, they give carbonates, alcohol-radicles, hydrogen and hydrocarbons of the form C^nH^{2n} and C^nH^{2n+2}.

Under the influence of chlorine (or bromine) they lose one or more atoms of hydrogen, and take up in exchange an equivalent quantity of chlorine, forming chloracids whose general properties usually resemble closely those of the normal acids from which they are formed.

$$\underbrace{C^2H^4O^2}_{\text{Acetic acid.}} + Cl^2 = \underbrace{C^2H^3ClO^2}_{\text{Chloracetic acid.}} + HCl.$$

$$\text{,,} \quad + Br^4 = \underbrace{C^2H^2Br^2O^2}_{\text{Dibrom-acetic acid.}} + 2HBr.$$

$$\text{,,} \quad + Cl^6 = \underbrace{C^2HCl^3O^2}_{\text{Trichlor-acetic acid.}} + 3HCl.$$

b. Acids represented by the formula $C^nH^{2n}O^3$, di-atomic, but usually monobasic. The acids of this series differ from those of series *a* by containing three, instead of two, atoms of oxygen.

Carbonic acid	CH^2O^3,
Glycollic „	$C^2H^4O^3$,
Lactic „	$C^3H^6O^3$,
Butylactic „	$C^4H^8O^3$,
Valerolactic „ (Buttlerow)	$C^5H^{10}O^3$,
Leucic „	$C^6H^{12}O^3$.

These acids are formed

1°. By the reaction of the protochloro- or protobromo- derivatives of the acids of series *a* with hydrates.

$$\underbrace{C^2H^3ClO^2}_{\text{Chloracetic acid.}} + HKO = \underbrace{C^2H^4O^3}_{\text{Glycollic acid.}} + KCl.$$

2°. By the oxidation of the diatomic alcohols, $C^nH^{2n+2}O^2$ (glycols).

$$\underbrace{C^2H^6O^2}_{\text{Glycol.}} + O^2 = \underbrace{C^2H^4O^3}_{\text{Glycollic acid.}} + H^2O.$$

3°. By the oxidation of certain amides of animal origin (glycocol and homologues), especially by nitrous acid.

$$\underbrace{C^2H^5NO^2}_{\text{Glycocol.}} + NHO^2 = \underbrace{C^2H^4O^3}_{\text{Glycollic acid.}} + N^2 + H^2O.$$

4°. By fermentation.

The acids of this series are decomposed by heat into anhydrides and water. (In the case of carbonic acid, this decomposition takes place at the ordinary temperature.)

With pentachloride of phosphorus, they produce diatomic chlorides of the formula $C^nH^{2n-2}OCl^2$; *e.g.*

$$\underbrace{C^3H^6O^3}_{\text{Lactic acid.}} + 2PCl^5 = \underbrace{C^3H^4OCl^2}_{\text{Chloride of lactyl.}} + 2POCl^3 + 2HCl$$

Lactic acid heated with hydriodic acid produces water, iodine and propionic acid (Lautemann):

$$\underbrace{C^3H^6O^3}_{\text{Lactic acid.}} + 2HI = \underbrace{C^3H^6O^2}_{\text{Propionic acid.}} + H^2O + I^2$$

This will probably be found to be a general method of converting acids of series *b* into the corresponding acids of series *a*.

c. Dibasic acids represented by the formula $C^nH^{(2n-2)}O^4$. The acids of this series represent the acids of series *b*, in which 2 at. hydrogen are replaced by an equivalent of oxygen.

Oxalic acid	$C^2H^2O^4$	Pimelic acid	$C^7H^{12}O^4$
Malonic „	$C^3H^4O^4$	Suberic „	$C^8H^{14}O^4$
Succinic „	$C^4H^6O^4$	Anchoic „	$C^9H^{16}O^4$
Lipic „	$C^5H^8O^4$	Sebacic „	$C^{10}H^{18}O^4$.
Adipic „	$C^6H^{10}O^4$		

These acids are, for the most part, products of oxidation. They are solid at ordinary temperatures, and are not volatile without partial or complete decomposition. Some of them are decomposed by heat into carbonic anhydride and a monobasic acid of series *a*.

$$\underbrace{C^3H^4O^4}_{\text{Malonic acid.}} = \underbrace{C^2H^4O^2}_{\text{Acetic acid.}} + CO^2.$$

Several of them also produce acids of series *a*, when fused with excess of alkaline hydrate; the reaction is accompanied by evolution of hydrogen (Gerhardt). Suberic and sebacic acids heated with a great excess of baryta, lose the elements of of 2 at. carbonic anydride and yield the hydrocarbons C^6H^{14} and C^8H^{18}; it is probable that other acids of this series would be decomposed in like manner if similarly treated. (Riche.)

Pentachloride of phosphorus reacts on the acids of this series, producing at first the corresponding anhydrides, which are afterwards converted by excess of the chloride into chlorides of the formula $C^nH^{2n-4}O^2Cl^2$; *e.g.*

$$1°.\quad \underbrace{C^4H^6O^4}_{\text{Succinic acid.}} + PCl^5 = \underbrace{C^4H^4O^3}_{\text{Succinic anhydride.}} + 2HCl + POCl^3.$$

$$2°.\quad \underbrace{C^4H^4O^3}_{\text{Succinic anhydride.}} + PCl^5 = \underbrace{C^4H^4O^2Cl^2}_{\text{Chloride of succinyl.}} + POCl^3$$

There is a certain number of acids which do not enter into any of these three series, but which are related to certain members of them in the same way that the acids belonging to the different series are related to each other. For instance, glyoxylic acid, $C^2H^4O^4$, differs from glycollic acid, $C^2H^4O^3$, in the same way that the latter differs from acetic acid, $C^2H^4O^2$; namely, by containing one more atom of oxygen. And just as bromacetic acid when boiled with oxide of silver produces bromide of silver and glycollic acid —

$$\underbrace{C^2H^3BrO^2}_{\text{Bromacetic acid.}} + HAgO = \underbrace{C^2H^4O^3}_{\text{Glycollic acid.}} + AgBr$$

bromoglycollic acid, when similarly treated, yields bromide of silver and glyoxylic acid (Perkin and Duppa), —

$$\underbrace{C^2H^3BrO^3}_{\text{Bromoglycollic acid.}} + HAgO = \underbrace{C^2H^4O^4}_{\text{Glyoxylic acid.}} + AgBr.$$

Similarly, there is the same difference between glyceric acid, $C^3H^6O^4$, (homologous with glyoxylic acid) and lactic acid, $C^3H^6O^3$, that there is between lactic acid and propionic acid, $C^3H^6O^2$. Again, malic and tartaric acids, $C^4H^6O^5$ and $C^4H^6O^6$, differ from succinic acid by containing respectively one and two atoms more oxygen and they can be converted into succinic acid by heating them with hydriodic acid, in the same way that lactic acid can be converted into propionic acid (Schmidt); moreover, dibromosuccinic acid is decomposed, when boiled with oxide of silver, into bromide of silver and tartaric acid, just as dibromacetic acid is decomposed under similar circumstances into bromide of silver and glyoxylic acid (Perkin and Duppa). The same relation that exists between malic and succinic acids exists also between their homologues, tartronic and malonic acids $C^3H^4O^5$ and $C^3H^4O^4$, but in the case of these acids, the conversion of one into the other has not yet been effected. There is little doubt that these acids — glyoxylic and glyceric, tartronic and malic, and tartaric — represent homologous series running parallel with the three first described, but of which the other terms are as yet unknown.

The relation of all the series of acids, of which we have yet spoken, to each other and to the alcohols homologous with common alcohol, glycol, and glycerine, is shown in the following Table, giving the general formulæ of each series. It will be seen that of the formulæ written one above another, each contains one atom of oxygen more than the formula next above it, and that of the formulæ written in the same horizontal line, each contains two atoms of hydrogen less, and one atom of oxygen more, than the one directly to the left of it. Where known, a special illustration of each general formula is given.

	ALCOHOLS.	ACIDS.		
		Monobasic.		
Monatomic.	$C^nH^{2n+2}O$ Propylic, C^3H^8O.	$C^nH^{2n}O^2$ Propionic, $C^3H^6O^2$ and acids of series *a*.	$C^nH^{2n-2}O^3$ Pyruvic, $C^3H^4O^3$?	$C^nH^{2n-4}O^4$
			Dibasic.	
Diatomic.	$C^nH^{2n+2}O^2$ Propylic glycol, $C^3H^8O^2$.	$C^nH^{2n}O^3$ Lactic, $C^3H^6O^3$ and acids of series *b*.	$C^nH^{2n-2}O^4$ Malonic, $C^3H^4O^4$ Succinic, $C^4H^6O^4$ and acids of series *c*.	$C^nH^{2n-4}O^5$ Mesoxalic, C^3H^2O
				Tribasic.
Triatomic.	$C^nH^{2n+2}O^3$ Glycerin, $C^3H^8O^3$	$C^nH^{2n}O^4$ Glyceric, $C^3H^6O^4$	$C^nH^{2n-2}O^5$ Tartronic, $C^3H^4O^5$ Malic, $C^4H^6O^5$	$C^nH^{2n-6}O^4$
Tetratomic.	$C^nH^{2n+2}O^4$	$C^nH^{2n+}O^5$	$C^nH^{2n-2}O^6$ Tartaric, $C^4H^6O^6$	$C^nH^{2n-4}O^7$ Citric, $C^6H^8O^7$

Another series of acids is represented by the general formula $C^nH^{2n-2}O^2$. They are monobasic like the acids of series *a*, but differ from these by containing 2 atoms less hydrogen combined with the same quantity of carbon and oxygen. None of them have yet been very thoroughly investigated, and the empirical composition even of some of them is still open to discussion. The terms of this series hitherto more or less known are —

Acrylic acid . .	$C^3H^4O^2$	Campholic acid . .	$C^{10}H^{18}O^2$
Crotonic „ . .	$C^4H^6O^2$	Moringic „ . .	$C^{15}H^{28}O^2$
Angelic „ . .	$C^5H^8O^2$	Hypogæic „ . .	$C^{16}H^{30}O^2$
Pyroterebic „ . .	$C^6H^{10}O^2$	Oleic „ . .	$C^{18}H^{34}O^2$
Damaluric „ . .	$C^7H^{12}O^2$	Brassic „ . .	$C^{22}H^{42}O^2$

The following dibasic acids represented by the general formula $C^nH^{2n-4}O^4$, are related — so far at least as composition is concerned — to the last series, in the same manner as the acids of series *c* are related to those of series *a*.

Fumaric acid	$C^4H^4O^4$	Terebic	$C^7H^{10}O^4$
Citraconic Itaconic Mesaconic } acids	$C^5H^6O^4$	Camphoric	$C^{10}H^{16}O^4$

There are still two other series of acids, presenting the same mutual relations as the series *a* and *b*, several terms of which have been very fully studied. They are, —

1. Monobasic acids of the general formula $C^nH^{2n-8}O^2$.

Benzoic acid	$C^7H^6O^2$
Toluylic „	$C^8H^8O^2$
Cuminic „	$C^{10}H^{12}O^2$

2. Diatomic acids of the general formula $C^nH^{2n-8}O^3$.

Oxybenzoic acid	$C^7H^6O^3$
Oxytoluylic „	$C^8H^8O^3$
Phloretic „	$C^9H^{10}O^3$
Oxycuminic „	$C^{10}H^{12}O^3$

The position which a few of the yet remaining organic acids occupy in relation to the series already recognised can be indicated with tolerable certainty; but the greater number are still so imperfectly known that they cannot be included in any classification which is not entirely artificial and empirical. — G. C. F.

ACONITIC ACID. $C^6H^6O^6 = \left.\begin{matrix}(C^6H^3O^3)'''\\ H^3\end{matrix}\right\}O^3$ [or $C^{12}H^6O^{12}$]. *Equisetic acid, Citridic Acid.* (Gm. xii. 408; Gerh. ii. 110; iii. 960; iv. 922.)—An acid found in the roots and leaves of monkshood (*Aconitum Napellus*) and other aconites, and in the herb of *Delphinium Consolida*, collected after flowering. It is also produced by the metamorphosis of citric acid under the influence of heat. It exists in the aconite as aconitate of calcium, which crystallises out on evaporating the juice, and on account of its insolubility may by freed from the colouring matters and other impurities, by washing with water and alcohol. The aconitate of calcium is then dissolved in very dilute nitric acid, and the filtered liquid is precipitated with acetate of lead. The aconitate of lead, after being well washed, is decomposed by hydrosulphuric acid, the sulphide of lead filtered off, and the solution which contains the aconitic acid is evaporated to dryness, and the residue treated with ether, in which the acid dissolves, leaving the impurities.

To obtain it from citric acid, the acid is heated till it ceases to give off inflammable vapours; and the residue dissolved in alcohol is treated with hydrochloric acid, by which aconitic ether is formed, and separates on addition of water, as an oily liquid, which by treatment with potash is converted into aconitate of potassium. This salt is next converted into a lead salt, and the acid is liberated by hydrosulphuric acid as in the preceding process.

On evaporating the ethereal solution, it is left as an amorphous mass, very soluble in water, alcohol, and ether. When heated to 160° it is converted into an oily liquid, which is *itaconic acid*, $C^6H^6O^6 = C^5H^6O^4 + CO^2$. It is distinguished from fumaric acid by being more soluble in water, and from maleic acid by not crystallising.

Aconitic acid is tribasic, and forms three classes of salts, viz. $C^6H^3M^3O^6$; $C^6H^3(M^2H)O^6$; and $C^6H^3(MH^2)O^6$. The aconitates of ammonium, potassium, sodium, magnesium and zinc, dissolve readily in water; the rest are insoluble or sparingly soluble. The soluble aconitates form with solutions of lead and silver, white flocculent precipitates, which do not become crystalline either by ebullition or after prolonged immersion in the liquid, whereas the lead and silver precipitates formed by fumaric and maleic acid are crystalline.

With *ammonium* and *potassium*, aconitic acid forms salts, corresponding to each of the three formulæ above given; with *sodium*, a disodic and a trisodic salt. *Aconitate of calcium*, $C^6H^3Ca^3O^6 + 3H^2O$? occurs in large quantity in extract of aconite. It may also be prepared by dissolving lime in aconitic acid, or by precipitating chloride of calcium with aconitate of sodium. It dissolves in 99 parts of cold water, more readily in boiling water. The solution evaporated at a gentle heat, and without agitation, yields a gelatinous mass which dries up to a gum; but if a few crystals of the salt be introduced into the solution, the whole is deposited in delicate crystals. *Aconitate of manganese*, $C^6H^3Mn^3O^6 + 6H^2O$, is obtained by boiling the acid with carbonate of manganese. Small rose-coloured octahedrons, sparingly soluble in cold water. *Aconitate of lead*, $2C^6H^3Pb^3O^6 + 3H^2O$, is sparingly soluble in boiling water, and gives off 6·29 per cent. water at 140°.—*Aconitate of silver*, $C^6H^3Ag^3O^6$. Nitrate of silver is not precipitated by the free acid, but with the alkaline aconitates it forms a white, amorphous, sparingly soluble precipitate, which is partly reduced to the metallic state by boiling with water.

Aconitate of Ethyl, $C^6H^3(C^2H^5)^3O^6$, is prepared by dissolving aconitic acid in five times its weight of absolute alcohol, and saturating the solution with hydrochloric acid. On addition of water, the ether separates in the form of an oily layer.

It is a colourless liquid, having an aromatic odour, and very bitter taste. Boils at 236°, and has a density of 1·074, at 14°.

Aconitanilic acid or *Phenyl-aconitamic acid.* $C^{12}H^9NO^4 = O\left\{\begin{matrix}N(C^6H^3O^3)'''.C^6H^5.\\ H\end{matrix}\right.$ an amic acid formed on the type $O\left\{\begin{matrix}NH^4\\ H\end{matrix}\right.$, three of the hydrogen-atoms in the ammonium being replaced by the triatomic radicle, aconityl, and the fourth by phenyl. It is obtained by the action of water on the (not yet isolated) compound, $C^{12}H^8NO^3Cl$, produced by treating citranilic (phenyl-citramic) acid with perchloride of phosphorus; probably thus:

$$\underbrace{C^{12}H^{11}NO^5}_{\text{Citranilic acid.}} + 2PCl^5 = C^{12}H^8NO^3Cl + 2POCl^3 + 3HCl;$$

and $$C^{12}H^8NO^3Cl + H^2O = C^{12}H^9NO^4 + HCl.$$

When 1 at. citranilic acid is mixed with 2 at. perchloride of phosphorus, added by small portions, and the action is assisted at intervals by a gentle heat, the whole dissolves, forming a yellow liquid; and on treating this liquid with water, hydrochloric acid is evolved, and aconitanilic acid separates in the form of a soft substance, which, by solution in hot water and cooling, may be obtained in small yellow needles, but cannot be rendered colourless even by repeated crystallisation. The acid dissolves sparingly in water, easily in alcohol, and very easily in aqueous ammonia; and the ammoniacal solution mixed with nitrate of silver, yields rose-coloured flakes of the *silver-salt*, $C^{12}H^8AgNO^4$. (Pebal, Ann. Ch. Pharm. xcviii. 83.)

Aconitodianil or *Diphenyl-aconito-diamide*, $C^{18}H^{14}N^2O^3 = N^2.(C^6H^3O^3.)'''(C^6H^5)^2.H$, is produced (together with aconitanilide), by the action of aconitic acid upon aniline:

$$C^6H^6O^6 + 2C^6H^7N = C^{18}H^{14}N^2O^3 + 3H^2O.$$

also by the action of oxychlorocitric acid upon aniline:

$$C^6H^8O^6Cl^2 + 2C^6H^7N = C^{18}H^{14}N^2O^3 + 3H^2O + 2HCl.$$

It is insoluble in water, very sparingly soluble in cold alcohol. From solution in a large quantity of boiling alcohol, it crystallises on cooling in slender, pale yellow needles. (Pebal.)

Aconitanilide or *Triphenyl-aconito-triamide*, $C^{24}H^{21}N^3O^3 = N^3(C^6H^3O^3)'''(C^6H^5)^3.H^3$, appears to be formed simultaneously with aconitodianil, by the action of aconitic acid or oxychlorocitric acid on aniline:

$$C^6H^6O^6 + 3C^6H^7N = C^{24}H^{21}N^3O^3 + 3H^2O$$

and $$C^6H^8O^6Cl^2 + 3C^6H^7N = C^{24}H^{21}N^3O^3 + 3H^2O + 2HCl.$$

It is an amorphous substance, insoluble in water, but very soluble in cold alcohol, and is thereby easily separated from aconito-dianil. (Pebal.)

The amides of aconitic acid have not yet been obtained.

ACONITINE. $C^{30}H^{47}NO^7$ [or $C^{60}H^{47}NO^{14}$]. (Geiger, Ann. Ch. Pharm. vii. 269; Morson, Pogg. xlii. 175; v. Planta, Ann. Ch. Pharm. lxxiv. 245)—The alkaloid contained in the *Aconitum Napellus*, and probably in all the acrid aconites. It is obtained by exhausting the leaves with alcohol, saturating the extract with milk of lime, separating the lime by sulphuric acid, evaporating the filtered solution of sulphate of acontine at a gentle heat to expel the alcohol, then diluting with water, and treating the solution with carbonate of potassium, which precipitates impure aconitine. The product is purified by redissolving it in alcohol, treating the solution with animal charcoal, reconverting the base into sulphate, again decomposing this salt with hydrate of lime, and treating the precipitate with ether, which dissolves nothing but the aconitine.

Pure aconitine is deposited from solution in dilute alcohol in white pulverulent grains, or sometimes in a compact, vitreous, transparent mass. It is inodorous, but has a persistent, bitter, and acrid taste. It dissolves sparingly in cold water, and in 50 parts of boiling water, forming a strongly alkaline solution. It is very soluble in alcohol, less in ether. At 80° it melts into a vitreous mass, without loss of weight; at 120° it turns brown, and at a higher temperature suffers complete decomposition. It is dissolved without colour by nitric acid. Sulphuric acid colours it first yellow, then violet; tincture of iodine forms with it a kermes-coloured precipitate. It is intensely poisonous, $\frac{1}{50}$ of a grain sufficing to kill a sparrow in a few minutes, and $\frac{1}{10}$ of a grain killing it instantly.

The salts of aconitine do not crystallise readily. They are not deliquescent, but dissolve easily in water and alcohol. The solutions yield a precipitate of aconitine with alkalies. The *hydrochlorate*, $C^{30}H^{47}NO^7.2HCl$, is obtained by passing dry hydrochloric acid gas over dry aconitine. Its solution is not precipitated by chloride of platinum, but yields a white precipitate with chloride of mercury, yellow with chloride of gold, and also with picric acid.

ACONITYL. $C^6H^3O^3$; the triatomic radicle of aconitic acid and its derivatives.

ACRENE. A name given by Laurent to the hydrocarbon, C^3H^4. (See ALLYLENE.)

ACROLEIN. C^3H^4O [or $C^6H^4O^2$]. (Redtenbacher, Ann. Ch. Pharm. xlvii. 114; Geuther and Cartmell, ibid. cxii. 1; Hübner and Geuther, ibid. cxiv. 35; Gm. ix. 365; xii. 550; Gerh. i. iv. 779, 914.)—This body constitutes the acrid principle produced by the destructive distillation of fatty bodies, resulting in fact from the decomposition of glycerin. It is also produced by the action of platinum-black or of a mixture of acid chromate of potassium and sulphuric acid on allyl-alcohol, being indeed the aldehyde of the allyl series. (Cahours and Hofmann.) (See ALLYL.)

Acrolein is best prepared by distilling in a capacious retort a mixture of glycerin and acid sulphate of potassium, or phosphoric anhydride. When phosphoric anhydride is used, the distillate consists entirely of acrolein; but the contents of the retort are very apt to froth over. With acid sulphate of potassium, the distillation is easier, but the acrolein is contaminated with acrylic acid, sulphurous acid, and other products. The distillate is collected in a receiver kept very cold, and provided with a long discharge-tube passing into the chimney in order to carry off the vapours, which are intensely irritating to the eyes. To purify the acrolein, it is digested with oxide of lead, which removes the acid impurities, then rectified in the water-bath, dehydrated over chloride of calcum, and again rectified. As acrolein oxidises very rapidly by contact with the air, all these operations must be conducted with a stream of dry carbonic acid gas passing through the apparatus. (Redtenbacher.)

Hübner and Geuther distil 1 pt. of glycerin with 2 pts. of acid sulphate of potassium, over an open flame, the bottom of the flask being protected by wire-gauze, and a quantity of oxide of lead being placed in the receiver to neutralise the acid products. According to these chemists, the process consists of two stages, the acid sulphate of potassium first dissolving in the glycerin, forming glycerosulphate of potassium, with elimination of water, so that the first portion of the distillate consists chiefly of water, with but little acrolein; but, afterwards, when the liquid becomes more concentrated, the glycerosulphate is decomposed, and acrolein passes over with only a small quantity of water. This latter portion of the distillate is subsequently purified as in Redtenbacher's process.

Acrolein is a colourless, limpid, strongly refracting liquid, lighter than water, and boiling at 52°·4 (Hübner and Geuther). Vapour-density 1·897. Its vapour is so intensely irritating, that a few drops diffused through a room are sufficient to render the atmosphere insupportable. It burns readily with a clear bright flame. It dissolves in about 40 parts of water, and very readily in ether. The solutions are neutral at first, but gradually turn acid by contact with the air.

Acrolein cannot be preserved long, even in closed vessels, as it changes spontaneously into a flocculent substance called by Redtenbacher *disacryl*, and more rarely into a resinous substance, *disacryl-resin*. It sometimes solidifies immediately after being prepared, even in sealed tubes. It undergoes the same transformation under water, which at the same time becomes charged with acrylic, formic and acetic acids. Vapour of acrolein passed through a red-hot tube is decomposed, with formation of water and deposition of charcoal.

Caustic alkalis convert acrolein into resinous products. By *oxidising agents* it is converted into acrylic acid. It reduces oxide of silver with considerable evolution of heat, forming acrylate of silver, which remains dissolved. Nitrate of silver forms with aqueous acrolein a white curdy precipitate (probably C^3H^3AgO) which, however, gradually decomposes, yielding metallic silver and acrylate of silver. On adding a few drops of ammonia, and boiling the liquid, the silver is immediately reduced, but not in the specular form as with aldehyde. *Nitric acid* attacks acrolein strongly, converting it into acrylic acid. *Strong sulphuric acid* blackens it, giving off sulphurous anhydride at the same time. With *chlorine* and *bromine*, it forms heavy oils, together with hydrochloric or hydrobromic acid. *Perchloride of phosphorus* acts violently on acrolein, forming dichloride of allylene $C^3H^4.Cl^2$ (see ALLYLENE), and another oily liquid which appears to be isomeric with it. With *acetic anhydride*, it unites directly, forming the compound $C^3H^4O.C^4H^6O^3$, which is identical in every respect with the compound resulting from the action of acetate of silver on dichloride of allylene (Hübner and Geuther), and may therefore be regarded as diacetate of allylene $(C^3H^4)''.(C^2H^3O)^2.O^2$.

Acrolein-ammonia. $C^{12}H^{20}N^2O^3 = C^{12}H^{18}N^2O^2.H^2O$. Acrolein acts strongly on ammonia, forming a solid compound (first obtained by Redtenbacher):

$$4C^3H^4O + 2NH^3 = C^{12}H^{20}N^2O^3 + H^2O.$$

It is best prepared by gradually adding a saturated solution of ammonia-gas in alcohol to an alcoholic or ethereal solution of acrolein, and precipitating by addition of ether. It is a white or yellowish, amorphous, odourless compound which turns brown at a gentle heat and begins to decompose at 100°, giving off volatile basic products. In the moist state it dissolves readily in cold water and warm alcohol; less in hot water. It dissolves readily in acids, and is precipitated therefrom by alkalis and alkaline carbonates. Hence it appears to be a base. Its solution in hydrochloric acid forms with dichloride of platinum, a light yellow precipitate containing, when dried at 100°, $C^{12}H^{18}N^2O^2.2HCl.2PtCl^2$, or $C^6H^{10}NO.HCl.PtCl^2$. (Hübner and Geuther.)

Acrolein with Acid Sulphite of Sodium.—When acrolein is poured into in aqueous solution of acid sulphite of sodium, its odour is destroyed, and by evaporation over the water-bath, a brown deliquescent syrup is obtained which does not deposit crystals, and from which neither acrolein can be separated by boiling with carbonate of sodium, nor sulphurous acid by boiling with sulphuric acid. (Hübner and Geuther.)

Hydrochlorate of Acrolein, $C^3H^4O.HCl$. Produced by passing dry hydrochloric acid gas into anhydrous acrolein in a vessel surrounded by cold water. The viscid product, washed and dried over oil of vitriol in vacuo, yields hydrochlorate of acrolein as a mass of velvety crystals, which melt at 32° into a thick oil, having the odour of rancid fat. It is insoluble in water, but readily soluble in alcohol and ether, on the evaporation of which it remains as a thick oil. It is resolved by heat into acrolein and hydrochloric acid. It is not apparently altered by boiling with water, or by the action of dilute solutions of the alkalis. Heated with ammonia to 100° in a sealed tube, it yields chloride of ammonium and acrolein-ammonia. Strong hydrochloric acid decomposes it, setting the acrolein free; a similar action is exerted by dilute sulphuric or nitric acid. Hydrochlorate of acrolein in alcoholic solution does not combine with dichloride of platinum, and very slowly reduces a boiling ammoniacal solution of nitrate of silver.

Gaseous *hydriodic acid* passed into acrolein exerts a violent action, attended with a hissing noise like that of red-hot iron plunged into water. The product is a resinous body which is insoluble in alcohol, ether, acids and alkalis, gives off iodine when heated, and yields a small quantity of free iodine to bisulphide of carbon.

METACROLEIN. Hydrochlorate of acrolein heated with hydrate of potassium gives off hydrogen, and yields an oily distillate, which solidifies in magnificent colourless, needle-shaped crystals, consisting of metacrolein, a compound isomeric or more probably polymeric with acrolein. It is lighter than water, has an aromatic odour, and a cooling taste with burning after-taste. It melts at 50°, solidifies at about 45°, or volatilises a little before melting, so that it may be distilled with vapour of water. By heat, it is changed into common acrolein. It is not affected by dilute alkalis, but when heated with mineral acids it is changed more or less into acrolein. In a stream of dry hydrochloric acid gas, it melts and is converted into the hydrochlorate of acrolein above described. Hence it is probable that the compound so named is really a ***hydrochlorate of metacrolein***, perhaps $C^6H^8O^2.2HCl$.

Hydriodate of Metacrolein is produced by passing dry hydriodic acid gas over metacrolein, as a heavy yellow liquid which resembles the hydrochlorate in taste and appearance, and after washing in water, shows a tendency to crystallise at ordinary temperatures. When placed over oil of vitriol, it decomposes, turning brown and giving off iodine.

Hydriodic acid gas acts violently upon acrolein, producing a resinous substance which is insoluble in alcohol, ether, acids and alkalis, and gives up iodine when heated or when digested with bisulphide of carbon. (Geuther and Cartmell.)

ACRYLIC ACID. $C^3H^4O^2 = C^3H^3O.HO$ (or $C^6H^4O^4$). (Gm. ix. 369; Gerh. 783; iv. 914.) *Acroleic acid.* This acid, discovered by Redtenbacher, is produced by the oxidation of acrolein. The best agent to employ is oxide of silver, which, when digested with acrolein, yields a deposit of metallic silver, and a solution of acrylate of silver. This salt is decomposed by hydrosulphuric acid, and the acrylic acid thus set free is purified by rectification. It is necessary carefully to cool the vessel during the decomposition of the silver salt; otherwise, the heat developed is so great that an explosion results. The acid is likewise obtained by the action of chromic acid on oxide of allyl. (Hofmann and Cahours.) (See ALLYL.)

When purified, it is a colourless liquid, of an agreeable, slightly empyreumatic odour. It is miscible with water in all proportions, and its boiling-point is intermediate between that of formic and acetic acids.

It is a monobasic acid, its salts having the formula, $C^3(H^3M)O^2$. They closely resemble the formates and acetates, and are generally very soluble in water.

Acrylate of Sodium. $2C^3(H^3Na)O^2 + 5H^2O$, is obtained by saturating the acid with carbonate of sodium and evaporating. It crystallises in transparent prisms.

Acrylate of Barium. $C^3(H^3Ba)O^2$, is also a soluble salt.

Acrylate of Silver, $C^3(H^3Ag)O^2$, forms white needles, having a silky lustre, and very soluble in water.

Acrylate of Ethyl is obtained, though not in the pure state, by distilling acrylic acid, or its sodium or barium-salt with alcohol and sulphuric acid. (Redtenbacher.)

ACTINOLITE. A variety of Hornblende (*q. v.*)

ADAMANT. See DIAMOND. — **ADAMANTINE SPAR.** See CORUNDUM.

ADAPTER or **ADOPTER.** A piece of tube of more or less conical form, used to elongate the neck of a retort, and to connect it with a receiver.

ADHESION. (See COHESION.)

ADHESIVE SLATE. (See SLATE.)

ADIAPHANOUS SPAR. (See GEHLENITE and SAUSSURITE.)

ADINOLE. A compact impure felspar, better known as *petrosilex*. It differs from jaspar, which it otherwise much resembles, in being fusible before the blowpipe.

ADIPIC ACID. $C^6H^{10}O^4 = O^2 \left\{ \begin{matrix} C^6H^8O^2 \\ H^2 \end{matrix} \right.$, [or $C^{12}H^{10}O^8 = C^{12}H^8O^6.2HO$]. A dibasic acid forming the fifth term of the series $C^nH^{2n-2}O^4$ the lowest term of which is oxalic acid, $C^2H^2O^4$, and the highest at present known, sebacic acid, $C^{10}H^{18}O^4$. It is produced by the action of nitric acid on oleic acid, suet, spermaceti, and other fatty bodies. To prepare it, tallow or suet is boiled in a capacious retort with nitric acid of ordinary strength, which must be frequently renewed, and the distillate poured back till the fatty matter disappears and crystals separate on cooling. The liquid is then evaporated over the water-bath till it solidifies in a crystalline mass on cooling; this mass is washed in a funnel, first with strong nitric acid, then with dilute nitric acid, and lastly with cold water; and the acid is finally purified by crystallisation from boiling water (Malaguti). Other acids of the same series are doubtless formed at the same time; but according to Malaguti, the crystals obtained in the manner just described have all the same appearance, excepting the very last. Wirz (Ann. Ch. Pharm. civ. 257) obtains this acid, together with several other members of the series, by the continued action of nitric acid on the solid fatty acids of cocoa-nut oil. The action is continued for several weeks till the mass solidifies to a crystalline magma. This product is resolved by water into a mixture of several acids of the above series, and a heavy oil; and the acids are separated one from the other by fractional crystallisation from water and alcohol, and lastly by fractional crystallisation of the silver-salts. (See ANCHOIC ACID.)

The acid separates from its aqueous solution in crystalline crusts composed of soft, white, opaque, hemispherical nodules, which appear to be aggregations of smaller crystals. According to Wirz, these crystals dried at 100° contain water of crystallisation, their formula being $2C^6H^{10}O^4 + H^2O$ [anal. 46·2, 46·4 and 47·8 p. c. carbon, 6·6 and 6·8 p. c. hydrogen; calc. 46·4 C and 7·0 H]. At 140° they melt and give off water, leaving the anhydrous acid $C^6H^{10}O^4$ [analysis, 48·2, and 48·3 C; 6·8 and 6·9 H; calc. 49. 3 C and 6·8 H]; which soon afterwards sublimes in long slender needles [the sublimed acid gave by analysis 49·5 C and 6·6 H].

100 parts of water at 18° dissolve 7·73 of the crystallised acid: a hot solution which deposited crystals abundantly on cooling, still retained 8·61 pts. of the acid in 100 pts. at 18° (Wirz). The acid dissolves very readily in hot *alcohol* and *ether*.

The *adipates*, $C^6H^8M^2O^4$, are for the most part soluble in water and crystallisable; insoluble in alcohol. The *ammonium*-salt crystallises in needles (Laurent, Bromeis). The *barium*-salt dried over sulphuric acid, forms opaque warty masses not containing water of crystallisation (Wirz). The *strontium*-salt forms microscopic needles containing $2C^6H^8Sr^2O^4 + 3H^2O$ (Laurent). The *calcium-salt* resembles the barium-salt in appearance, but contains 1 atom of water [$C^6H^8CaO^4 + H^2O$] which is given off between 100° and 200° (Wirz). The *silver-salt*, $C^6H^8Ag^2O^4$, obtained by precipitating the ammonium-salt with a considerable quantity of nitrate of silver, is a white powder.

Adipate of Ethyl, $C^6H^8O^4(C^2H^5)^2$, obtained by saturating the alcoholic solution of the acid with hydrochloric acid gas, is a yellowish oil of sp. gr. 1·001 at 20·5° which boils, with decomposition, at 230°. It has a strong odour of apples and a bitter caustic taste. Chlorine decomposes it, giving off hydrochloric acid and forming a viscous mass. (Malaguti.)

ADIPOCERE. (From *adeps*, fat; and *cera*, wax.) A peculiar white substance, produced by the decomposition of animal matters under the influence of moisture and in situations from which the air is excluded. It was first found by Fourcroy in the *Cimetière des Innocents* at Paris. A number of coffins had been piled one upon another, and remained interred for about 20 years. The bodies were found compressed, as it were, at the bottom of the coffins, and converted into a soft white substance resembling cheese, which bore the imprints of the linen in which they had been wrapped. This matter enclosed the bones, which were broken on the slightest pressure. It was found to consist chiefly of margarate of ammonium together with the margarates of potassium and calcium.

ADULARIA. (See Felspar.)

AEDELFORSITE. (See Edelforsite.)

AECIRIN or **AEGYRIN.** (Handwört. d. Chem. i. 169.) A mineral of the augite family, occurring in the neighbourhood of Brevig in Norway, sometimes in very large and well-defined crystals belonging to the monoclinic system, and having the general character and cleavage of augite. Colour greenish-black to leek-green. Lustre vitreous. The edges exhibit various degrees of translucence, down to complete opacity. Sp. gr. 3·43 to 3·50. Hardness about that of orthoclase. The mineral contains a considerable quantity of iron, partly in the state of protoxide, partly of sesquioxide, besides alumina, lime, magnesia, and soda, sometimes also protoxide of manganese and potash, associated with silica, and sometimes with titanic acid. The formula is not perfectly established, but it is probably of the general form,

$$3(M^2O.SiO^2) + n(M^4O^3.3SiO^2) = 3M^2SiO^3 + nM^4Si^3O^9$$

AERATED WATERS. (See Carbonic Acid and Water.)

AEROLITE. (See Meteorite.)—**AEROSITE.** (See Pyrargyrite.)

AESCHYNITE. (Handwört. d. Chem. i. 192.) A mineral occurring at Miask in the Ural, and consisting, according to Hartwall's analysis, of 56 titanic acid, 20 zirconia, 15 ceric oxide, 3·8 lime, 2·6 ferric oxide, 0·5 stannic oxide (making together 97·9), but according to Hermann's more recent analysis, of 25·90 titanic acid, 33·20 columbic acid, 22·20 ceric oxide, 5·12 cerous oxide, 5·45 ferrous oxide, 6·22 oxide of lanthanum, 1·28 yttria, and 1·20 water (= 100·57). By its crystalline form and properties, as well as by its chemical constitution, it appears to be closely related to Polymignite, Polycrase, Euxenite, &c.

AESCULETIN or **ESCULETIN.** $C^9H^6O^4$, or $C^{18}H^6O^8$. A product of the decomposition of æsculin, discovered in 1853 by Rochleder and Schwartz (Ann. Ch. Pharm. lxxxvii. 186; lxxxviii. 356), and independently by Zwenger (ib. xc. 63). It is obtained; 1. By boiling æsculin with hydrochloric or dilute sulphuric acid. The liquid on cooling deposits a crystalline mass which, when washed with cold water, dissolved in hot alcohol, and treated with acetate of lead, yields a lead-compound of æsculetin from which the latter may be separated by hydrosulphuric acid.—2. A cold saturated solution of æsculin mixed with emulsin (the fermenting principle of sweet almonds) and left in a warm place, deposits after a while, small crystals of æsculetin.

Æsculetin forms shining needles or scales which are bitter, sparingly soluble in cold water and alcohol, more soluble in the same liquids when warm, but nearly insoluble in ether. The aqueous solution is fluorescent like that of æsculin (*q. v.*), but in a much less degree; the fluorescence is however considerably exalted by addition of a small quantity of carbonate of ammonium.

When gradually heated, it gives off 6·64 p.c. water at 100, melts above 270°, and then distils with decomposition. Hydrochloric acid dissolves it without alteration; nitric acid converts it into oxalic acid. It is also decomposed by hot concentrated sulphuric acid. It dissolves in alkalis, forming solutions of a fine gold-yellow colour; its solution in boiling aqueous ammonia deposits on cooling a yellow substance, which decomposes rapidly in contact with the air. Æsculetin imparts a dark green colour to ferric salts. It reduces nitrate of silver at the boiling heat; precipitates red oxide of copper from cupric salts dissolved in potash; and forms with acetate of lead a yellow precipitate containing $C^9H^4Pb^2O^4$.

AESCULIC ACID. Obtained as a white precipitate by boiling *saponin* (a substance contained in the horse-chesnut and in many other plants) with dilute hydrochloric or sulphuric acid, or by boiling saponin with potash-ley and decomposing the resulting æsculetate of potassium with an acid. It is insoluble in water, but soluble in alcohol, and is deposited therefrom in granular crystals on cooling. Nitric acid transforms it into a yellow resinous nitro-compound. It is but a weak acid. The alkaline æsculates are soluble in water, and crystallise from solution in alcohol. The formula of æsculic acid, according to Fremy (Ann. Ch. Phys. [3] lviiii. 101) is $C^{26}H^{16}O^{12}$. Bolley (Ann Ch. Pharm. xc. 211), who calls it *sapogenin*, assigns to it the formula $C^{12}H^{18}O^5$. According to Rochleder and Schwarz (Ann. Ch. Pharm. lxxxviii. 357) it is identical with *chinovatic acid* $C^6H^{10}O^2$.

AESCULIN or **ESCULIN.** $C^{21}H^{24}O^{13}$, or $C^{42}H^{24}O^{26}$. (Gerh. iv. 291, Handwört. d. Chem. i. 196.) A crystalline fluorescent substance obtained from the bark of the horse-chestnut (*Aesculus Hippocastanum*) and of other trees of the genera *Aesculus* and *Pavia*. It was first observed by Frischmann, more closely investigated by Trommsdorff the younger in 1835 (Ann. Ch. Pharm. xiv. 198), afterwards by Rochleder and Schwarz (ibid. lxxxvii. 186; lxxxviii. 156), and by Zwenger (ibid. xc. 63).

The aqueous extract of the bark is precipitated with acetate of lead; the precipitate is washed, suspended in water, and decomposed by hydrosulphuric acid; and the liquid is filtered at the boiling heat. Or better: the aqueous extract is mixed with solution of alum and excess of ammonia; the liquid filtered to separate the fawn-coloured precipitate of alumina mixed with the colouring matter of the bark; the yellowish filtrate neutralised with acetic acid and evaporated to dryness; the residue containing the sulphates and acetates of potassium and ammonium, boiled with a little strong alcohol to extract the æsculin; the alcoholic filtrate evaporated till it crystallises; and the æsculin thus obtained, is purified by pressure between bibulous paper, and recrystallisation. (Rochleder, J. pr. Chem. lxxi. 414; Chem. Gaz. 1858, 96.)

Aesculin forms colourless, needle-shaped crystals. It is inodorous, has a bitter taste, is sparingly soluble in cold water and alcohol, more soluble in the same liquids at the boiling heat, and nearly insoluble in ether.

Aesculin is coloured red by chlorine; it forms a yellow precipitate with subacetate of lead, and reduces the protoxide of copper to suboxide, like glucose. It melts at 160° and decomposes at a somewhat higher temperature, yielding various products among which is a small quantity of æsculetine. Boiled with hydrochloric or dilute sulphuric acid, it is resolved into æsculetin and glucose:

$$C^{21}H^{24}O^{13} + 3H^2O = C^9H^6O^4 + 2C^6H^{12}O^6$$

The aqueous solution of æsculin is highly fluorescent (see Light), the reflected light being of a sky-blue colour. Nearly the same fluorescent tint is exhibited by an infusion of horse-chestnut bark. The colour is however slightly modified by the presence of another fluorescent substance, *paviin*, recently discovered by Prof. Stokes (Chem. Soc. Qu. J. xi. 17). The latter is separated from æsculin by its greater solubility in ether. Its solution exhibits a blue-green fluorescence. Aesculin and paviin appear to exist together in the barks of all species of the genera *Asculus* and *Pavia*, æsculin being however more abundant in the former and paviin in the latter (see Paviin). The fluorescence of both æsculin and paviin is augmented by alkalis, but destroyed by acids.

AETHAL. (See Cetyl.)

AETHER, AETHYL, &c. (See Ether, Ethyl, &c.)

AETHIOPS. An old pharmaceutical term applied to various mineral preparations of black colour or approaching thereto: *e. g. Aethiops antimonialis* obtained by triturating together mercury, sulphide of antimony, and sulphur; *Aethiops martialis* black oxide of iron; *Aethiops mineralis*, black sulphide of mercury obtained by triturating mercury with sulphur; *Aethiops narcoticus* (or *hypnoticus*,) sulphide of mercury obtained by precipitation; *Aethiops per se*, the grey powder obtained by exposing impure mercury to the air.

AETHOKIRRIN. The yellow colouring matter of the flowers of *Antirrhinum Linaria*.

AFFINITY. (See Chemical Affinity.)

AFTONITE. (See Aphtonite.)

AGALMATOLITE [from ἄγαλμα, an image; and λίθος, stone]; *Bildstein*. This name was originally given to a soft mineral or rather a number of such minerals used by the Chinese for carving grotesque figures and idols. These minerals vary in colour from greyish-green to yellow and red; they are all more or less soft and unctuous to the touch and capable of being cut and polished.

The Chinese agalmatolites are of three kinds: viz.

1. Hydrated silicates of aluminium and potassium:

a. $9SiO^2.3Al^4O^3.1K^2O.3H^2O = 6SiO^3.3Al^2O^3.1KO.3HO$

b. $3SiO^2.1Al^4O^3.M^2O.1H^2O = 6SiO^3.3Al^2.3MO^{*}.3HO$

---

* M denotes potassium, sodium, calcium, magnesium, &c.

2. Hydrated silicates of aluminium.

$$a.\ 9\mathrm{SiO^2.2Al^4O^3.6H^2O} = 3SiO^3.1Al^2O^3.3HO$$
$$b.\ 15\mathrm{SiO^2.4Al^4O^3.4H^2O} = 5SiO^3.2Al^2O^3.2HO$$

3. Hydrated silicates of magnesium:

$$15\mathrm{SiO^2.12Mg^2O.4H^2O} = 5SiO^3.6MgO.2HO$$

There are also several European minerals which in composition and physical character closely resemble the Chinese agalmatolites.

4. Agalmatolite from Magyag in Hungary has the same composition as the Chinese mineral, 1, *a*.

5. Agalmatolite, from Ochsenkopf in the Saxon Harz, and *Onkosin* from Posseggen in Salzburg, have a composition expressed by the formula:

$$9\mathrm{SiO^2.3Al^4O^3.2M^2O.3H^2O} = 6SiO^3.3Al^2O^3.2MO.3HO.$$

6. *Mother of Diaspore*, a mineral in which the diaspore of Schemnitz in Hungary is intergrown, has the composition 2, *a* above.

7. *Parophite* from Canada has a composition corresponding to the formula:

$$9\mathrm{SiO^2.3Al^4O^3.3M^2O.4\tfrac{1}{2}H^2O} = 6SiO^3.3Al^2O^3.MO.4\tfrac{1}{2}HO$$

8. *Dysyntribite*, from Diana and other localities in St. Lawrence county, New York, appears also to have a constitution resembling that of the agalmatolites.

9. *Kaolin*, which is a hydrated silicate of aluminium, containing

$$(2\mathrm{SiO^2.Al^4O^3.2H^2O}) = 4SiO^3.3Al^2O^3.6HO,$$

exactly resembles the agalmatolites in physical character.

10. *Neolite*, from Eisenach and other localities, containing

$$9\mathrm{SiO^2.Al^4O^3.3M^2O.H^2O} = 6SiO^3.1Al^2O^3.3MO.1HO,$$

also forms masses resembling agalmatolite.

All these minerals have a specific gravity ranging from 2·75 to 2·85; rarely as high as 2·90. In hardness, they are intermediate between gypsum and calcspar. They are more or less translucent, unctuous to the touch, do not adhere to the tongue, and are easily carved and wrought.

The true agalmatolites are 1, *a*; 4, 5, 6, and 7: the rest may be regarded as allied species. (Handw. d. Chem. i. 375.)

AGAPHITE. (See TURQUOISE.)

AGAR-AGAR, or Bengal Isinglass: a dried sea-weed from Singapore, consisting of small transparent colourless strips, is almost completely soluble in water, and forms a large quantity of thick, tasteless, and odourless jelly.

AGARICIN. (See AMANITIN.)

AGARICUS. A genus of the order *Fungi*. Many fungi, especially of the genus *Agaricus* are commonly used as food, and it is remarkable that the amount of nitrogen contained in their dried substance exceeds that in peas and beans, which are generally regarded as the most nutritious of all articles of food.

The following table exhibits the percentage of nitrogen and of ash in various species of fungi, as determined by Schlossberger and Döpping (Ann. Ch. Pharm. lii. 106 to 120). The plants were dried at 100° C. The quantity of water averaged about 90 per cent.

	Nitrogen.	Ash.
Agaricus deliciosus	4·68	6·9
„ *arvensis*	7·26	19·82
„ *glutinosus*	4·61	4·8
„ *russula*	4·25	9·5
„ *cantharellus*	3·22	11·2
„ *muscarius*	6·34	9·0
Boletus aurens	4·7	6·80
Lycoperdon echinatum	6·16	5·2
Polyporus fomentarius	4·46	3·0
Dædalea quercina	3·19	3·1

The ash contains a large proportion of phosphates. The solid tissue of fungi, formerly regarded as a peculiar substance, *fungin*, is nothing but cellulose: it may be extracted by treating the fungi successively with water, weak soda-ley, hydrochloric acid, and alcohol. Agarics were found by Schlossberger and Döpping to contain mannite and fermentable sugar, but no starch. The acid contained in agarics and other fungi was formerly supposed to be of peculiar nature, and called *boletic* or *fungic* acid; but it has been shown by Bolley and Dessaignes that many agarics contain fumaric acid, sometimes associated with malic, citric, and phosphoric acid.

AGARICUS MINERALIS, the *mountain milk*, or *mountain meal*, of the Germans, is one of the purest of the native carbonates of lime, found chiefly in the clefts of rocks, and at the bottom of some lakes, in a loose or semi-indurated form.

The name of *mineral agaric*, or *fossil meal*, was also applied by Fabroni to a stone of a loose consistence found in Tuscany in considerable abundance, of which bricks may be made, either with or without the addition of a twentieth part of clay, so light as to float in water, and which he supposes the ancients used for making their floating bricks, This, however, is very different from the preceding, not being even of the calcareous genus, since it appears, on analysis, to be a hydrated silicate of magnesium mixed with lime, alumina, and a small quantity of iron. Kirwan calls it *argillo-murite*.

AGATE. A mineral, whose basis is calcedony, blended with variable proportions of jasper, amethyst, quartz, opal, heliotrope, and carnelian. *Ribbon agate* consists of alternate and parallel layers of calcedony with jasper, or quartz, or amethyst. The most beautiful comes from Siberia and Saxony. It occurs in porphyry and gneiss.—*Brecciated agate;* a base of amethyst, containing fragments of ribbon agate, constitutes this beautiful variety; it is of Saxon origin.—*Fortification agate*, is found in nodules of various imitative shapes, imbedded in amygdaloid. This occurs at Oberstein on the Rhine, and in Scotland. On cutting it across and polishing it, the interior zig-zag parallel lines bear a considerable resemblance to the plan of a modern fortification. In the very centre, quartz and amethyst are seen in a splintery mass, surrounded by the jasper and calcedony.—*Mocha stone.* Translucent calcedony, containing dark outlines of arborisation, like vegetable filaments, is called Mocha stone, from the place, in Arabia, where it is chiefly found. These curious appearances were ascribed to deposits of iron or manganese, but more lately they have been thought to arise from mineralised plants of the cryptogamous class.—*Moss agate*, is a calcedony with variously coloured ramifications of a vegetable form, occasionally traversed with irregular veins of red jasper. Dr. M'Culloch has detected, what Daubenton merely conjectured, in mocha and moss agates, aquatic confervæ, unaltered both in colour and form, and also coated with iron oxide. Mosses and lichens have also been observed, along with chlorite, in vegetations. An onyx agate set in a ring, belonging to the Earl of Powis, contains the chrysalis of a moth.

Agate is found in most countries, chiefly in trap rocks and serpentine. Hollow nodules of agate, called *geodes*, present interiorly crystals of quartz, colourless or amethystine, having occasionally scattered crystals of stilbite, chabasite, and capillary mesotype. These geodes are very common. Bitumen has been found by M. Patrin in the inside of some of them, among the hills of Dauria, on the right bank of the Chilca. The small geodes of volcanic districts occasionally contain water in their cavities. These are chiefly found in insulated blocks of a lava having an earthy fracture. When they are cracked, the liquid escapes by evaporation; it is easily restored by plunging them for a little in hot water. Agates are artificially coloured by immersion in metallic solutions. Agates were more in demand formerly than at present. They were cut into cups and plates for boxes; and also into cutlass and sabre handles. They are still cut and polished on a considerable scale and at a moderate price, at Oberstein. The surface to be polished is first coarsely ground by large millstones of a hard reddish sandstone, moved by water. The polish is afterwards given on a wheel of soft wood, moistened and imbued with a fine powder of a hard red *tripoli* found in the neighbourhood. M. Faujas thinks that this *tripoli* is produced by the decomposition of the porphyrated rock which serves as a gangue to the agates. The ancients employed agates for making cameos (see CALCEDONY). Agate mortars are valued by analytical chemists, for reducing hard minerals to an impalpable powder.

The oriental agate is almost transparent, and of a vitreous appearance. The occidental is of various colours, and often veined with quartz or jasper. It is mostly found in small pieces covered with a crust, and often running in veins through rocks like flint and petrosilex, from which it does not seem to differ greatly. Agates are most prized when the internal figure nearly resembles some animal or plant.—U.

AGEDOÏL. A name applied by Caventou to a crystallisable substance obtained from liquorice-root; identical with asparagin. (Henry and Plisson.)

AGNESITE. Syn. with BISMUTITE.

AGROSTEMMINE. A crystalline basic substance obtained from the seeds of the corn-cockle (*Agrostemma Githago*). The seeds are exhausted with weak alcohol acidulated with acid; the acid is concentrated by evaporation and mixed with magnesia; and the dried precipitate is treated with alcohol.

Agrostemmin crystallises in pale yellow scales which are but slightly soluble in water, but very soluble in alcohol, to which they impart an alkaline reaction. It is decomposed by boiling potash, with evolution of ammonia.

The sulphate, chloro-aurate and chloroplatinate of agrostemmine are crystallisable; the phosphate forms a bulky precipitate. (Schulze, Ann. Ch. Pharm. lxviii. 350.)

AIKINITE. Syn. with ACICULITE.

AIR. The term "air" (Latin, *aer*) is now exclusively employed to denote the component gases of the earth's atmosphere. Amongst the older writers on science, we find the word "air" made use of to designate the gaseous or aeriform condition of a body; thus carbonic acid gas was called "fixed air," hydrochloric acid gas "marine acid air," hydrogen gas "inflammable air," &c. (See ATMOSPHERE.)

AJUGA REPTANS (*Creeping Bugle*). (Handw. d. Chem. i. 385.) This plant, grown on the even ground of the Lechthal, yielded, when gathered in the beginning of June, 84·3 p.c. water, and 10·4 p.c. ash (*a*); that which grew on the chain of hills adjoining the valley, yielded at the end of June, 81·6 p.c. water and 9·5 p.c. ash (*b*).

	a.	*b.*
Potash	37·31	36·39
Soda	—	4·81
Lime	23·73	15·70
Magnesia	10·70	5·43
Sesquioxide of iron	2·79	1·70
Manganoso-manganic oxide	trace	2·29
Phosphoric anhydride	5·46	5·51
Sulphuric	3·63	3·68
Chloride of potassium	5·04	—
Chloride of sodium	2·66	2·78
Silica	8·61	21·71

AKANTICON. (See EPIDOTE.)

AKCETHIN. (See ACETONE.)

AKMITE. (See ACHMITE.)

AKONTITE. A variety of arsenical pyrites.

ALABANDIN. (See MANGANESE-GLANCE.)

ALABASTER. *Granular gypsum, Albâtre gypseux.* The technical name for granular gypsum or sulphate of calcium. Alabaster is among the several varieties of gypsum what marble is among carbonates of calcium, and like marble is used for sculpture, especially for objects of small dimensions. The hard, fine-grained, snow-white, translucent alabaster from Volterra near Florence, is especially valued for these purposes.

ALALITE. (See DIOPSIDE.)

ALANINE. $C^3H^7NO^2$. (A. Strecker, Ann. Ch. Pharm. lxxv. 29; Gm. ix. 434; Gerh. i. 678.) An organic base obtained by heating aldehyde-ammonia with hydrocyanic acid in presence of excess of hydrochloric acid.

$$C^2H^3O^2.NH^4 + CNH + HCl + H^2O = C^3H^7NO^2 + NH^4Cl.$$

To prepare it, an aqueous solution of 2 pts. aldehyde-ammonia is mixed with aqueous hydrocyanic acid containing 1 pt. of the anhydrous acid, hydrochloric acid is added in excess, and the mixture is boiled and afterwards evaporated to dryness over the water-bath. The residue consisting of hydrochlorate of alanine and a large quantity of sal-ammoniac, is digested in a little cold water, which leaves the greater part of the sal-ammoniac undissolved; the solution of hydrochlorate of alanine is boiled with hydrate of lead, added in small portions as long as ammonia continues to escape; the liquid is filtered; and the dissolved lead is precipitated from the solution by sulphuretted hydrogen. The filtered liquid yields crystals of alanine by evaporation, and an additional quantity may be obtained from the mother-liquor by addition of alcohol. Another and better method is to treat the mixture of hydrochlorate of alanine and sal-ammoniac with alcohol and ether, in which the former only is readily soluble, concentrate the solution by evaporation, and remove the hydrochloric acid by boiling with hydrate of lead.

Properties. — Alanine crystallises on cooling from a hot saturated solution in colourless needles having the form of oblique rhombic prisms united in tufts. They have a pearly lustre, are hard, and grate between the teeth. At 200°, it sublimes and falls down again in fine snowy crystals; when rapidly heated, it melts and suffers partial decomposition. It dissolves in 4·6 pts. of water at 17°, and in a smaller quantity of hot water; it is very sparingly soluble in cold alcohol, and quite insoluble in ether. The aqueous solution has a sweet taste, does not affect vegetable colours, and forms no precipitates with any of the ordinary reagents.

Alanine is isomeric with urethane, lactamide, and sarcosine; from the two former it is distinguished by not melting below 100°; from the last by being soluble in water, and by its behaviour with metallic oxides.

Decompositions.—Alanine is not altered by boiling with dilute acids, or with alkalis. It dissolves in strong sulphuric acid, and the solution does not blacken on boiling. Fused with hydrate of potassium, it gives off hydrogen and ammonia, and yields cyanide and acetate of potassium. When its aqueous solution is boiled with peroxide of lead, it is resolved into aldehyde, carbonic anhydride, and ammonia:

$$C^3H^7NO^2 + O = C^2H^4O + CO^2 + NH^3.$$

The aqueous solution is also decomposed by nitrous acid, with evolution of nitrogen and formation of lactic acid:

$$\underbrace{C^3H^7NO^2}_{\text{Alanine.}} + \underbrace{NO^2H}_{\text{Nitrous acid.}} = \underbrace{C^3H^6O^3}_{\text{Lactic acid.}} + 2N + H^2O.$$

Compounds of Alanine.—Alanine acts both as a base and as an acid. It unites directly with acids, and when boiled with metallic oxides forms compounds consisting of alanine with 1 atom of hydrogen replaced by a metal. With *hydrochloric acid*, it forms two compounds, viz. $2C^3H^7NO^2.HCl$, obtained by treating alanine with dry hydrochloric acid gas, and $C^3H^7NO^2.HCl$, produced by evaporating a solution of alanine in excess of hydrochloric acid. Both these compounds dissolve readily in water, sparingly in alcohol; the latter is very deliquescent, but may with some difficulty be obtained in crystals. On mixing a solution of alanine in hydrochloric acid with excess of bichloride of platinum, and evaporating, the chloroplatinate, $2C^3H^7NO^2.HCl.PtCl^2$, crystallises in slender yellow needles, soluble in water and alcohol, and even in a mixture of alcohol and ether. *Nitrate of alanine*, $C^3H^7NO^2,HNO^3$ is obtained by evaporating a solution of alanine in dilute nitric acid, in long colourless needles, which deliquesce in damp air, and dissolve very readily in water, less in alcohol; at 100°, they turn yellow and decompose. *Sulphate of alanine* is very soluble in water, and remains as a syrupy mass when its solution is evaporated; it may be washed with cold alcohol. It is not precipitated from its aqueous solution by alcohol, but a mixture of ether and alcohol separates it in the form of a thick syrup.

The *copper-compound* of alanine, $2C^3H^6CuNO^2 + H^2O$ crystallises from a solution of alanine which has been boiled with cupric oxide, in dark blue needles and thicker rhombic prisms. It forms a dark blue solution in water, but is nearly insoluble in alcohol. The crystals remain unaltered at 100°, but at 120° they give off water, and are reduced to $C^3H^6CuNO^2$ assuming at first a lighter blue colour, and afterwards crumbling to a bluish-white powder. *The silver-compound*, $C^3H^6AgNO^2$, is obtained in a similar manner, and separates as the liquid cools, in small yellow needles united in hemispherical groups. They assume a darker colour when exposed to light, and also when heated to 100° in the moist state; but when dry they sustain that temperature without alteration. A solution of nitrate of silver mixed with alanine, yields by spontaneous evaporation, colourless rhombic tables, which are decomposed by heat, with slight detonation, and leave a residue of spongy silver. A *lead-compound*, $C^3H^6PbNO^2.PbHO$, is obtained in colourless glassy needles, by boiling protoxide of lead in aqueous alanine, and evaporating and cooling the solution. It is also precipitated in radiating crystals, on mixing the aqueous solution with alcohol. The crystals dried over sulphuric acid, give off water and crumble to a powder which is no longer completely soluble in water.

ALANTIN. (See Inulin.)

ALBAN. A white, crystalline, resinous substance extracted from gutta percha by alcohol or ether. It is best obtained by treating gutta percha with ether, and digesting the resulting extract with alcohol, which dissolves a yellow resin, and leaves a white substance to which Payen gives the name of alban. After recrystallisation from absolute alcohol, it forms a white pulverulent mass, which begins to melt at 100°, is perfectly fluid and transparent between 175° and 180°, and contracts strongly in cooling. It dissolves with facility in oil of turpentine, benzol, sulphide of carbon, ether, hot alcohol, and chloroform, and separates from the solutions in the crystalline form. The crystals are wetted by watery liquids. They exhibit with sulphuric acid the same reactions as native gutta percha. (Payen, Compt. rend. xxxv. 109.)

ALBENE. A name given by Völckel to a white substance which, according to his observations, remains undissolved when melam is boiled with water. Völckel assigns to this substance the composition $C^{12}H^9N^{10}O^3$ (Ann. Ch. Phys. [2] lxii. 90).

ALBIN. (See Apophyllite.)

ALBITE. Soda-felspar. (See Felspar.)

ALBUM GRÆCUM. An obsolete name for the excrements of the dog, formerly used as a remedy in medical practice. The substance contains about 79 per cent. of phosphate of calcium.

ALBUMIN. (Gerh. iv. 433; Lehmann, Physiological Chemistry i. 330; also Zoochemie in Gmelin's Handbuch, Bd. viii. Pelouze et Frémy, Traité de Chimie générale, vi. 67.) Albumin is the chief and characteristic constituent of white of egg and of the serum of blood, and occurs in all those animal substances which supply the body or individual parts of it with the materials required for nutrition and renovation. It forms about 7 p. c. of blood and 12 p. c. of white of egg; it is a principal constituent of chyle, lymph and of all serous fluids. It occurs also in the juice of flesh, in the brain, the pancreas, the amniotic liquid, and generally in a greater or smaller quantity in all the liquids (transudates) effused from the blood-vessels into the cellular tissues of the organs, into the cavities of the body, or on to the surface. It is found in the solid excrements of man and of other animals, the quantity increasing in disorders of the mucous membrane of the intestinal canal. It is not found in normal urine, but is present in that liquid in many states of disease, especially in affections of the respiratory organs, which interfere with the process of oxidation.

Albumin exists in two very distinct modifications, viz. the *soluble* form, in which it always occurs in the animal body, and the *insoluble* form, into which it may be brought by the action of heat, as when white of egg or blood-serum is boiled. These two modifications of albumin are identical in chemical composition, the difference between them being due, partly, perhaps, to peculiarity of molecular aggregation, but chiefly to the presence of certain mineral salts which are always associated with the soluble variety. In fact, albumin does not occur in the animal body in the free state, but in the form of an alkaline albuminate; white of egg, serum, and all liquids which contain albumin, leave, when incinerated, an ash chiefly consisting of alkaline carbonate. Insoluble albumin does not appear to exist in the living animal organism, unless indeed, fibrin may be regarded as coagulated albumin, which is by no means improbable, inasmuch as there is no exact method of distinguishing between the two.

Preparation.— Albumin may be prepared either from white of egg, or from blood-serum. White of egg consists of transparent thin-walled cellules, enclosing an alkaline solution of albuminate of sodium. On beating it up with water, the cellular substance separates in pellicles, while the albuminate of sodium remains in solution, together with chloride of sodium and phosphate of calcium. To remove these mineral substances, the liquid, after being filtered from the cellular substance, is mixed with a small quantity of subacetate of lead, which produces an abundant precipitate (an excess of the lead-salt would redissolve it). The mass, after being washed, is stirred up with water to the consistence of a paste, and carbonic acid gas is passed through the liquid. The albuminate of lead is thereby decomposed, carbonate of lead remains suspended in the liquid, and the albumin in the free state remains dissolved. The solution is filtered through paper previously washed with dilute acid, and, as it still retains traces of lead, it is treated with a few drops of aqueous hydrosulphuric acid, and cautiously heated to 60°, till it begins to show turbidity; the first flocks of albumin thus precipitated carry down the whole of the sulphide of lead. When the liquid which after filtration is perfectly colourless, is evaporated in large capsules at 40°, a residue is obtained consisting of pure *soluble* albumin (Wurtz, Ann. Ch. Phys. [3] xii. 27). The same method applied to the albumin of blood-serum does not yield a pure product.

To obtain pure albumin in the coagulated state, white of egg, diluted with an equal bulk of water, filtered, and reduced to its original volume by evaporation at 40°, is mixed with a strong solution of potash, whereby it is soon converted into a translucent, yellowish elastic mass. This is divided into small portions and exhausted with cold water as long as the water removes any alkali, the whole being kept as much as possible from contact with the air. It is then dissolved in water or boiling alcohol, and the solution is precipitated by acetic or phosphoric acid. The precipitate, after washing, leaves no appreciable residue when incinerated. (Lieberkühn.)

Properties.— Soluble albumin, dried in the air, forms a pale yellowish, translucent mass, easily triturated and reduced to a white powder. The specific gravity of the albumin of the hen's egg, from which the salts had not been removed, was found by C. Schmidt (Ann. Ch. Pharm. xi. 156–167), to be 1·3144, and after calculating for the elimination of the salts, the density of pure albumin was found to be 1·2617. It becomes electric by friction, and is tasteless, inodorous and neutral to vegetable colours. It swells in water, assuming a gelatinous appearance; it does not dissolve freely in pure water, but very readily in water containing any alkaline salt. After being dried in vacuo, or at a temperature below 50°, it may be heated to 100° without passing into the insoluble modification. Soluble albumin dried at 60° loses 4 p. c. water at 140°, remaining, however, soluble in water.

The aqueous solution of albumin deviates the plane polarisation of a ray of light to the left. It becomes opaline at 60°, begins to deposit the albumen at 61° to 63°, and at a temperature a little higher the whole coagulates in a mass. When very dilute, it becomes turbid without coagulating; but if the liquid be then concentrated by evaporation, it deposits the albumin in pellicles or flocks.

Coagulated albumin is white, opaque, elastic, and reddens litmus (Hruschauer, Ann. Ch. Pharm. xlvi. 348). When dried, it assumes a yellow colour, and becomes brittle and translucent like horn. When immersed in water, after drying, it gradually absorbs about five times its weight of the liquid, and resumes its primitive consistence.

When coagulated albumin is boiled in *water* for about 60 hours, it gradually disappears, being transformed into a substance soluble in water, and consisting, according to Mulder and Baumhauer (J. pr. Chem. xx. 346; xxxi. 295), of *trioxide of protein*, $C^{40}H^{31}N^{5}O^{8}$ (C = 50·98 p. c.; H = 6·69; O and S = 5·01; N = 27·32). Coagulated albumin, heated to 150° with a small quantity of water in a sealed tube, gradually forms a limpid solution, which has no longer the property of coagulating by heat. (L. Gmelin.)

Albumin is insoluble in *alcohol* and in *ether*. Strong alcohol added in large excess, precipitates albumin from its aqueous solution in the same state as when it is coagulated by heat; but the precipitate produced by a small quantity of weak alcohol redissolves completely in water. When alcohol is added to a somewhat dilute solution of albumin, so as to render it slightly opaline, the liquid after a while, solidifies in a jelly, which, however, is again liquefied by heat. Coagulated serum, or white of egg, may be made to dissolve in alcohol by the addition of a little alkali. (Scherer.)

Ether shaken up with a solution of albumin coagulates but a small portion of it; if, however, the albuminous solution is concentrated, it thickens so much as to appear coagulated. Albumin is not acted upon by oils either fixed or volatile.

Nearly all *acids* precipitate albumin from its solutions. *Nitric acid* precipitates it with peculiar facility, and may therefore be used as a test of the presence of soluble albumin. Strong *hydrochloric acid* aided by heat dissolves coagulated albumin, forming a blue or violet solution, which turns brown when boiled in an open vessel, and according to Bopp (Ann. Ch. Pharm. lxix. 30) yields chloride of ammonium, leucine, tyrosine, and other products of unknown composition. With *aqua regia*, albumin yields both chlorinated and nitro-compounds.

Strong *sulphuric acid* coagulates albumin by the heat which is evolved when the two liquids come in contact. Dilute sulphuric acid precipitates albumin after some time only, not however combining with it, as the acid may be completely removed from the precipitate by washing.

Tribasic phosphoric acid, *acetic*, *tartaric*, and most other organic acids do not form precipitates in moderately concentrated solutions, of albumin; but when either of these acids is added in excess to a highly concentrated solution of serum or white of egg, the liquid solidifies in the cold to a jelly which liquefies like gelatin when heated, and again forms a gelatinous mass on cooling. The aqueous solution of this jelly remains perfectly transparent when boiled, but it is precipitated by a neutral salt of either of the alkali-metals. (Lieberkühn.)

When a small quantity of acetic acid is added to white of egg or serum, so as just to saturate the alkali, and the liquid is then largely diluted with water, flocks of albumin are deposited after awhile. If the supernatant liquid be then decanted, and the precipitate treated with a small quantity of solution of nitre or common salt, it immediately dissolves, and the solution is coagulated by boiling. (Scherer.)

Serum or white of egg mixed with a certain quantity of *common salt* or other salt of an alkali-metal, forms a liquid precipitable by phosphoric, acetic, tartaric, oxalic, lactic acid, &c. Conversely, a solution of albumin (or other albuminoïdal substance) in acetic acid is precipitated by the salts of the alkali-metals. The precipitation is greatly facilitated by heat, and likewise takes place with greater facility as the proportion of salt added is greater. The precipitate dissolves in pure water, with greater facility in proportion as less heat has been applied in producing it; the solution is not coagulated by heat. It is soluble also in acetic acid, phosphoric acid, and even in alcohol, provided it has not been altered by desiccation, or by contact with the air. The aqueous solution is precipitated by certain salts, ferrocyanide of potassium, for example.

Dried soluble albumin suspended in acetic, tartaric, or citric acid, swells up and is converted into coagulated albumin, which may be completely freed from acid by washing. Acetic, tartaric, and tribasic phosphoric acid dissolve coagulated albumin when heated with it. Arsenious acid does not combine with albumin. Chlorine and bromine precipitate albumin.

Alkalis do not in general precipitate albumin from its solutions; but a strong solution of potash added in considerable quantity to a solution of albumin, forms a gelatinous mass of albuminate of potassium. Dilute solutions of potash and soda mix with albumin in all proportions, and on boiling the liquid, an alkaline sulphide is formed. When albumin is heated with hydrate of potassium melted in its water of crystallisation, the water being renewed as it evaporates, ammonia and hydrogen are evolved, leucine and tyrosine are produced, together with oxalate, butyrate valerate, &c. of potassium. *Alkaline carbonates* added to a solution of albumin prevent its coagulation by heat. Coagulated albumin digested at a gentle heat with neutral carbonate or acid carbonate of sodium, displaces the carbonic acid, and forms with the alkali a compound, which, after washing, is perfectly neutral to test paper, but leaves when incinerated a considerable quantity of alkaline carbonate.

Albumin subjected to *dry distillation* yields water, carbonate of ammonium, hydrosulphate of ammonium, volatile alkalis of undetermined composition, empyreumatic oils, &c. Coagulated albumin putrifies when left in contact with water, yielding valeric and butyric acids, a crystalline body having a penetrating odour, an oily acid, and a substance which dissolves in hydrochloric acid, producing a liquid of beautiful violet colour and yielding tyrosine, together with other products (Bopp, Ann. Ch. Pharm. lxix. 30). The *oxygen* of the air has no action on serum or white of egg. Recently extracted serum left for a fortnight in contact with oxygen in a tube standing over mercury absorbs but a very small quantity of the gas, and does not form carbonic acid.

Albumin distilled with a mixture of *peroxide of manganese and sulphuric acid* yields acetic, propionic, butyric, and benzoic aldehydes, together with formic, acetic, butyric, valeric, and benzoic acids, and probably also propionic and caproic acids. Nearly the same products are obtained by distilling albumin with *sulphuric acid and acid chromate of potassium*, this mixture yielding in fact, hydrocyanic acid, a heavy oil having the odour of cinnamon, cyanide of tetryl (valeronitrile), also benzoic, acetic and butyric acids, with small quantities of formic, caproic and propionic acids, and of benzoic and propionic aldehydes (Guckelberger, Ann. Ch. Pharm. lxiv. 39). Albumin does not decompose *oxygenated water*.

Composition of Albumin. — Albumin obtained from various animal fluids exhibits the same composition, as shown by the following analyses: —

	From White of Egg.					
	Mulder.	Scherer.	Dumas and Cahours.	Rüling.	Wurtz.	Lieberkühn.
Carbon	53·4	54·3	53·4	53·4	52·9	53·3
Hydrogen	7·0	7·1	7·1	7·0	7·2	7·1
Nitrogen	15·7	15·9	15·8	..	15·6	15·7
Oxygen	..	..	..	..	..	22·1
Sulphur	..	..	..	1·7 to 1·8	..	1·8

Wurtz's analysis was made with soluble, the rest with coagulated albumin. Mulder supposes that albumin contains also 0·4 per cent. phosphorus. Most of the preparations with which the above analyses were made, contained small quantities of phosphorus in the form of phosphate of calcium.

	From Blood-serum.				
	Dumas and Cahours.		Mulder.	Rüling.	Scherer.
Carbon	53·3	53·5	53·4	53·1	54·5
Hydrogen	7·1	7·3	7·1	7·0	7·0
Nitrogen	15·7	15·8	15·6	..	15·7
Oxygen	..	..	..	..	..
Sulphur	..	..	1·3	1·3	..

Mulder supposes that blood-albumin contains also 0·3 per cent. phosphorus. Rüling found the amount of sulphur in eight analyses to vary from 1·29 to 1·39 per cent.

	Scherer.			Weidenbusch.	Baumhauer.

Oxygen	..	..	..	..	..
Sulphur	..	..	..	..	..

a from a hydrocele; *b* from a congestion-abscess; *c* from pus; *d* from flesh of poultry; *e* from the flesh of fish.

From these and other analyses, Liebig deduces the formula $C^{216}H^{339}N^{54}S^{3}O^{68}$: Mulder, $C^{[illegible]}H^{[illegible]}N^{[illegible]}SO^{[illegible]}$: Lieberkühn, $C^{72}H^{112}N^{18}SO^{22}$. Each of these formulæ gives numbers agreeing nearly with the analytical results. Mulder regards albumin as a compound of (hypothetical) protein with (hypothetical) sulphamide, viz.:

$$C^{90}H^{139}N^{22}SO^{30} = \underbrace{5C^{18}H^{27}N^{4}O^{6}}_{\text{Protein.}} + \underbrace{N^{2}H^{4}S}_{\text{Sulphamide.}}$$

Liebig's formula is intended merely to express in a simple form certain relations between albumin and other animal substances. Lieberkühn, on the other hand, regards his formula as actually expressing the composition of the molecule of albumin as it exists in the metallic albuminates (*q. v.*)

According to Lebonte and Goumoens (J. Pharm. [3] xxiv. 17) albumin is not a pure proximate element, but a mixture of two bodies, one of which is insoluble in glacial acetic acid, while the other dissolves in that acid and is precipitated therefrom by potash.

The properties of albumin vary in some degree with the source from which it is derived. The differences may in some cases be attributed to the presence of different mineral substances; but in others they are of such a nature as rather to point to the existence of different modifications of albumin. Thus, Frémy and Valenciennes have found (Ann. Ch. Phys. [3] l. 138) that the albumin of the eggs of certain tribes of birds exhibits peculiar modifications. That from the eggs of different species of gallinaceous birds always exhibits the characters above described; but the eggs of swimming and wading birds yield an albumin which, when diluted with 3 measures of water, is not coagulated by heat, but is precipitated by nitric acid; and the albumin from the eggs of predaceous birds, and of some kinds of perching and climbing birds is neither coagulated by heat nor precipitated by nitric acid. The composition was, however, found to be the same in all cases.

Blood-albumin exhibits the same reactions as that from white of egg, excepting that the latter when boiled gives up part of its sulphur in the form of sulphuretted hydrogen, which blood-albumin does not; nevertheless coagulated white of egg appears to contain more sulphur than blood-albumin.

Paralbumin. — Scherer found in a liquid obtained from a case of ovarian dropsy, a substance resembling albumin, but differing from it in not being completely precipitated by ebullition, even after addition of acetic acid, and in dissolving in water after being precipitated by alcohol. *Metalbumin* is the name given by the same chemist to another supposed modification of albumin, likewise obtained from a pathological fluid, which exhibited similar peculiarities to the preceding, and was further distinguished by giving no precipitate with hydrochloric acid, or with ferrocyanide of potassium after acidulation with acetic acid.

Other substances more or less resembling albumin are: *globulin* or *crystallin* existing in blood-globules and in the crystalline lens of the eye; *hæmatocrystallin*, a crystalline body obtained from blood, and *vitellin*, existing in the yolk of eggs (see these substances).

Quantitative Estimation of Albumin. — The best mode of precipitating albumin from alkaline liquids (serum, for example), for quantitative estimation, is to neutralise or slightly acidulate the liquid with acetic acid, and then coagulate the albumin by boiling. The precipitate thus obtained is flocculent and may be easily collected on a filter and washed, the liquid passing through perfectly clear, whereas if the albumin be coagulated by heat alone, it is very apt to clog the filter. Another reason for using the acetic acid is, that mere boiling does not precipitate the albumin completely from alkaline solutions. The precipitated albumin, after being thoroughly washed, may be dried in vacuo over sulphuric acid or in a current of warm air.

Uses of Albumin.— Albumin is much used for clarifying vinous and syrupy liquids, inasmuch as, when boiled with them, it coagulates, and takes hold of the colouring matter and other impurities, thereby removing them, and carrying them to the bottom or to the surface of the liquid, according to its density. In cookery, white of egg is employed for this purpose, but in large operations, such as sugar-refining, the serum of blood is used. Albumin is applied to a considerable extent for fixing colours in calico-printing; it is also used in photography. Its property of forming a hard compound with lime renders it very useful for making cement for laboratory purposes and for mending broken earthenware. A paste made of white of egg and slaked lime, acquires after a while the hardness of stone.

ALBUMINATES. (Lassaigne, Ann. Ch. Phys. [3] lxiv. 90; Lieberkühn, J. Pharm. [3] xxxiii. 398; Lehmann, Physiol. Chem. i. 332; Gerh. iv. 447.) — Albumin is a weak acid, and apparently dibasic. Its compounds with the alkalis are soluble and are obtained directly by treating albumin with caustic alkalis or alkaline carbonates. The other albuminates are insoluble and are obtained by precipitation.

Albuminate of Barium, $C^{72}H^{111}BaN^{18}SO^{22} + H^{2}O$ (?) — A solution of albuminate of potassium in dilute alcohol forms with barium-salts, a precipitate which dries up to a white powder, insoluble in water, alcohol and ether. White of egg mixed with caustic baryta, strontia or lime, forms an insoluble compound, which becomes very hard when dry.

Albuminate of Copper, $C^{72}H^{110}Cu^2N^{18}SO^{22} + H^2O$ (?) — Obtained in like manner forms when dry, a green, brittle mass, insoluble in water and alcohol. Acids decolorise, but do not dissolve it (Lieberkühn). According to Lassaigne, double albuminates of copper with potassium, or barium, or calcium, may be obtained by heating hydrate of copper with solution of albumin and solution of potash, baryta or lime. There is also an albuminate of copper and magnesium which is insoluble and has a lilac colour.

Albuminate of Lead is a white insoluble salt, obtained by mixing the solution of albumin and subacetate of lead; it is soluble in excess of the lead-salt, and is decomposed by all acids.

Mercuric Albuminate is a white substance obtained by precipitating corrosive sublimate with albuminate of sodium (white of egg). It is insoluble in pure water, but soluble in saline liquids; for this reason, when white of egg is used as an antidote in cases of poisoning by corrosive sublimate, endeavours should always be made to produce vomiting; otherwise a portion of the mercuric albuminate may remain dissolved in the gastric juice, which contains chloride of sodium.

Albuminate of Potassium, $C^{72}H^{110}K^2N^{18}SO^{22} + H^2O$. — Prepared by mixing a concentrated solution of white of egg with strong potash-ley, and washing the resulting gelatinous mass with cold water, as long as any alkali dissolves out, then dissolving the residue in boiling alcohol, and precipitating by ether. After drying, it is no longer soluble in boiling alcohol or in water. The aqueous solution is not coagulated by boiling or by addition of alcohol. With a small quantity of acetic, tartaric, citric or phosphoric acid, it yields an abundant white precipitate easily soluble in excess of acid. These characters are the same as those of casein; hence, Gerhardt considers it probable that casein may be really albuminate of potassium.

Albuminate of Sodium is contained in blood-serum and in white of egg, together with chloride of sodium and phosphate of calcium. Serum and white of egg have a slight alkaline reaction, are more soluble in water than pure albumin, and when boiled, coagulate in a gelatinous mass, not in flakes. After boiling, the filtered liquid is more alkaline than before, and still contains albuminate of sodium, whereas the coagulum is free from alkali. Hence, Gerhardt thinks it probable that serum and white of egg contain an acid albuminate of sodium, $C^{72}H^{111}NaN^{18}SO^{22}$, which is decomposed by heat into the neutral albuminate, and free albumin which separates from the liquid. This view is, moreover, in accordance with the composition of dried white of egg, which, according to Lehmann's analysis, contains 1·6 per cent. of soda, the formula $C^{72}H^{111}NaN^{18}SO^{22} + H^2O$ requiring 1·8 per cent. White of egg or serum treated with strong caustic soda, yields a gelatinous mass nearly insoluble in cold water, and closely resembling the compound produced under the same circumstances by potash. This gelatinous salt appears to be the neutral *albuminate of sodium*, $C^{72}H^{110}Na^2N^{18}SO^{22} + H^2O$. It contains, according to Lehmann, 3·14 per cent. soda (by calculation 3·7).

Albuminate of Silver, $C^{72}H^{110}Ag^2N^{18}SO^{22} + H^2O$ (?) — Obtained by precipitation. White, flocculent, blackens when exposed to light.

Albuminate of Zinc, $C^{72}H^{110}Zn^2N^{18}SO^{22} + H^2O$ (?)—White powder insoluble in water, alcohol, and ether.

ALBUMIN, VEGETABLE. (Gerh. iv. 444; Handw. d. Chem 2te Aufl. ii. 147.) — Most vegetable juices contain a substance which appears to be identical in composition and properties with the albumin of blood or of white of egg. The same compound appears also to exist in the solid form in certain parts of plants, especially in the seed. Vegetable juices containing albumin deposit it, when heated to 65° or 70°, in flocks, which are often coloured greenish by chlorophyll, and contain fatty and waxy substances mechanically enclosed. To remove these matters, the coagulum must be washed, first with water, then with boiling alcohol and with ether.

Albumin is especially abundant in the juice of carrots, turnips, cabbages, and the green stems of peas, but it is more easily prepared from potatoes, by cutting them into slices, covering them with very dilute sulphuric acid (of 2 p.c.), leaving the liquid to itself for 24 hours, then adding fresh potatoes, and repeating the same operation once more, afterwards neutralising the solution with potash, and boiling. A considerable quantity of albumin is then deposited in thick white flocks.

Wheat-flour also contains a considerable quantity of albumin, which may be extracted with cold water. For this purpose, the water which runs off in washing the paste of wheat-flour for the preparation of gluten (*q. v.*) is left at rest till the starch is completely deposited; the clear liquid is then heated to the boiling point, whereupon it deposits a small quantity of albumin; on evaporating the solution a larger quantity is obtained.

Oleaginous seeds likewise contain albumin, which may be extracted by beating the seeds with water into an emulsion, extracting the fat by agitation with ether, and the albumin by boiling.

When sweet almonds which have been freed from their envelopes are reduced to a pulp by rasping, and the pulp is digested for a few minutes in boiling water, the sugar, gum, and the greater part of the legumin contained in the almonds enter into solution; and on depriving the residue of fatty matter by means of ether, nothing is left but coagulated albumin, exhibiting the same characters as coagulated white of egg.

a, albumin from rye, analysed by Jones (Ann. Ch. Pharm. xl. 66); *b*, from wheat-flour, by Dumas and Cahours (Ann. Ch. Phys. [3] vi. 309); *c*, from wheat-flour by Boussingault (ibid. [2] lxiii. 225); *d*, from potatoes by Rüling (Ann. Ch. Pharm. lviii. 306); *e*, from peas by Rüling; *f*, *g*, from rye, by Mulder.

Vegetable albumin is distinguished from legumin (vegetable casein) by being coagulated by heat, and not precipitated by acetic acid. It exhibits the same reactions as animal albumin with acids, alkalis, tannin, chloride of mercury, &c. The mode of its occurrence differs, however, remarkably from that of animal albumin in this respect, that it is always found in plants in neutral or acid liquids, whereas animal albumin exists only in alkaline liquids (p. 25).

The albumin of sweet almonds is remarkable for the facility with which it decomposes, and by its property of acting as a ferment, and determining the metamorphosis of amygdalin, salicin, and other organic bodies. This altered albumin is distinguished by the terms *emulsion* and *synaptase* (*q. v.*)

The *myrosin* of mustard-seeds likewise resembles vegetable albumin. Lastly, the *diastase* of germinated barley, *beer-yeast*, and *wine-lees* are likewise albuminoïdal substances in a state of alteration.

ALBUMININ. *Oonin.* (Handw. d. Chem. 2^{te} Aufl. i. 404.)—The name given by Couerbe to the substance of the cells which enclose the white of birds' eggs. It is obtained by exposing white of egg for a month to temperature between 0° and—8°, in the form of a white filmy substance, which when dried is white, translucent in thin laminæ and easily friable. It does not contain nitrogen, and consequently does not evolve ammonia when heated. It is insoluble in water, whether hot or cold, but swells up in hot water, forming a gummy mass. It is not acted upon by alcohol, ether, or acetic acid. Nitric and sulphuric acids decompose it. It dissolves in hydrochloric acid, and on adding water to the solution, a white powder is precipitated. It dissolves in caustic potash, forming a solution which is rendered turbid by acids, but not precipitated.

ALBUMINOÏDS. *Protein-compounds. Blutbilder.* (Gerh. iv. 430; Handw. d. Chem. 2^{te} Aufl. ii. 120.) — This term is applied to a class of compounds which play an important part in the functions of animal and vegetable life. Three of them, *albumin*, *casein*, and *fibrin* are distinguished by well-marked characters.

Fibrin separates spontaneously in the solid form from blood, soon after its removal from the living body; albumin is contained in the serum or more liquid portion of the blood, and separates from it as a coagulum on the application of heat; and casein is contained in milk, from which it may be separated, not by heat, but by the addition of an acid. The same substances are found in plants, viz. fibrin, in the grain of wheat and other cereal plants; albumin in most vegetable juices, and casein (or legumin) in the seeds of the pea, bean and other leguminous plants.

The other bodies of this class are less distinctly characterised; indeed, most of them appear to be mere modifications of the one or other three above-mentioned: thus, *syntonin*, the essential constituent of the muscular fibre, closely resembles blood-fibrin; *vitellin*, a substance occurring in the yolk of eggs, is scarcely distinguishable from albumin; and *globulin* and *hæmatocrystallin*, two substances contained in the blood, resemble albumin in the property of coagulating by heat.

Moreover, albumin, fibrin, and casein, though clearly distinguished from one another by the different conditions under which they pass from the liquid to the solid state, nevertheless possess many characters in common. They all dissolve in caustic potash or soda, and when boiled with those alkalis, yield solutions from which acids precipitate them in a more or less altered state, and at the same time eliminate hydrosulphuric acid. When subjected to dry distillation, they all give off ammonia (or compound ammonias). They all decompose and putrefy with great facility when exposed to moist air, and in that form are very active as *ferments;* thus, yeast, wine-lees, diastase, &c., are merely albuminoïdal substances in a peculiar state of decomposition.

All albuminoïds treated with oxidising agents, such as mixtures of peroxide of manganese or acid chromate of potassium and sulphuric acid, yield the same products, viz. acids and aldehydes of the acetic and benzoic series (see ALBUMIN, p. 67).—Albuminoïds dissolve in very strong hydrochloric acid, forming a solution which is yellow if kept from contact with the air, but assumes a fine blue or violet colour on exposure to the air.—A solution of mercury in an equal weight of nitric acid imparts to these bodies a very deep red colour, this test serving to detect the presence of 1 part of albumin in 100,000 parts of water.

All the albuminoïds exhibit the same or nearly the same constitution. In the living organism, albumin, fibrin, and casein are constantly being converted one into the other. The casein of milk supplies the material for the formation of albumin and fibrin; and conversely, albumin and fibrin are converted into casein. Indeed, the analyses of different bodies of the class do not differ from one another more than analyses of the same body from different sources or by different experimenters. They contain 50 to 54 p. c. carbon, about 7 p. c. hydrogen, 15 to 17 p.c. nitrogen, about 25 p. c. oxygen, and from 0·9 to 1·8 sulphur. According to some analyses, however, fibrin contains rather less carbon and more nitrogen than albumin. Albumin and fibrin have been supposed by some chemists to contain also a small quantity of phosphorus as an organic constituent, but its existence is not well established. Most albuminoids are associated with small quantities of mineral substances, including phosphate of calcium, which cannot be separated from the organic matter by acids.

This great similarity of composition and properties exhibited by these bodies has led to various views of the relation between them. Mulder supposed that all the albuminoïds contain the same organic group, $C^{18}H^{27}N^{4}O^{6}$, which he called *protein,* combined with different quantities of sulphur and phosphorus, and that the conversion of one of these bodies into the other depends upon the assumption or elimination of small quantities of one or both of those elements (see PROTEIN). Mulder also stated, that when an albuminoïd is treated with caustic alkali, the sulphur and phosphorus are removed and the protein remains. The researches of other chemists have shown, however, that this view is untenable. Neither of the albuminoïds contains phosphorus, and the proportion of sulphur appears to be the same in them all: at all events, fibrin and egg-albumin, which perhaps exhibit the greatest difference of physical and chemical properties, do not differ perceptibly in amount of sulphur. Moreover, the sulphur of albuminoïds cannot be completely extracted by the action of alkalis, so that the existence of the so-called protein is merely hypothetical.

Gerhardt was of opinion that all the albuminoïds are identical, not only in composition, but in chemical constitution, and that they differ from one another only in molecular arrangement, and by the nature of the mineral substances with which they are associated; in fact, that they contain a common proximate element which, like many other organic compounds, is capable of existing in a soluble and in an insoluble modification. Designating this common element by the name albumin, he supposed that white of egg and serum consist of acid albuminate of sodium (p. 99), which is separated by heat into free albumin and neutral albuminate of sodium, the latter remaining dissolved; that casein, which is soluble and non-coagulated by heat, consists of neutral albuminate of potassium, from which the organic compound may be precipitated by neutralising the alkali with an acid; and that fibrin is albumin in the insoluble state, more or less mixed with earthy phosphates. This view is in accordance with the fact that fibrin and casein may be dissolved in neutral potassium-salts (better with addition of a little caustic alkali), forming a liquid which coagulates by heat, and deflects the plane of polarisation of a luminous ray to the left, like albumin; and that fibrin and albumin, dissolved in a certain quantity of caustic alkali, exhibit the characters of soluble casein. Nevertheless, it is possible to obtain the albuminoïds in some cases wholly, in others very nearly, free from mineral matters, and nevertheless exhibiting their distinguishing characteristics. Moreover, it is certain that all these bodies contain the same proportions of carbon, nitrogen, and sulphur.

Strecker (Handw. d. Chem. 2te Aufl. ii. 124) supposes the albuminoïds to be composed of a great number of radicles (a supposition in accordance with the variety of their products of decomposition); that the greater number of these radicles are the same in all — hence their great similarity, — but that each contains one or more such radicles peculiar to itself. Thus, when casein is converted in the animal body into albumin and fibrin, it may take the radicles required for that transformation from the other constituents of the milk, viz. the fat and the sugar. (See Albumin, Blood, Casein, Crystalline, Fibrin, Globulin, Hæmatocrystallin, Legumin, Milk, Vitellin.)

ALBUMINOSE. This term is applied by Bouchardat to a product of the decomposition of animal fibrin by very dilute hydrochloric acid (see Fibrin), and by Mialhe, to a peculiar substance into which he supposes albumin to be converted by the action of the gastric juice before it is assimilated.

ALCARRAZAS. Very porous vessels of slightly burnt clay used in hot climates for cooling water and other liquids. The liquid oozes through the pores and stands on the outside of the vessel in a sort of dew, which rapidly evaporates, especially if the vessel is exposed to a current of air, and thereby cools the liquid.

ALCHEMILLA VULGARIS. 100 pts. of the fresh plant contain, according to Sprengel: 76·0 pts. water, 10·3 pts. extractable by water, and 7·8 by dilute potash-ley; 5·6 woody fibre and 1·66 ash free from carbonic acid. The ash contained in 100 pts.; 30·5 potash, 2·4 soda, 33·6 lime, 4·9 magnesia, 0·9 alumina, 14·4 silica, 4·4 sulphuric anhydride, 5·4 phosphoric anhydride, 3·5 chlorine, and traces of the oxides of iron and manganese.

ALCOHOL. $C^2H^6O = C^2H^5.H.O$ [or $C^4H^6O^2 = C^4H^5O.HO.$]. This compound, which is the spirituous or intoxicating principle of wine, beer, and other fermented liquors, may be regarded as the hydrate or hydrated oxide of ethyl, or as a molecule of water, HHO, in which half the hydrogen is replaced by the radicle *ethyl*, C^2H^5. It has also been regarded as a compound of ethylene and water, $C^2H^4.H^2O$.

History.— Intoxicating drinks produced by fermentation of vegetable juices containing sugar, have been known from the earliest times; but it was not till the twelfth century that the method of obtaining pure spirit of wine or hydrated alcohol from these liquids by distillation, was discovered by Abucasis; and the dehydration of this liquid was first partially effected by means of carbonate of potassium by Raimond Lullius in the thirteenth century. The mode of obtaining perfectly anhydrous alcohol was afterwards discovered by Lowitz.

Formation.—1. By the decomposition of glucose (grape-sugar) under the influence of ferments, that is to say, of nitrogenous organic substances, such as yeast, which are themselves undergoing decomposition. The sugar is then resolved into alcohol and carbonic anhydride:

$$C^6H^{12}O^6 = 2C^2H^6O + 2CO^2.$$

Other kinds of sugar, cane-sugar for example, as well as starch, woody fibre and other vegetable substances, also yield alcohol under the influence of ferments, but they are first converted into glucose.

2. From ethylene or olefiant gas, by addition of the elements of water:

$$C^2H^4 + H^2O = C^2H^6O.$$

Olefiant gas briskly agitated for a long time with strong sulphuric acid, is absorbed, and on diluting the liquid with water and distilling, alcohol passes over. This mode of formation, first observed by Hennel (Phil. Trans. 1826, p. 240), has lately been confirmed and fully examined by Berthelot (Ann. Ch. Phys. [3] xliii. 385). As olefiant gas can be obtained from inorganic materials, it follows that alcohol may be produced without the agency of living organisms.

Preparation. 1. *Of Hydrated or Aqueous Alcohol.*—When wine and other liquids which have undergone the vinous fermentation are distilled, alcohol passes over together with a considerable quantity of water; and by subjecting the product to repeated distillations, spirit is obtained continually richer in alcohol, because the alcohol, being more volatile than the water, passes over in larger quantity than the latter. But it is not possible to remove the whole of the water by simple distillation. The residue of the distillation, if continued long enough, is nothing but water containing small quantities of acetic acid (produced by oxidation of the alcohol) and fusel oil. Portions of these impurities also pass into the rectified spirit. The greater part of the acetic acid however, and a considerable portion of the fusel oil are left in the residues of the several distillations. The last portion of the acid is easily removed by distillation over a small quantity of carbonate of potassium or wood-ashes: and the fusel oil, which adheres more obstinately, and imparts a very unpleasant odour to the spirit, is best removed by adding to the spirit about 0·7 of its weight of coarsely powdered charcoal, leaving the mixture to stand for several days, and stirring it repeatedly, then decanting and distilling. Bone-black or blood-charcoal may also be used.

2. *Of Anhydrous or Absolute Alcohol.*—Alcohol cannot be completely dehydrated by distillation, because, at the boiling-point of pure alcohol (78° C.), the vapour of water possesses a considerable tension. The most highly rectified spirit obtained by frac-

tional distillation, still retains about 9 per cent. of water. The last portions of water must be removed by the agency of some substance which has a powerful attraction for it. Carbonate of potassium, chloride of calcium, and quick lime, are the substances most commonly used for this purpose, more rarely acetate of potassium, sulphate of copper, and other salts.

a. By *Carbonate of Potassium.*—Highly rectified spirit is shaken up with ignited carbonate of potassium, which forms a watery or pasty layer at the bottom. The alcohol, whose density is thereby lowered to 0·815, is poured off into a distilling vessel containing twice the quantity of pulverised and recently ignited carbonate of potassium, left to stand for 24 hours, and then two-thirds of it are distilled off (Lowitz). This method does not however remove the last minute portions of water.—*b.* A more complete dehydration is effected by *chloride of calcium.* The salt fused or dehydrated by a heat of 400° C. is added in thick lumps to twice its weight of spirit containing 90 per cent. of real alcohol; and the mixture left for some days in a closed vessel and occasionally shaken up, after which it is distilled in a retort over a fresh quantity of fused chloride of calcium. The retort is heated in a sand or oil bath with its neck directed upwards to prevent the contents from spirting over. When the quantity of alcohol is large, a second treatment with chloride of calcium is necessary to effect complete dehydration.

c. By *Quick lime.*—A retort is two-thirds filled with small pieces of quick lime, and a quantity of 90 per cent. spirit poured in sufficient to nearly cover the lime. The lime soon slakes and becomes heated; the mixture is left to digest for some hours; and the anhydrous alcohol is then distilled off in the water-bath. The distillation must be carefully conducted, otherwise the distillate will be contaminated with lime. Alcohol containing fusel oil acquires a very unpleasant odour when treated with lime. This is by far the easiest method of obtaining absolute alcohol.

d. When aqueous alcohol is enclosed in a bladder, and exposed to warm air, the water gradually percolates through the bladder and evaporates, and absolute alcohol is left inside. (Sömmering.)

Alcohol may be regarded as anhydrous if sulphate of copper previously burnt white does not acquire any blue colour when immersed in the alcohol in a close vessel (Cassoria), or if it forms a perfectly clear mixture with benzol (Görgeu). It is doubtful however whether either of these tests will indicate the presence of a very minute quantity of water.

Properties.—Alcohol is a transparent, colourless, very mobile liquid, having a strong refracting power. Its specific gravity, according to Kopp (Pogg. Ann. lxxii. 1), is 0·792 at 20°; or 0·7939 at 15·5°, or 0·8095 at 0°. If its volume at 0° C. be taken for unity, the volume at any temperature t° is given by the formula:

$$v = 1 + 0{\cdot}001041139t + 0{\cdot}0000007836t^2 + 0{\cdot}000000017618t^3.$$

and therefore for the temperatures:

0° C.	5° C.	10° C.	15° C.	20° C.	25° C.	30° C.
1·00000	1·00523	1·01052	1·01585	1·02128	1·02680	1·03242

the volumes of a given quantity of alcohol are as the numbers (second row above).

Alcohol has never been reduced to the solid state, but becomes viscid at very low temperatures, as when it is surrounded with a mixture of solid carbonic acid and ether under an exhausted receiver. It boils at 78·4° C. (173·1° Fah.) when the barometer stands at 0·76 met. (Gay-Lussac, Kopp.) Vapour-density = 1·613 (Gay-Lussac); by calculation, for a condensation to 2 volumes, it is 1·591 when referred to air as unity, and 23 when referred to hydrogen as unity $\left(\frac{2 \times 12 + 6 \times 1 + 16}{2} = 23.\right)$ Alcohol has an enlivening odour and a burning taste, and when unmixed with water exerts a poisonous action. It is a very slow conductor of electricity.

Decompositions. 1. *By Heat.*—Alcohol-vapour passed through a red-hot glass or porcelain tube yields carbonic anhydride, water, hydrogen, marsh-gas, olefiant gas, naphthalin, empyreumatic oil and a deposit of charcoal. If the tube be filled with fragments of pumice-stone, the solid and liquid products consist of nalphthalin, benzol, hydrate of phenyl, acetic acid (?) and aldehyde, together with a number of solid compounds of not very definite character, some of them smelling like musk, others like garlic (Berthelot, Ann. Ch. Phys. [3] xxxiii. 285). Alcohol-vapour does not undergo decomposition at 300° C. in a tube containing fragments of porcelain, but gives off gas even at 220°, if the tube contains spongy platinum. (Reiset and Millon, Ann. Ch. Phys. [3] viii. 280.)

2. *By Electricity.*—Absolute alcohol scarcely conducts the voltaic current, but when potash or potassium is dissolved in it, decomposition takes place, hydrogen being

evolved at the negative pole and aldehyde-resin formed at the positive pole. (Connell.)

3. *By Oxygen.* — Alcohol is very inflammable, and burns in the air with a dull blue flame, yielding water and carbonic acid. It does not readily deposit soot, even when the supply of air is limited, but absolute alcohol deposits it more readily than ordinary spirit. Alcohol-vapour mixed with air explodes by contact with flame or by the electric spark.

Imperfect Combustion. — When alcohol or its vapour comes in contact with air, and at the same time with platinum or certain other metals, an imperfect oxidation of the alcohol takes place, the metal being generally heated to redness, and the alcohol being converted, partly into carbonic acid and water, partly into aldehyde, acetic acid, formic acid, acetal, and a peculiar compound having an excessively pungent odour. Some metals excite this action at ordinary temperatures, others only when more or less heated; but in all cases the action is more powerful as the metal is more finely divided and consequently exposes a larger surface to the alcohol-vapour. The most powerful action is exerted by *platinum black.* When this substance is shaken on paper moistened with alcohol, it makes a hissing noise and becomes red-hot, sometimes setting fire to the alcohol, or else continuing to glow, and inducing the slow combustion above mentioned. If the platinum be previously moistened with a small quantity of water, or at once covered completely with alcohol, the ignition is prevented, and the slow combustion induced with greater certainty. If a number of watch-glasses containing moist platinum black, be placed above a dish containing alcohol, and a bell jar open at top inverted over them, the alcohol turns sour in a few weeks, and is found to contain aldehyde, acetal, acetic acid, and acetic ether.

This action of platinum black affords an excellent means of discovering the presence of alcohol in the air or in watery liquids. The liquid, neutralised, if necessary, with alkali, to prevent the escape of volatile acids, is introduced into a retort, into the neck of which, and near the bulb, is thrust a little boat containing platinum black, and on each side of this boat is placed a piece of litmus paper, in contact with the platinum. The retort is then gently heated in the water-bath, when, if alcohol is present, its vapour will be converted into acetic acid by contact with the platinum black and the paper will be reddened (Buchheim). [Other volatile organic liquids might exert a similar action.]

Spongy platinum and clean platinum wire act in a similar manner to platinum black, but not so quickly. If a coil of platinum wire be placed round the wick of a spirit-lamp, the alcohol set on fire till the wire becomes red-hot, and the flame then blown out, the wire will continue to glow and the alcohol-vapour to burn slowly, producing acetic acid, aldehyde, &c. The same effect is produced by a ball of spongy platinum. This is the *lamp without flame*, or *glow lamp* of Sir H. Davy.

4. *By Chlorine.* — Chlorine gas is rapidly absorbed by alcohol, imparting to it a yellow colour and causing considerable rise of temperature, which, if the liquid is exposed to light, may even cause it to take fire. At the same time it rapidly abstracts hydrogen, which is partly replaced by chlorine, thereby producing hydrochloric acid, aldehyde, acetal, acetic acid, acetate of ethyl, chloride of ethyl, and finally chloral. The mixture of these substances, freed by washing with water from the soluble constituents, was formerly called *heavy hydrochloric ether.* The formation of these several products is represented by the following equations:

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + 2\,Cl = \underbrace{C^2H^4O}_{\text{Aldehyde.}} + 2\,HCl$$

$$\underbrace{C^2H^4O}_{\text{Aldehyde.}} + 6\,Cl = \underbrace{C^2HCl^3O}_{\text{Chloral.}} + 3\,HCl$$

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + HCl = \underbrace{C^2H^5Cl}_{\substack{\text{Chloride of}\\ \text{ethyl.}}} + H^2O$$

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + H^2O + 4\,Cl = \underbrace{C^2H^4O^2}_{\text{Acetic acid.}} + 4HCl$$

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + \underbrace{C^2H^4O^2}_{\text{Acetic acid.}} = \underbrace{C^2H^3O^2.C^2H^5}_{\text{Acetate of ethyl.}} + H^2O$$

Acetate of ethyl may also be formed by the direct action of chlorine on the alcohol; thus:

$$2\,C^2H^6O + 4Cl = C^2H^3O^2.C^2H^5 + 4\,HCl$$

The acetal, which is probably formed at the beginning of the process, according to the equation:

$$3C^2H^6O + 2\,Cl = C^6H^{14}O^2 + H^2O + 2HCl,$$

is for the most part subsequently converted into acetic acid:

$$C^6H^{14}O^2 + 4H^2O + 10Cl = 3C^2H^4O^2 + 10HCl.$$

When the action of the chlorine is continued for a long time, chloral is always the principal product.

Chlorine in presence of alkalis, converts alcohol into chloroform and carbonic anhydride:

$$C^2H^6O + 8Cl + O = CHCl^3 + 5HCl + CO^2.$$

The same products are formed by distilling dilute alcohol with hypochlorite of calcium (chloride of lime, bleaching powder). (See CHLOROFORM.)

Bromine acts upon alcohol in a similar manner to chlorine, producing bromal, hydrobromic acid, bromide of ethyl, bromide of carbon, formic acid, and other products not yet thoroughly examined. *Iodine* is at first dissolved by alcohol without decomposition, and forms a brown solution; but after a while, hydriodic acid is produced, and acting upon a portion of the alcohol, forms iodide of ethyl. An alcoholic solution of potash treated with iodine yields iodoform and iodide of potassium, the former of which compounds may be separated by water.

9. *Chloric acid*, in the concentrated state, sets fire to alcohol; when diluted, it forms acetic acid, the action being sometimes attended with evolution of chlorine. *Perchloric acid* mixes with alcohol without decomposition at ordinary temperatures, but the liquid when heated first gives off alcohol, then ether, and ultimately white vapours smelling like oil of wine, the residue at the same time turning black.

10. *Strong Nitric acid* decomposes alcohol, with great evolution of heat and brisk ebullition, a mixture of various elastic fluids, the *ethereal nitrous gas* of the older chemists, being evolved and an acid liquid remaining behind; if the nitric acid is dilute, the action does not take place without application of heat. Part of the nitric acid unites directly with the alcohol, forming nitrate of ethyl, but the greater part is reduced to nitrous acid which then forms nitrite of ethyl (nitrous ether) with a portion of the alcohol, while the remainder of the alcohol is oxidised and converted into aldehyde, acetic acid, formic acid, saccharic acid, oxalic acid, glyoxal, glyoxylic acid, and glycollic acid, together with water and carbonic anhydride, which escapes as gas, together with nitric oxide and the vapours of the more volatile among the compounds just mentioned. The formation of glyoxal, glyoxylic acid, and glycollic acids is represented by the equations:

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + 3O = \underbrace{C^2H^2O^2}_{\text{Glyoxal.}} + 2H^2O$$

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + 3O = \underbrace{C^2H^4O^3}_{\text{Glycollic acid.}} + H^2O$$

$$\underbrace{C^2H^2O^2}_{\text{Glyoxal.}} + O + H^2O = \underbrace{C^2H^4O^4}_{\text{Glyoxylic acid.}}$$

If urea be added to the mixture of nitric acid and alcohol so as to decompose the nitrous acid as fast as it is formed (see UREA), the chief product of the action is nitrate of ethyl $NO^3.C^2H^5$. Hydrocyanic acid has also been observed among the products of the action of nitric acid upon alcohol.

When strong alcohol is heated with red fuming nitric acid (containing nitrous acid) and nitrate of silver or mercuric nitrate is added, white fumes are given off, containing aldehyde and other oxidised products, and a crystalline deposit of fulminate of silver or mercury is formed, its production being due to the action of the nitrous acid on the alcohol: *e.g.*

$$\underbrace{C^2H^6O}_{\text{Alcohol.}} + 2\,\underbrace{NO^2Hg}_{\text{Mercuric nitrite.}} = \underbrace{C^2N^2Hg^2O^2}_{\text{Fulminate of mercury.}} + 3\,H^2O$$

But when a solution of mercury in nitric acid free from nitrous acid is added at a temperature below 100° C. to alcohol of sp. gr. 0.844, no action takes place at first; but on raising the temperature to 100°, a white crystalline precipitate is formed, which is a compound of mercuric nitrate with a nitrate of ethyl in which the whole of the hydrogen is replaced by mercury (Sobrero and Selmi; Gerhardt):

$$2\,NO^3H + 3\,Hg^2O + C^2H^6O = \underbrace{NO^3Hg.NO^3(C^2Hg^5) + H^2O}_{\text{Crystalline compound.}} + 3\,H^2O$$

11. *Sulphuric acid* forms with alcohol, a number of products varying in quantity according to the proportions in which the two liquids are mixed, their degree of concentration, and the temperature to which the mixture is exposed.

Strong sulphuric acid mixes with alcohol, producing considerable evolution of heat, and forms ethyl-sulphuric or sulphovinic acid, the acid being at the same time brought to a greater state of dilution:

$$\underbrace{C^2H^5.H.O}_{\text{Alcohol.}} + SO^4.H^2 = \underbrace{SO^4.H.C^2H^5}_{\text{Ethyl-sulphuric acid.}} + H^2O$$

When the strongest sulphuric acid (sp. gr. 1·825) is digested for some time at a gentle heat, with excess of absolute alcohol, more than half the sulphuric acid is converted into ethyl-sulphuric acid. If the acid or the alcohol is diluted with water, a considerable quantity of the sulphuric acid remains unaltered. Sulphuric acid containing 1 at. water ($SO^4H^2.H^2O$) forms ethyl-sulphuric acid only when heated. As the formation of ethyl-sulphuric acid is necessarily accompanied by that of water, a certain portion of the sulphuric acid must always remain unconverted into ethyl-sulphuric acid.

Formation of Ether.—A mixture of 1 pt. alcohol, and from 1 to 2 pts. strong sulphuric acid heated in a distillatory apparatus, boils between 120° and 140° C., at first giving off ether, together with more or less undecomposed alcohol, then at 140° scarcely anything but ether, at 160° ether and water,—and at length when, in consequence of the decomposition of the alcohol, the proportion of sulphuric acid has become excessive, and the temperature rises above 160°, the mixture blackens and gives off olefiant gas together with sulphurous acid and other products hereafter to be mentioned. If however the alcohol be allowed to flow constantly into the vessel in a thin stream, so as to maintain the proportion of 5 pts. alcohol to 9 pts. sulphuric acid, the temperature remains constant at about 140°, no sulphurous acid or olefiant gas is formed, but the alcohol, as fast as it is supplied, is given off again in the form of ether and water.

The alcohol converts a molecule of sulphuric acid into ethyl-sulphuric acid and water, as above:

$$\underbrace{C^2H^5.H.O}_{\text{Alcohol.}} + \underbrace{SO^4.H^2}_{\text{Sulphuric acid.}} = \underbrace{SO^4.C^2H^5.H}_{\text{Ethyl-sulphuric acid.}} + \underbrace{H^2O}_{\text{Water.}}$$

and the ethyl-sulphuric acid coming in contact with another molecule of alcohol, yields ether and sulphuric acid:

$$\underbrace{SO^4.C^2H^5.H}_{\text{Ethyl-sulphuric acid.}} + \underbrace{C^2H^5.H.O}_{\text{Alcohol.}} = \underbrace{(C^2H^5)^2O}_{\text{Ether.}} + \underbrace{SO^4H^2}_{\text{Sulphuric acid.}}.$$

The sulphuric acid thus reproduced acts in like manner upon another molecule of alcohol, and in this way the process continues as long as the supply of alcohol is kept up. Etherification is therefore a continuous process, a given quantity of sulphuric acid being capable of etherifying a very large quantity of alcohol. The water, however does not all pass off as it is formed, so that the sulphuric acid becomes continually though slowly weaker, and consequently a continually larger quantity of alcohol passes over undecomposed with the ether and water.

The explanation just given of the process of etherification is due to Williamson (Chem. Soc. Qu. J. iv. 106, 229). Its correctness is strikingly exhibited by the analogous reaction which takes place between common alcohol and amyl-sulphuric acid. When amyl-alcohol is dissolved in sulphuric acid, amyl-sulphuric acid is produced:

$$C^5H^{11}.H.O + SO^4H^2 = SO^4.C^5H^{11}.H + H^2O.$$

Now, on heating this mixture and passing a stream of ordinary alcohol through it, as above, ethamylic ether, or oxide of ethyl and amyl passes over first, then common ether, and ethyl-sulphuric acid remains behind in place of amyl-sulphuric acid:

$$\underbrace{SO^4.C^5H^{11}.H}_{\text{Amyl-sulphuric acid.}} + \underbrace{C^2H^5.H.O}_{\text{Alcohol.}} = \underbrace{C^2H^5.C^5H^{11}.O}_{\text{Oxide of ethyl and amyl.}} + \underbrace{SO^4H^2}_{\text{Sulphuric acid.}}$$

The sulphuric acid thus reproduced acts upon the ethyl-alcohol in the manner already described, the products being ethyl-sulphuric acid, ether, and water. The same products are obtained by distilling a mixture of ethyl-alcohol and amyl-alcohol with sulphuric acid.

The formation of ether from alcohol was formerly regarded as a simple process of dehydration. Ether being regarded as C^4H^5O and alcohol as its hydrate, $C^4H^5O.HO$, it was supposed that the sulphuric acid simply abstracted the water and left the ether. Against this view, however, it must be alleged that the quantity of water given off in the distillation is very nearly equal to the whole quantity supposed to be separated from the alcohol, which could not be the case if it were retained by the sulphuric acid. Moreover, the molecule of ether referred to the same vapour-volume as that of alcohol,

$C^4H^6O^2$, is not C^4H^5O, but $C^8H^{10}O^2$; or, according to the atomic weights adopted in this work, alcohol being C^2H^6O, ether is $C^4H^{10}O$. For these reasons, Mitscherlich, Berzelius, and other chemists have regarded the action of sulphuric acid upon alcohol as a *contact-action*, or *catalytic action*, a mode of expression which simply states the fact without explaining it.

Another objection to the views just mentioned, is that they take no account of the formation of ethyl-sulphuric acid. That this, however, is an essential step in the process of etherification is shown by the fact that, on distilling a mixture of alcohol and strong sulphuric acid, the quantity of ethyl-sulphuric acid constantly diminishes as the ether passes over, and that, if the acid be diluted so far as not to form ethyl-sulphuric acid, the mixture yields no ether by distillation. Liebig therefore supposed that the ethyl-sulphuric acid is resolved at a certain temperature (120° to 140° C.) into ether, sulphuric acid, and sulphuric anhydride:

$$2(C^2H^5.H.SO^4) = C^4H^{10}O + SO^4H^2 + SO^3$$

and that the sulphuric anhydride, uniting with water also present in the mixture, reproduces sulphuric acid. But ethyl-sulphuric acid when heated alone gives off, not ether but alcohol, even when heated to 140° or above in sealed tubes; but when heated with alcohol, it immediately yields ether. We are therefore led to regard the formation of ether as a result of the mutual decomposition of alcohol and ethyl-sulphuric acid, in the manner already explained.

When alcohol and strong sulphuric acid are heated together in sealed tubes, the alcohol being in excess, a layer of ether forms on the top of the liquid, but no ethyl-sulphuric acid is found in the lower stratum. If the sulphuric acid is in excess, no ether is formed (Graham, Chem. Soc. Qu. J. iii. 24). In the former case, it is probable that ethyl-sulphuric acid was first formed, and afterwards converted by the excess of alcohol into ether and sulphuric acid. Acid sulphate of potassium (Graham) and various other sulphates heated with alcohol in sealed tubes, also etherify it more or less completely, the sulphate being in some cases converted into a basic salt. The alums, namely common alum, ammonia-alum, potassio-ferric sulphate, and potassio-chromic sulphate heated with an equal weight of 98 per cent. alcohol, etherify it completely. In all these cases, the sulphate appears to give up a portion of its sulphuric acid, which then acts on the alcohol as above. (Reynoso, Ann. Ch. Phys. [3] xxviii. 385.)

Formation of Olefiant gas.—When 1 pt. of alcohol is heated with 3 or 4 pts. of strong sulphuric acid, the mixture begins, between 160° and 180° C., to blacken and thicken, swells up considerably and gives off olefiant gas C^2H^4, together with variable quantities of sulphurous anhydride, carbonic anhydride, carbonic oxide, oil of wine, acetic acid, acetic ether and formic acid, and a black residue is ultimately left consisting of a peculiar acid called thiomelanic acid and free sulphuric acid. By passing alcohol-vapour through a boiling mixture of 10 pts. of strong sulphuric acid and 3 pts. of water, olefiant gas and water are obtained, with scarcely any coloration of the mixture or formation of secondary products:

$$C^2H^6O = C^2H^4 + H^2O.$$

12. *Sulphuric anhydride*, SO^3, is dissolved by absolute alcohol, with evolution of heat, and forms neutral sulphate of ethyl $SO^4.(C^2H^5)^2$. When the vapour of the anhydride is passed into absolute alcohol, crystals of sulphate of carbyl, $C^2H^4.2SO^3$, are formed, together with ethionic, isethionic, ethyl-sulphuric and sulphuric acids.

13. *Phosphoric acid* mixed with alcohol at ordinary temperatures, converts part of it into ethyl-phosphoric acid. A mixture of phosphoric acid with a small quantity of alcohol yields olefiant gas but no ether; but if the alcohol is in excess, ether is first given off, then olefiant gas and a thick acid distillate probably consisting of neutral phosphate of ethyl, $PO^4.(C^2H^5)^3$. *Phosphoric anhydride* absorbs the vapour of anhydrous alcohol, forming ethyl-phosphoric acid $PO^4.C^2H^5.H^2$, and diethylphosphoric acid, $PO^4.(C^2H^5)^2.H$. *Arsenic acid* acts very much like phosphoric acid, producing ether and ethyl-arsenic acid. *Boric anhydride* (vitrefied boric acid) in the state of powder heated with absolute alcohol, gives off olefiant gas and leaves boric acid.

14. *Hydrochloric* acid gas is absorbed in large quantity by alcohol, and the solution when heated gives off chloride of ethyl. The same compound is obtained by distilling alcohol with strong hydrochloric acid, or with a mixture of common salt and sulphuric acid; but when a mixture of hydrochloric acid with a large excess of alcohol, either anhydrous or hydrated, is heated to 240° in a sealed tube, ether is formed as well as chloride of ethyl, these two liquids forming a layer on the surface, while the lower stratum consists chiefly of water and hydrochloric acid. The ether results from the action of alcohol on the chloride of ethyl already formed:

$$C^2H^5.Cl + C^2H^5.H.O = (C^2H^5)^2O + HCl.$$

The same transformation takes place, though slowly, even at 100° C. (A. Reynoso, Ann. Ch. Phys. [3] xlviii. 385.)

15. Many *metallic chlorides* act upon alcohol in a similar manner to hydrochloric acid, producing ether and chloride of ethyl. *Chloride of zinc* converts anhydrous alcohol into chloride of ethyl with a small quantity of ether. With hydrated alcohol, it yields at 155°C., ether and oil of wine, the quantity of which increases as the distillation goes on; hydrochloric acid is also given off, and basic chloride of zinc remains. When dichloride of tin is distilled with a considerable quantity of alcohol, ether and chloride of ethyl pass over between 140° and 170°, afterwards a compound of chloride of ethyl with dichloride of tin. (Kuhlmann, Ann. Ch. Pharm. xxxiii. 97, 192.)

Crystallised *protochloride of tin* distilled with alcohol yields ether, but no chloride of ethyl (Marchand); the same decomposition takes place in a sealed tube at 240°. Crystallised *chloride of manganese* and *protochloride of iron* also etherify alcohol completely when heated with it in sealed tubes to 240°; the chlorides of *cadmium, nickel, and cobalt* partially; in all these cases, the etherification takes place without blackening of the contents of the tube, and with little or no escape of gas when it is opened (Reynoso, Ann. Ch. Phys. [2] xlviii. 385). The formation of ether in these reactions may be explained by the following equations, given by Williamson for the case of chloride of zinc:

$$
\begin{aligned}
C^2H^5.H.O &+ ZnCl = C^2H^5.Zn.O + HCl.\\
C^2H^5.H.O &+ HCl = C^2H^5.Cl + H^2O.\\
C^2H^5.Cl &+ C^2H^5.Zn.O = (C^2H^5)^2O + ZnCl.
\end{aligned}
$$

With *sesquichloride of iron*, alcohol yields ether and chloride of ethyl between 130° and 140°C., afterwards hydrochloric acid and water, the residue consisting of sesquichloride of iron mixed with sesquioxide. With *chloride of aluminium*, chloride of ethyl is given off between 170° and 200°, afterwards hydrochloric acid, and alumina is left behind. *Trichloride* and *pentachloride of antimony* convert alcohol into chloride of ethyl, with a little ether, the residue consisting chiefly of oxychloride of antimony.

Protochloride of platinum boiled with alcohol of sp. gr. 0·813 to 0·893 is converted into a black explosive powder called *detonating platinum-deposit*, $C^2H^4Pt^2O$, the liquid acquiring a strong acid reaction and the odour of chloride of ethyl:

$$C^2H^6O + 2PtCl = C^2H^4Pt^2O + 2HCl.$$

The chloride of ethyl is formed by the action of the hydrochloric acid on another portion of the alcohol. (Zeise.)

A solution of 1 pt. of *dichloride of platinum* in 10 pts. of alcohol of sp. gr. 0·823, distilled to $\frac{1}{6}$, yields aldehyde, chloride of ethyl, and hydrochloric acid. The residual dark brown liquid deposits a considerable quantity of the black detonating powder just mentioned, and retains in solution the so-called *inflammable chloride of platinum*, $C^2H^4Pt^2Cl^2$, according to Zeise, or $C^2H^3Pt^2Cl^2$, according to Liebig. Its formation is represented by one of the following equations:

$$2C^2H^6O + 2PtCl^2 = C^2H^4Pt^2Cl^2 + \underbrace{C^2H^4O}_{\text{Aldehyde.}} + H^2O + 2HCl.\ \text{(Zeise.)}$$

$$3C^2H^6O + 4PtCl^2 = 2C^2H^3Pt^2Cl^2 + \underbrace{C^2H^4O}_{\text{Aldehyde.}} + 2H^2O + 4HCl.\ \text{(Liebig.)}$$

The formation of the black deposit is not an essential part of the reaction, and indeed takes place most abundantly when the dichloride of platinum contains protochloride.

Mercuric chloride, HgCl, dissolved in alcohol is slowly reduced to mercurous chloride Hg^2Cl. Potash added in excess to the alcoholic solution heated to 50°C., forms an amorphous yellow precipitate containing carbon, hydrogen, oxygen and mercury, the hydrogen being in smaller proportion than in alcohol. This precipitate heated to 200°, explodes without leaving any residue; heated in the moist state, it decomposes less violently, yielding mercury, water, and acetic acid (Sobrero and Selmi). Gerhardt and Werther did not succeed in preparing this compound.

16. *Trichloride of phosphorus* readily decomposes alcohol, forming chloride of ethyl, hydrochloric acid, tribasic phosphite of ethyl and phosphorous acid. (Béchamp Compt. rend. xl. 944.)

$$6(C^2H^5.H.O) + 2\,PCl^3 = 3C^2H^5Cl + 3\,HCl + PO^3.(C^2H^5)^3 + PO^3.H^3.$$

17. With *pentachloride* of phosphorus, the products are chloride of ethyl, hydrochloric and chlorophosphoric acid, PCl^3O:

$$C^2H^5.H.O + PCl^3.Cl^2 = C^2H^5Cl + HCl + PCl^3.O.$$

18. *Pentasulphide of phosphorus*, on the other hand, converts alcohol, not into two separate sulphides, but into the single compound *mercaptan*, or sulphide of ethyl and hydrogen:

$$5(C^2H^5.H.O) + P^2S^5 = 5(C^2H^5.H.S) + P^2O^5.$$

These last two reactions illustrate in a striking manner, the difference between monatomic and diatomic elements or radicles. In the former, the single atom of oxygen in alcohol is replaced by two atoms of chlorine, one of which unites with the ethyl, and the other with the hydrogen of the alcohol, forming two perfectly distinct chlorides; whereas in the latter, the oxygen of the alcohol is replaced by 1 atom of the diatomic element, sulphur, which being indivisible, binds together the ethyl and hydrogen into one single molecule of mercaptan. (Compare page 11.)

19. The *bromides* and *iodides* of phosphorus, hydrogen, and the metals, act like the chlorides. *Hydrofluoric* acid appears to convert alcohol into fluoride of ethyl.

20. *Potassium* and *sodium* rapidly decompose absolute alcohol, 1 atom of hydrogen being evolved and its place supplied by the metal; the resulting compound is an ethylate of potassium (C^2H^5KO) or ethylate of sodium, which crystallises from the saturated solution. The same compound appears to be formed by dissolving hydrate of potassium or sodium in absolute alcohol:

$$C^2H^5.H.O + KHO = C^2H^5.K.O + H^2O$$

The solution thus obtained exhibits in many cases the same reactions as that which is produced by dissolving the metal in alcohol.

21. Alcohol heated with *hydrate of potassium* (or sodium) yields hydrogen gas and an acetate:

$$C^2H^6O + KHO = C^2H^3KO^2 + 4H.$$

To produce this decomposition, a mixture of equal weights of the alkaline hydrate and pounded quick lime is moistened with alcohol, the excess of alcohol driven off at 100°, and the mixture gently heated without access of air. Hydrogen is then evolved, together with a small quantity of marsh gas, and the residue contains acetate of potassium, which, at a higher temperature, is resolved into marsh gas and carbonate of potassium (p. 17).

22. Alcohol-vapour passed over *anhydrous baryta* heated nearly to redness, yields olefiant gas, marsh gas and hydrogen, with a residue of carbonate of barium.

23. Gaseous *chloride of cyanogen* is readily absorbed by alcohol, but does not decompose it immediately. After a few days however, or more quickly if a little water is present or if the liquid is heated to 80°, chloride of ammonium separates out, while chloride of ethyl, carbamate of ethyl (urethane) and carbonate of ethyl remain in solution. The urethane and carbonate of ethyl are formed in the manner represented by the two following equations:

$$C^2H^6O + CNCl + H^2O = \underbrace{C^3H^7NO^2}_{\text{Urethane.}} + HCl$$

$$2C^2H^6O + CNCl + H^2O = \underbrace{CO^3(C^2H^5)^2}_{\text{Carbonate of ethyl.}} + NH^4Cl$$

The chloride of ethyl results from the action of the hydrochloric acid, produced as in the first equation, on the alcohol. (Wurtz. Ann. Ch. Pharm. lxxix. 77.)

24. Many *organic acids* when heated with alcohol convert it into compound ethers, with elimination of 1, 2, or 3 atoms of water, according as the acid is monobasic dibasic, or tribasic: *e. g.*

$$\underbrace{C^2H^5.H.O}_{\text{Alcohol.}} + \underbrace{C^2H^3O.H.O}_{\text{Acetic acid.}} = \underbrace{C^2H^3O.C^2H^5.O}_{\text{Acetic ether.}} + H^2O$$

$$2\underbrace{(C^2H^5.H.O)}_{\text{Alcohol.}} + \underbrace{CO^2.H^2.O^2}_{\text{Oxalic acid.}} = \underbrace{CO^2(C^2H^5)^2O^2}_{\text{Oxalic ether.}} + 2H^2O$$

$$3\underbrace{(C^2H^5.H.O)}_{\text{Alcohol.}} + \underbrace{C^6H^5O^4.H^3.O^3}_{\text{Citric acid.}} = \underbrace{C^6H^5O^4.(C^2H^5)^3.O^3}_{\text{Citric ether.}} + 3H^2O$$

With some acids, *e. g.* acetic and butyric acids, the transformation is easily effected; with others, as oxalic and hippuric acid, it takes a considerable time: in other cases again, as with benzoic acid, no ether is formed when the acid and the alcohol are merely distilled together; but on passing hydrochloric gas into the alcoholic solution of the acid, the ether is quickly formed. In this case, chloride of ethyl is first formed and afterwards decomposed by the organic acid. Other strong mineral acids, such as sulphuric acid, also facilitate the formation of these compound ethers.

Many polybasic organic acids form acid ethers when digested with alcohol; thus tartaric acid forms ethyl-tartaric acid $C^4H^4O^4(C^2H^5.H)O^2$.

The anhydrides of monobasic acids quickly convert alcohol into the corresponding ethers. (See *Dictionary of Arts, Manufactures, and Mines.*)

Compounds of Alcohol. Alcohol has a very strong affinity for *water*, and mixes with it in all proportions. The mixture is attended with slight evolution of heat, and also with contraction of volume, which gradually increases till the mixture contains 116 pts. water to 100 pts. alcohol. Strong alcohol absorbs moisture from the air. It abstracts water from the moist parts of the animal body, and coagulates them if they are of albuminous nature; hence its use in the preservation of anatomical preparations. From the same cause it destroys life in the veins.

Alcohol dissolves *iodine* and *bromine;* also *sulphur* and *phosphorus* in small quantities. *Gases* for the most part dissolve in alcohol more readily than in water. (See GASES, ABSORPTION OF.) Salts are, generally speaking, less soluble in alcohol than in water; indeed many salts quite insoluble in alcohol are easily soluble in water; *e. g.* the alkaline carbonates and sulphates. Chloride of mercury is, however, an exception to the general rule, being more soluble in alcohol than in water. Inorganic compounds, sparingly soluble in water, are, for the most part, quite insoluble in alcohol; so likewise are efflorescent compounds. But all deliquescent salts, excepting carbonate and phosphate of potassium and a few others, are soluble in alcohol.

Since alcohol does not dissolve all compounds which are soluble in water, it follows that many substances, when dissolved in alcohol, do not exhibit the same reactions towards other substances as when dissolved in water. Thus many acids, when dissolved in absolute alcohol do not redden litmus or decompose carbonate of barium or calcium, probably because the resulting calcium or barium salt would be insoluble in alcohol.

Alcohol readily dissolves *resins, ethers, essential oils, fats, alkaloids,* many *organic acids,* and in general, all substances containing a larger proportion of hydrogen.

ALCOHOLATES. Alcohol unites in definite proportion with several salts, forming crystallisable compounds, which however have but little stability and are almost all decomposed by water. These compounds were first obtained by Graham. (Graham, Phil. Mag. Ann. iv. 265. 331; Einbrodt, Ann. Ch. Pharm. lxv. 115; Chodnew, ibid. lxxi. 241; Lewy, Compt. rend. xxi. 371; Robiquet, J. Pharm. [3] xxvi. 161.)

Nitrate of magnesium dissolved in alcohol forms, on cooling from a boiling hot solution, a crystalline mass like margarin, containing $3C^2H^6O.NO^3Mg$.

Fused *chloride of calcium* dissolves in absolute alcohol, and the solution if surrounded with ice, deposits crystals containing $2C^2H^6O.CaCl$. This compound subjected to dry distillation yields nothing but carburetted hydrogen. If the alcohol contains a small quantity (about 1 per cent.) of water, the solution yields by evaporation sometimes a crystalline mass, sometimes a syrup, which dries up in vacuo to a white amorphous mass. Both the crystals and the syrup contain $2C^2H^6O.3CaCl + H^2O$.

Chloride of zinc forms with absolute alcohol a crystalline compound which contains $C^2H^6O.ZnCl$, and yields when heated, alcohol, chloride of ethyl, hydrochloric acid and oxide of zinc, but no ether.

Dichloride of tin and absolute alcohol, brought together in a vessel immersed in a freezing mixture, unite immediately, and on evaporating the solution in vacuo, over sulphuric acid and sticks of potash, crystals are formed containing $4C^2H^6O.Sn^2Cl^6O$. The crystals are very soluble in alcohol. They distil at 80° almost without decomposition (Lewy.) By cooling a mixture of 11·5 pts. of anhydrous alcohol, and 32·4 pts. of dichloride of tin in a frigorific mixture, Robiquet obtained a white powder which, when dissolved in alcohol, yielded by evaporation in vacuo over sulphuric acid, crystals containing $2C^2H^6O.SnCl^4$.

With *baryta,* alcohol forms the compound $2C^2H^6O.Ba^2O$, which is obtained by adding anhydrous baryta to absolute alcohol, filtering, and again adding baryta. If the alcoholic solution be then boiled, the compound separates in the form of a granular precipitate which redissolves on cooling. Water added to the solution throws down hydrate of barium. (Berthelot, Ann. Ch. Phys. [3] xlvi. 222.)

The following substances also form crystalline compounds with alcohol: sesquichloride of iron, protochloride of iron nitrate of calcium, and protochloride of manganese. (Graham.)

The alcohol in all these compounds may be regarded as analogous to water of crystallisation.

ALCOHOL-BASES. This name is frequently applied to the organic bases produced by the substitution of alcohol-radicles for the hydrogen in ammonia; such, as ethylamine, phenylamine, &c. (See AMINES.)

ALCOHOLOMETRY. (*Alcoométrie.*) The value of spirituous liquors depends upon the quantity of alcohol which they contain. This may be determined in various ways: viz. by the specific gravity of the mixture, by its boiling-point, by the tension of its vapour, by its rate of expansion, and by estimating the proportion of carbon contained in it by combustion with oxide of copper. But of all these methods, that which depends upon the density is almost always employed for practical purposes, other methods being resorted to only when the mixture of alcohol and water is associated with foreign substances, such as sugar, or colouring matter, or salts, in sufficient quantity to produce a material alteration of the density.

To determine the amount of alcohol in a spirituous liquor by its density, it is necessary to know beforehand the density corresponding to each particular proportion of alcohol and water. If these liquids were capable of mixing without alteration of volume, the specific gravity of each particular mixture might be calculated from the proportions of alcohol and water contained in it, and the known specific gravity of absolute alcohol. This however is not the case, the combination of alcohol and water being attended with a contraction of volume varying in amount with the temperature. For this reason the specific gravity of each mixture of alcohol and water must be determined by direct experiment, and the results collected in tables.

The importance of this object for the purposes of revenue induced the British government to employ Sir Charles Blagden to institute a very extensive and accurate series of experiments on the density of spirit of various degrees of strength. The determinations, which were made by Gilpin under Blagden's direction, were first published in 1790, afterwards twice repeated to obtain greater accuracy, and published in the Philosophical Transactions for 1794.

The specific gravity of the mixtures of alcohol and water was determined by accurately weighing a quantity of the liquid in a flask having a long narrow neck, and filled with it up to a certain mark, the weight of an equal quantity of distilled water having been previously ascertained. In this manner, the specific gravity of 40 mixtures was determined, each at 15 different temperatures. The standard alcohol used to mix with the water was not absolute, but had a specific gravity of 0·82514; for convenience, however, it was supposed to be = 0·825, a corresponding deduction being made from all the numbers in the table.

TABLE I.—*Showing the Specific Gravity of various mixtures of Alcohol (of Specific Gravity* 82500 *at* 60° *Fahr.) and Water at different Temperatures, the Specific Gravity of water at* 60° *Fahr. being* 100000.

Gilpin's tables do not give directly the quantity of absolute alcohol contained in spirit of any given density. In this respect, however, they have been completed by the experiments of Tralles, who in 1811 (Gilbert's Annalen, xxxviii. 386), determined the specific gravity of alcohol, dehydrated as completely as possible by means of chloride of calcium, and likewise the strength of Gilpin's standard spirit, having a specific gravity of 0·825 at 60° F. He found that the specific gravity of absolute alcohol at 60° F. compared with that of water at its maximum density is 0·7939 (or 0·7946 compared with water at 60°) and that Gilpin's standard spirit contains in 100 parts by weight, 89·2 parts of anhydrous alcohol, and 10·8 parts of water. Proceeding upon these data, Tralles calculated the proportions of absolute alcohol and water contained in spirit of various densities; the results are given in Table II. p. 83.

The proportions of alcohol in spirit of wine may be expressed either by weight or by volume. The former mode of expression is by far the simpler and more definite, because the proportion by weight is independent of the temperature, whereas the proportion by volume varies with the temperature, being affected by the different rates of expansion of alcohol and water. For scientific purposes, therefore, the strength of spirit is always expressed in percentage by weight. In commerce, on the contrary, the method by volume is always adopted, spirit being generally bought and sold by measure, not by weight. It becomes therefore necessary to know how to calculate the composition by volume from the composition by weight and the observed specific gravity.

Let S be the specific gravity of the spirit (mixture of alcohol and water): a the quantity of alcohol in 100 parts by weight, and therefore $100 - a$ the quantity of water; V the volume of the spirit referred to a unit of volume, such that a quantity of water which fills it is the unit of weight (*e. g.* if the weight is expressed in grammes, V is measured in cubic centimetres) then:

$$100 = V \,.\, S$$

If then, the specific gravity of anhydrous alcohol at the observed temperature compared with water at the same temperature be s, the volumes of alcohol and water contained in the spirit are:

$$\frac{a}{s} \quad \text{and} \quad 100 - a$$

and consequently, the proportions of alcohol and water in 100 volumes of the spirit are:

$$\frac{a}{s} \cdot \frac{100}{V} = a . \frac{S}{s} \text{ volumes of alcohol.}$$

$$\text{and: } (100 - a) \cdot \frac{100}{V} = (100 - a)\, S \text{ volumes of water.}$$

For example: from the table p. 85 it appears that spirit containing 77·09 per cent. of alcohol by weight has at 60° F. a sp. gr. of 0·8555, referred to water at the same temperature, and the specific gravity of absolute alcohol referred to the same standard is 0·7946: hence the percentage of alcohol by volume is:

$$77{\cdot}09 \cdot \frac{8555}{7946} = 83{\cdot}00$$

and the percentage by volume of water is:

$$(100 - 77{\cdot}09) \,.\, 0{\cdot}8555 = 22{\cdot}91 \,.\, 0{\cdot}8555 = 20{\cdot}60$$

the whole being measured at 60° F.

The volumes of alcohol and water thus obtained amount together to more than 100, in the preceding example to 103·60; and accordingly, if 83·00 measures of alcohol be mixed with 20·60 measures of water, both at 60° F., the mixture, after it has cooled to 60° F., will fill exactly 100 measures, and the spirit thus produced will contain 83 volumes per cent. of alcohol. (Respecting the contraction which takes place on mixing alcohol and water in various proportions, see Rudberg, Pogg. Ann. xiii. 196; also Kopp, ibid. liii. 356.)

When the volume per cent. in a mixture of alcohol and water is given, the weight per cent. is found from the equation:

$$a = V \cdot \frac{s}{S}$$

Thus, according to the table (p. 85) spirit containing 68 volumes per cent. of alcohol has a sp. gr. of 0·8949 at 60° F. Hence the weight per cent. of alcohol is:

$$a = 68 \,.\, \frac{7946}{8949} = 60{\cdot}38$$

that is to say: 100 lbs. of this spirit contain 69·38 lbs. of alcohol and 39·62 lbs. of water.

The specific gravity of aqueous alcohol may be determined by any of the ordinary methods; either by weighing in a specific gravity bottle, or by means of the hydrometer (See SPECIFIC GRAVITY and HYDROMETER) and thence the percentage of anhydrous alcohol by weight and by volume may be determined by means of the preceding formulæ and the tables to be given hereafter. To facilitate these determinations, hydrometers are constructed with scales marking directly the percentage of alcohol by volume, and sometimes also by weight, of the spirit in which they are immersed. Such instruments are called ALCOHOLOMETERS. Three of them are in use, viz. the alcoholometer of Tralles, which gives the percentage volume for the temperature of 60° F. = $12\frac{4}{9}$ R. = $15\frac{5}{9}$ C.; Gay-Lussac's alcoholometer, which likewise indicates percentage by volume at 15° C.; and Meissner's, which gives percentages both by weight and volume, the latter for the temperature of 14° R = 17·5° C.

As the scales of these instruments are constructed for different temperatures, they cannot be expected to agree exactly; but the differences arising from this cause are trifling. Greater discrepancies however arise from the different experimental data upon which the scales have been constructed; that of Tralles being founded on the exact and extensive observations of Gilpin, and Meissner's on experiments of his own. Gay-Lussac has not stated on what experimental data his observations are founded, but his numbers agree very nearly with those of Tralles, the differences never exceeding ⅓ per cent. for the same specific gravity.

The following table gives the percentages of anhydrous alcohol both by weight and volume of mixtures of alcohol and water, according to their specific gravity as determined by Tralles from the observations of Gilpin; also the specific gravities as determined by Gay-Lussac. They are deduced from Tralles' numbers by multiplying by 1·0009. The corresponding indications of the hydrometers of Beck, Baumé, and Cartier, are likewise added.

99	98·39	7995	—	42·7	46	43
100	100·00	7946	7947	43·9	47	—

The use of this table may be extended to intermediate numbers by interpolation. Thus, if it be required to find the composition by volume of a mixture of 50 lbs. of anhydrous alcohol and 50 lbs. of water, we find from the table that:

49·23 p. c. by weight corresponds to 57 p. c. by volume
and: 50· 2 „ „ 58 „
difference 0·98 and 1

Hence, to find the fraction which must be added to the number 57 to give the percentage required, we have the proportion:

$$0{\cdot}98 \ : \ (50 - 49{\cdot}23) = 1 \ : \ x$$

which gives: $$x = \frac{77}{98} = 0{\cdot}8$$

Whence it appears that 100 volumes (measured at 60° F.) of a spirit containing equal weights of alcohol and water contain 57·8 volumes of alcohol, also at 60°.

Again, let it be required to find the composition of a spirit having at 60° Fahr. the specific gravity 0·8955, compared with water at the same temperature; this number is intermediate between the numbers 8949 and 8973 in the third column of the table, which correspond to the volume per centages 67 and 68; hence the proportion:

$$8973 - 8949 \ : \ 8973 - 8955 = 1 \ : \ x$$

which gives $$x = \frac{18}{24} = \tfrac{3}{4}$$

that is to say, 100 measures of spirit of sp. 0·8955 at 60° Fahr. contain $67\frac{3}{4}$ measures of anhydrous alcohol.

Meissner's results are given in his "Aräometrie in ihrer Anwendung auf Chemie und Technik," Wien, 1816. Th. ii. 27. They differ somewhat from the preceding.

It is often necessary to take the specific gravity of spirit at a temperature different from the standard. In that case, the percentage of alcohol may be determined by means of the two following tables, given by Tralles.

TABLE III. — *Specific Gravity of Spirit of different strengths at Temperatures from 30° Fahr. to 100° Fahr. that of Water at 39·83 Fahr. being* = 10000.

REDUCTIONS FOR A *Brass* INSTRUMENT.

To be deducted from the Specific Gravities.						To be added to the Specific Gravities.					
−5	−4	−3	−2	−2	−1	0	+1	+2	+2	+3	+4

In Table III. the specific gravity of the spirit is supposed to be compared with that of water at the maximum density, and to be corrected for the expansion of the vessel or instrument with which the determination is made. These densities may be reduced to those compared with water at 60° F. (as in Table II.), by multiplying them all by 1·0009.

To find by means of this table the strength of a spirit, when either the specific gravity or the temperature is not given exactly as in the tables, we proceed by interpolation as in the calculations connected with Table II. (p. 85.) But if neither temperature nor specific gravity is exactly given in the table, the calculation is made as in the following example. Let it be required to find the strength of a spirit of sp. gr. 0·9321 at 77° F.

Per cent. of Alcohol.	Specific Gravity at 75° F.	Specific Gravity at 80° F.	Difference.
45	9367	9347	20
50	9272	9251	21
Difference 5	95	96	

Hence the sp. gr. for 77° F., and for:

$$45 \text{ p. c. alcohol is } 9367 - 2 \times \frac{20}{5} = 9359$$

$$50 \quad ,, \quad 9272 - 2 \times \frac{21}{5} = 9263·6$$

$$\text{Difference} = 95·4$$

Calling this difference 95, it follows that to each 1 per cent. of alcohol there corresponds at 77° F. a difference of 19 in the specific gravity, and consequently the volume per cent. of alcohol corresponding to the specific gravity 9321 is

$$45 + \frac{9359 - 9321}{19} = 45 + \frac{38}{19} = 47 \text{ vol. p. c.}$$

This result shows that the spirit in question, when cooled down to the normal temperature of 60° F. contains in 100 measures, 47 measures of absolute alcohol; this is not, however, the actual proportion by volume at 77°, because alcohol and water expand at different rates.

Table IV. exhibits in the same manner as Table III. the strength of spirit according to its specific gravity, but on the supposition that the specific gravity is determined with a glass instrument, and is not corrected for the expansion of the glass: hence the expression "apparent specific gravity."

If the specific gravity of a sample of spirit has been determined at one temperature and its volume measured at another, the amount of alcohol in it may be calculated as in the following example: 350 quarts of spirit are measured out at 75° F., and the specific gravity determined with a glass instrument at 65° F. is 0·8609. By Table IV. the strength of this spirit is 80 per cent., that is to say, 100 volumes of it measured at 60° F. contain 80 vol. of alcohol. By Table III. the specific gravities of spirit of 80° per cent. for the temperatures 60° and 75° are 8631 and 8560. Consequently the volumes of a given weight of the spirit at 60° and 75° are as 8560 : 8631, and therefore the 350 quarts of spirit would, if cooled to 60°, measure $350 \times \frac{8560}{8631} = 347·12$ quarts; and this volume of liquid at the strength of 80 per cent. contains 277·7 quarts of real alcohol.

To ensure perfect accuracy, the expansion of the vessel in which the spirit is measured ought to be taken into account; but for commercial purposes, to which calculations of this kind chiefly apply, this correction is too small to be of any importance.

The quantity of alcohol of 60° F. in 100 volumes of spirit of the same temperature is called the *strength* (*Stärke; force*), of the spirit; and the quantity of alcohol of 60° F. in 100 volumes of spirit of any given temperature is called the *real amount of alcohol* (*wahrer Alkoholgehalt; Richesse*). Thus in the example just given, the strength of the spirit is 80. but the real amount of alcohol is $\frac{277·7}{350} \times 100 = 79·3$.

The following Tables, V. and VI., exhibit the *strength* and the *real amount of alcohol* of a sample of spirit, according to the indications of the alcoholometer and the thermometer. If, for example, the alcoholometer marks 75 per cent. in a spirit whose temperature is 50° F., we find from line 16, column 6, of Table V. that the strength of the spirit is 76·7, and from the corresponding place in Table VI. that its real amount of alcohol is 77·1 per cent.

Table V.—*Showing the Amount of Alcohol which a given sample of Spirit would contain at 60° F. according to the indication of a glass Alcoholometer, immersed in it at any other temperature.*

The scale of Tralles' alcoholometer is constructed as follows. Suppose the cylindrical or prismatic stem of the instrument to be divided into a number of equal parts, of arbitrary length; and let v be the volume of that portion of the neck between two consecutive divisions; V the volume of liquid of sp. gr. 1, displaced by the alcoholometer, and P the weight of the alcoholometer; then

$$P = V \, . \, 1.$$

If now the division to which the instrument sinks in this liquid be marked 0, the divisions being numbered upwards therefrom, and if the instrument be immersed in spirit of specific gravity s to the mark n, we have

$$P = (V + n\,v)\,s,$$

which equations give,

$$V = (V + nv)\,s, \text{ or } n = \frac{V}{v}\left(\frac{1}{s} - 1\right) = \frac{V}{v} \cdot \frac{1-s}{s}$$

The arbitrary quantity v is fixed by Tralles at such a magnitude that

$$n = 10000 \cdot \frac{1-s}{s}$$

Now for 60° F. the specific gravity of water compared with that of water at its maximum density (Table I.) is 0·9991: hence for the division in which the instrument sinks in pure water at 60°, we find,

$$n = 10000 \cdot \frac{1-0{\cdot}9991}{0{\cdot}9991} = 9.$$

Again, spirit of 80 per cent. has at 60° F. the sp. gr. 0·8631: hence, for the division to which the instrument sinks therein, we have

$$n = 10000 \cdot \frac{1-0{\cdot}8631}{0{\cdot}8631} = 1587,$$

and in like manner the values of the other divisions of the scale may be found: they are given in Table VII.

To graduate an alcoholometer by means of this table, the instrument is first immersed in pure water at 60° F., and the point of the stem to which it sinks is marked 9. It is next immersed in spirit of known strength, and the point marked to which it sinks when the liquid is at 60° F. Thus if spirit of 90 per cent. be used, the number of the division will be

$$n = 10000 \cdot \frac{1-0{\cdot}8340}{0{\cdot}8340} = 2002.$$

The interval between these two marks is then to be divided into 2002 − 9 = 1993 equal parts, and the divisions continued upwards as far as 2597, which corresponds to absolute alcohol. The percentages in the first column of Table VII. are then marked on the scale by the side of the numbers of the divisions in the second column.

To verify the scale of an alcoholometer already divided, the specific gravities of a number of samples of spirit varying in strength by nearly equal intervals between 0 and 100 per cent. may be determined by any of the ordinary methods; the corresponding strength found from Tables I., II., or III.; the temperatures of them all then reduced to 60° F.; and the alcoholometer immersed in them in order to ascertain whether its indications agree with the strengths so determined. The intermediate points may be tested by comparison with the numbers in the columns of Table VII. marked "Differences."

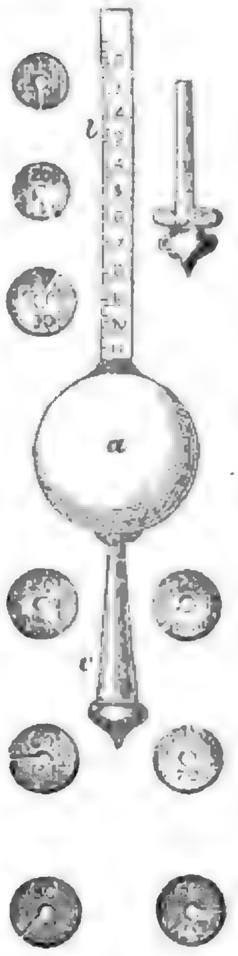
Fig. 3.



Various other hydrometers or areometers are also used for taking the specific gravity and ascertaining the strength of spirits. Sikes's hydrometer is the one used in levying the spirit duty in this country. This instrument has a four-sided stem *b*, divided into 11 equal parts, and fitting into a brass ball *a*, which carries at the bottom a small conical stem *c*, terminating in a pear-shaped loaded bulb. It is also provided with 9 circular weights, numbered 10, 20, 30, 40, 50, 60, 70, 80, 90, having slits by which they fit into the stem. The instrument is adjusted so as to float with the zero of the scale coinciding with the surface of the liquid in spirit of specific gravity 0·825 at 60°F. which is the "*standard alcohol*" of the excise (p. 82). In weaker spirit it will not sink so low; and if the density of the liquid be much greater, it will be necessary to add one or more of the weights, to cause the entire immersion of the bulb. The sum of the numbers of the weights together with the number on the scale which is at the level of the liquid, gives, by means of a table provided for the purpose, the amount of *proof spirit* in the sample, proof spirit being, according to Act of Parliament, such as at 51° Fahr. weighs $\frac{12}{13}$ as much as an equal bulk of water, or in other words has a specific gravity of 0·923077 at 51°, or 0·919 at 60° F.

When spirit is said to be 30 per cent. (for example) *above proof*, the meaning is, that 100 measures of this spirit, when diluted with water, would yield 130 measures of proof spirit; on the other hand, spirit 30 per cent. *below proof* contains in 100 measures, 100 − 30 or 70 measures of proof spirit.

It is often required to find the quantity of water which must be added to spirit containing a given percentage of alcohol in order to reduce it to a lower percentage. If the actual and required amounts are given in weights per cent., a and a', the weight x of water to be added to 100 lbs of spirit to reduce the percentage of alcohol from a to a', is given by the proportion:

$$100 + x : a = 100 : a',$$

$$\text{whence } x = 100\left(\frac{a}{a'} - 1\right)$$

If, for example. spirit containing 90 lbs. of alcohol in 100 lbs. is to be reduced to spirit containing 60 lbs. per cent., the quantity of water required is

$$100\left(\frac{90}{60} - 1\right) = 100 \times 0{\cdot}5 = 50 \text{ lbs.}$$

Next, let it be required to find what volume of water must be added to 100 volumes of spirit containing v volumes per cent. of alcohol to reduce it to v' volumes per cent.

If P be the weight, and S the specific gravity of the spirit we have:

$$P = 100\,S.$$

and if to this we add w volumes of water, the weight of which will also be w (its specific gravity being 1), we obtain a volume V of spirit, whose specific gravity may be denoted by S', and its amount of alcohol in volumes per cent. by v'. Then,

$$P + w = 100\,S + w = VS',$$

$$\text{and} \qquad V : 100 = v : v',$$

$$\text{or,} \qquad V = 100 \cdot \frac{v}{v'},$$

because the diluted spirit still contains the v volumes of alcohol which were present in the liquid before dilution. From these two equations we find

$$w = 100\left(\frac{v}{v'}\,S' - S\right)$$

For example, to reduce spirit of 80 volumes p. c. to spirit of 40 volumes p. c. we find,

$$w = 100 \cdot \left(\frac{80}{40} \cdot 0{\cdot}9519 - 0{\cdot}8639\right) = 103{\cdot}99$$

so that 100 measures of the given spirit require 103·99 measures of water at 60°F. to reduce them from 80 to 40 per cent.

The volume of diluted spirit produced by the mixture is

$$v = 100\,\frac{v}{v'}$$

In the example just given, $100 \cdot \frac{80}{40} = 200$ volumes, less therefore than the sum of the volumes of the liquids mixed.

On the principles just explained, the numbers in the following table are calculated. It must be observed, however, that the specific gravities are given as determined by Gay-Lussac, and correspond to 15° C. on which account the result of the calculation just given does not agree exactly with the number in the table.

The original volumes per cent. of the spirit are placed at the tops of the columns, and the percentages to which they are to be reduced in the first column of the table. Thus to find how much water is required to reduce spirit of 75 per cent. to 40 per cent. look in the column headed 70 for the number on a level with 40 in the first column; we thus find that 77·58 volumes is the quantity of water required:

Table IX.—*Showing the quantity of Water required to reduce* 100 *volumes of a stronger Spirit to a Spirit of lower strength.*

10	804·54	753·65	702·89	651·21	601·60	551·06	500·59	450·19	399·85

A similar but much more extended table for this purpose is given by Gay-Lussac. (See Handworterbuch d. Chem. i. 504.)

To determine what quantity of a weaker spirit must be added to a stronger one to produce a spirit of given mean percentage, we proceed as follows.

Let v be the volume of alcohol in 100 measures of the stronger spirit, S its specific gravity, and P its weight. Also let V_1 be the volume of the weaker spirit added, v_1 its percentage of alcohol, S_1 its specific gravity, and P_1 its weight; and lastly, let V_2 be the volume of spirit resulting from the mixture, v_2 its percentage of alcohol, S_2 its specific gravity, and P_2 its weight. Then:

$$P = 100\,S \;:\; P_1 = V_1 S_1 \;:\; P_2 = P + P_1$$

$$\text{or } 100\,S + V_1 S_1 = V_2 S_2 \quad . \quad . \quad . \quad (1).$$

The quantity of alcohol contained in this mixture is,

$$v + \frac{V_1}{100}\,v_1$$

But since the mixed spirit is to contain V_2 volumes per cent. of alcohol, this quantity of alcohol is also represented by

$$\frac{V_2}{100}\,v_2$$

Hence the equation:

$$V_2 v_2 = 100\,v + V_1 v_1 \,. \quad . \quad . \quad (2).$$

And eliminating V_2 between the equations (1) and (2), we have,

$$\frac{100\,S + V_1 S_1}{S_2}\,v_2 = 100\,v + V_1 v_1$$

whence we obtain:

$$V = \frac{100\,\frac{v}{v_2}\,S - 100\,S}{S_1 - \frac{v_1}{v_2}\,S_2}$$

The numerator of this fraction is the quantity of water which must be added to 100 volumes of the stronger spirit to produce a spirit of the required strength. The denominator may be written in the form,

$$\frac{v_1}{v_2}\left(\frac{v_2}{v_1}\,S_1 - S_2\right)$$

and is therefore the volume of water which must be added to $\frac{v_1}{v_2}$ volumes of spirit containing v_2 per cent. of alcohol to bring it to the percentage v_1.

To determine the amount of alcohol in spirituous liquors, such as wine or beer, containing foreign matters, as volatile oils, sugar, mucilage, saline substances, &c., the liquid may be distilled, and the distillate, which will be free from the fixed impurities, may be treated by the methods already described. Volatile oils are for the most part of nearly the same specific gravity as alcohol, and the small quantities of them existing in vinous liquors do not make any essential difference in the specific gravity.

Other physical characters have also been resorted to for determining the strength of spirituous liquors, viz. the boiling-point, vapour-density, rate of expansion, &c.

The *boiling-point* of hydrated alcohol has been proposed by Gröning as a means of determining its strength. For this purpose, he has constructed the following table.

Per Cent. of Alcohol.	Boiling-Point.	Per Cent. of Alcohol.	Boiling-Point.	Per Cent. of Alcohol.	Boiling-Point.
5	96·3 C.	40	84·1 C.	70	80·9 C.
10	92·9	45	83·4	75	80·3
15	91·0	50	83·1	80	79·7
20	89·1	50	82·2	85	79·4
25	87·5	60	81·9	90	79·0
30	86·2	65	81·5	95	78·4
35	85·0				

According to Dalton, alcohol of 43 per cent. boils at 84° C.

J. J. Pohl (Denkschriften d. math. naturw. Classe d. Wien, Akad. II. abstr. Wien, Akad. Ber. 1850; Marz. 246; Jahresber. 1850, 455) has also determined the boiling-point of hydrated alcohol of various strengths. He finds that, at the commencement of the ebullition, the thermometer remains constant for a short time, then slowly rises a little, and afterwards remains constant for a somewhat longer time (from 4 to 16 seconds when 14·6 grms. of liquid were used). The temperatures at the second stationary interval are given in the following table (Bar. at 760 mm.)

Percentage of Alcohol.	Boiling-Point.	Percentage of Alcohol.	Boiling-Point.
0	100·00° C.	7	93·43° C.
1	98·79	8	92·70
2	97·82	9	92·03
3	96·85	10	91·40
4	95·90	11	90·83
5	95·02	12	90·27
6	94·21		

The presence of sugar in the liquid up to 15 p. c. appears not to exert any perceptible influence on the boiling-point (a mixture of 10 pts. alcohol with 15 sugar and 75 water boiled at the same temperature as a mixture of 10 alcohol and 90 water).

Instruments, called *Ebullioscopes*, for directly ascertaining the strength of hydrated alcohol by its boiling-point, have been constructed by Broissard-Vidal and by Conaty. (See a report on these instruments by Despretz, Pouillet, and Babinet, Compt. rend. xxvii. 374. A description and figure of a Vidal-instrument are given in the Pharm. J. Trans. vii. 166.) Ure (Pharm. J. Trans. vii. 166; Pharm. Centr. 1847, 422) by means of an instrument similar to Conaty's (which is merely an ordinary thermometer, having a moveable scale which can be shifted so as to correspond with the variations of the barometer, and has the percentages of alcohol marked on it) has determined the boiling-points of hydrated alcohol as follows:

Specific Gravity.	Boiling-Point.	Specific Gravity.	Boiling-Point.
0·9200	81·4° C.	0·9665	85·3° C.
0·9321	82·1	0·9729	87·2
0·9420	82·5	0·9786	88·8
0·9516	83·3	0·9850	91·3
0·9600	84·1	0·9920	94·4

Silbermann has proposed to determine the strength of hydrated alcohol by its rate of expansion by heat, and has constructed an instrument for the purpose (Compt. rend. xxvii. 418). A thermometer is filled up to a certain mark with the spirit at 25° C. and after this liquid has been exhausted of air by the air-pump, an observation is made of the amount by which it expands when heated to 50° C. The amount of alcohol is then found by means of a scale graduated by direct observation upon a number of samples of spirit of known strength. The indications of this instrument are not sensibly affected by the presence of sugar or salts in the liquid.

Another instrument for the same purpose has been constructed and described by Makin. (Chem. Soc. Qu. J. ii. 224.)

For further details on alcoholometry, see the new edition of *Ure's Dictionary of Arts, Manufactures and Mines*, vol. i. pp. 44-64.

ALCOHOL-RADICLES. The radicles which, when they replace half the hydrogen in a molecule of water form alcohols, are capable of uniting, though not directly, with chlorine bromine, iodine, cyanogen, oxygen, sulphur, &c., with the radicles of acids, and with metals: in short they exhibit in their chemical relations the character of electro-positive elements or metals. Only a few of them have yet been isolated; and of these, all but one (allyl) belong to the first series of alcohols mentioned in the preceding article, and are represented by the general formula C^nH^{2n+1}, or $C^{2n}H^{4n+2}$. They are obtained:

1. By the action of sodium, potassium, zinc, &c., at high temperatures, on their iodides or bromides. In this manner ethyl was first isolated by Frankland.—2. By the electrolysis of the acids of the series $C^nH^{2n}O^2$. The general formula of the decomposition is,

$$C^nH^{2n}O^2 = C^{n-1}H^{2n-1} + CO^2 + H.$$

In this manner, acetic acid, $C^2H^4O^2$, yields methyl, CH^3; valeric acid, $C^5H^{10}O^2$, yields tetryl or butyl, C^4H^9; caproic acid, $C^6H^{12}O^2$, yields amyl, C^5H^{11}; and œnanthylic acid $C^7H^{14}O^2$ yields hexyl or caproyl, C^6H^{13}.—3. Some of these radicles, viz. trityl or propyl, tetryl, amyl and hexyl, are also found among the products of the dry distillation of Boghead Cannel coal. (Gr. Williams, Chem. Gaz. 1857, pp. 29 and 95.)

Methyl and ethyl are gaseous at ordinary temperatures; trityl, tetryl, amyl, and hexyl, are liquids, the first boiling at 68° C, the second at 108°, the third at 155°, and and the fourth at 202°. They do not unite directly with any of the elementary bodies, and it has not yet been found possible to reproduce from them, by direct union, any of the bodies of the methyl, ethyl series, &c. At the moment of isolation, however, from their iodides by the action of metals, they exhibit a strong tendency to unite with the metal: in this manner, zinc-ethyl, C^2H^5Zn and zinc-methyl, C^2H^3Zn, are formed by the action of zinc on the iodides of those radicles.

The constitution of these bodies has given rise to considerable discussion. The formulæ CH^3, C^2H^5, &c., originally assigned to them by Frankland and Kolbe, represent their vapours as condensed to 1 volume, whereas the usual mode of condensation in organic compounds is to 2 volumes (see ATOMIC VOLUME). For this reason, and likewise because all organic compounds whose formulæ are well established, are found to contain even numbers of hydrogen-atoms, Gerhardt (Compt. chim. 1848, 19; 1849, 11) proposed to double the formulæ of these radicles in the free state, making them C^2H^6 or $\left.\begin{matrix}CH^3\\CH^3\end{matrix}\right\}$, C^4H^{10} or $\left.\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right\}$ &c. This duplication of the formulæ was afterwards supported by Hofmann (Chem. Soc. J. iii. 121) on the ground that the boiling-points of the consecutive terms of the series of these bodies differ by about 47° C., an interval more than double of that which generally corresponds to a difference of CH^2 in bodies of the methyl, ethyl, trityl series, &c. But the decisive argument in favour of the double formulæ is afforded by the experiments of Wurtz, who has shown that by the action of mixtures of the iodides of these radicles (iodide of ethyl and iodide of tetryl, for example) with sodium, or by the electrolysis of a mixture of the potassium-salts of two fatty acids, *e. g.* acetate and œnanthylate of potassium, compound radicles are obtained, viz. ethyl-tetryl, $\left.\begin{matrix}CH^3\\C^4H^9\end{matrix}\right\}$, methyl-hexyl $\left.\begin{matrix}CH^3\\C^6H^{13}\end{matrix}\right\}$ &c.; and moreover that when these mixed radicles are compared with the simple radicles with double formulæ, a regular gradation of physical properties is observed as the number of atoms in the molecule increases. This will be seen from the following table.

Radicle.	Formula.	Specific Gravity at 0° C.	Vapour-Density		Boiling Point.
			Observed.	Calculated.	
Ethyl-tetryl .	$C^6H^{14} = \left\{\begin{matrix}C^2H^5\\C^4H^9\end{matrix}\right.$	0·7011	3·053	2·972	62°
Ethyl-amyl .	$C^7H^{16} = \left\{\begin{matrix}C^2H^5\\C^5H^{11}\end{matrix}\right.$	0·7069	3·522	3·455	88°
Methyl-hexyl .	$C^7H^{16} = \left\{\begin{matrix}CH^3\\C^6H^{13}\end{matrix}\right.$	?	3·426	3·455	82 ?
Tetryl . .	$C^8H^{18} = \left\{\begin{matrix}C^4H^9\\C^4H^9\end{matrix}\right.$	0·7057	4·070	3·939	106
Tetryl-amyl .	$C^9H^{20} = \left\{\begin{matrix}C^4H^9\\C^5H^{11}\end{matrix}\right.$	0·7247	4·465	4·423	132
Amyl . .	$C^{10}H^{22} = \left\{\begin{matrix}C^5H^{11}\\C^5H^{11}\end{matrix}\right.$	0·7413	4·956	4·907	158
Tetryl-hexyl .	$C^{10}H^{22} = \left\{\begin{matrix}C^4H^9\\C^6H^{13}\end{matrix}\right.$	?	4·917	4·907	155
Hexyl . .	$C^{12}H^{26} = \left\{\begin{matrix}C^6H^{13}\\C^6H^{13}\end{matrix}\right.$	0·7574	5·983	5·874	202

It is clear that if the simpler formulæ of tetryl, amyl and hexyl were retained, accordance between the gradation of properties and increase of atomic weight wh the preceding table exhibits would be completely lost.

Viewed in this light, the formation of the simple radicles is strictly analogou that of the mixed radicles, as will be seen from the following equations:

$$C^2H^5I + C^4H^9I + ZnZn = 2ZnI + C^2H^5.C^4H^9$$

and

$$2C^2H^5I + ZnZn = 2ZnI + C^2H^5.C^2H^5.$$

ALCOHOLS. The term alcohol, originally limited to one substance, viz. spiri wine, is now applied to a considerable number of organic compounds, many of wh in their external characters, exhibit but little resemblance to common alcohol. alcohols are all compounds of carbon, hydrogen, and oxygen. They are divided several homologous groups, but their rational formulæ may all be derived from two, or three molecules of water, $\left.\begin{matrix}H\\H\end{matrix}\right\}O$, $\left.\begin{matrix}H^2\\H^2\end{matrix}\right\}O^2$, $\left.\begin{matrix}H^3\\H^3\end{matrix}\right\}O^3$, by substitution of an ganic radicle containing hydrogen and carbon for half the hydrogen in the t Alcohols are accordingly monatomic, diatomic, or triatomic, *e.g.* Ethyl-alco (monatomic) = $\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O$, — Glycol (diatomic) = $\left.\begin{matrix}(C^2H^4)''\\H^2\end{matrix}\right\}O^2$, — Glycerin (t tomic) = $\left.\begin{matrix}(C^3H^5)'''\\H^3\end{matrix}\right\}O^3$

A. **Monatomic Alcohols.** Of these there are several series, containing rad whose general formulæ are C^nH^{2n+1}, C^nH^{2n-1}, C^nH^{2n-3}, C^nH^{2n-7}.

1. Alcohols of the form $C^nH^{2n+2}O = \left.\begin{matrix}C^nH^{2n+1}\\H\end{matrix}\right\}O$. These alcohols, of w nine, or perhaps ten, are at present known, are intimately related to the fatty acid 50). To every alcohol of this series there corresponds an acid of the series C^nH^2 which may be formed from the alcohol by oxidation, O being substituted for H^2. following table exhibits the names and formulæ of these alcohols, together with t of those of the corresponding acids:

Alcohols, $\left.\begin{matrix}C^nH^{2n+1}\\H\end{matrix}\right\}O$		Acids, $\left.\begin{matrix}C^nH^{2n-1}O\\H\end{matrix}\right\}O$	
Methylic or protylic . . .	CH^4O	Formic	CH^2
Ethylic or deutylic . . .	C^2H^6O	Acetic	C^2H
Propylic or tritylic . . .	C^3H^8O	Propionic	C^3H
Butylic or tetrylic . . .	$C^4H^{10}O$	Butyric	C^4H
Amylic or pentylic . . .	$C^5H^{12}O$	Valeric	C^5H
Caproylic or hexylic . . .	$C^6H^{14}O$	Caproic	C^6H
Œnanthylic or heptylic . .	$C^7H^{16}O$	Œnanthylic	C^7H
Caprylic or octylic . . .	$C^8H^{18}O$	Caprylic	C^8H
Cetylic	$C^{16}H^{34}O$	Palmitic	C^{16}
Cerotylic	$C^{27}H^{56}O$	Cerotic	C^{27}
Melissylic	$O^{30}H^{62}O$	Melissic	C^{30}

These alcohols are also designated as *Hydrates*, or *Hydrated Oxides, of Methyl, Ethyl*, &c., or as *Methylate, Ethylate, Tritylate, &c.* of *Hydrogen*. The numerical terms *protyl, deutyl, trityl*, &c. were proposed by Gerhardt. They are in most cases preferable to the older names: but the terms, methyl, ethyl, and amyl, are too much consecrated by use to be discarded.

Methyl-alcohol, or wood-spirit, was first recognised as a compound similar in nature and constitution to common alcohol by Dumas and Peligot in 1835. In the following year, the same chemists showed that ethal (cetyl-alcohol), a substance first obtained from spermaceti by Chevreul in 1823, is also of alcoholic nature. Fusel-oil was recognised as an alcohol somewhat later by Cahours and Balard. Cerotyl-alcohol and melissyl-alcohol were discovered by Brodie in 1848; octyl-alcohol by Bouis in 1851; tetryl-alcohol by Wurtz in 1852; trityl-alcohol by Chancel in 1852, and hexyl-alcohol by Faget in the same year.

Methyl-alcohol is found among the products of the distillation of wood. *Ethyl-alcohol* and the four following alcohols are produced by fermentation of sugar, ($C^6H^{12}O^6$), perhaps in the manner represented by the following equations:

$$C^6H^{12}O^6 = \underset{\substack{\text{Ethyl-}\\\text{alcohol.}}}{2C^2H^6O} + 2CO^2$$

$$2C^6H^{12}O^6 = \underset{\substack{\text{Trityl-}\\\text{alcohol.}}}{2C^3H^8O} + \underset{\substack{\text{Ethyl-}\\\text{alcohol.}}}{C^2H^6O} + 4CO^2 + H^2O$$

$$C^6H^{12}O^6 = \underset{\substack{\text{Tetryl-}\\\text{alcohol.}}}{C^4H^{10}O} + 2CO^2 + H^2O$$

$$3C^6H^{12}O^6 = \underset{\substack{\text{Amyl-}\\\text{alcohol.}}}{2C^5H^{12}O} + \underset{\substack{\text{Ethyl-}\\\text{alcohol.}}}{C^2H^6O} + 6CO^2 + 3H^2O$$

$$2C^6H^{12}O^6 = \underset{\substack{\text{Amyl-}\\\text{alcohol.}}}{C^5H^{12}O} + \underset{\substack{\text{Trityl-}\\\text{alcohol.}}}{C^3H^8O} + 4CO^2 + 2H^2O$$

$$5C^6H^{12}O^6 = \underset{\substack{\text{Amyl-}\\\text{alcohol.}}}{4C^5H^{12}O} + 10CO^2 + 6H^2O$$

$$3C^6H^{12}O^6 = \underset{\substack{\text{Hexyl-}\\\text{alcohol.}}}{2C^6H^{14}O} + 6CO^2 + 4H^2O$$

Octyl-alcohol is said to be obtained by saponifying castor-oil with potash, and distilling the resulting ricinolate of potassium with excess of the alkali at a high temperature. The ricinolic acid is then converted into octyl-alcohol, sebate of potassium, and free hydrogen:

$$\underset{\substack{\text{Ricinolic}\\\text{acid.}}}{C^{18}H^{34}O^3} + 2KHO = \underset{\substack{\text{Octyl-}\\\text{alcohol.}}}{C^8H^{18}O} + \underset{\substack{\text{Sebate of}\\\text{potassium.}}}{C^{10}H^{16}K^2O^4} + 2H$$

Bouis (Compt. rend. xxiii. 141). Other chemists, however, who have examined this reaction, state that the alcohol produced by it is not octylic, but heptylic. According to **Städeler** (J. pr. Chem. lxxii. 241) two reactions take place simultaneously, the one giving rise to the formation of heptylic alcohol, sebate of potassium, and hydride of methyl (marsh gas), the other to the formation of *methyl-œnanthyl*, an acetone isomeric with caprylic aldehyde, $C^8H^{16}O$, and free hydrogen; thus:

$$\underset{\substack{\text{Ricinolic}\\\text{acid.}}}{C^{18}H^{34}O^3} + 2KHO = \underset{\substack{\text{Heptyl-}\\\text{alcohol.}}}{C^7H^{16}O} + \underset{\substack{\text{Sebate of}\\\text{potassium.}}}{C^{10}H^{16}K^2O^4} + \underset{\substack{\text{Hydride}\\\text{of methyl.}}}{CH^3.H}$$

$$\underset{\substack{\text{Ricinolic}\\\text{acid.}}}{C^{18}H^{34}O^3} + 2KHO = \underset{\substack{\text{Methyl-}\\\text{œnanthyl.}}}{CH^3.C^7H^{13}O} + \underset{\substack{\text{Sebate of}\\\text{potassium.}}}{C^{10}H^{16}K^2O^4} + H^4$$

According to **Dachauer**, on the contrary (Ann. Ch. Pharm. cvi. 270), the products of the distillation are methyl-œnanthyl and octylic alcohol, the formation of this alcohol differing from that of methyl-œnanthyl only by the elimination of two atoms of hydrogen instead of four. It does not appear that Städeler actually observed the evolution of marsh gas.

Cetyl-alcohol (or ethal) is obtained by decomposing spermaceti (which consists chiefly of *cetin*, $C^{32}H^{64}O^2$) with alkalis, palmitic acid being formed at the same time:

$$\underset{\text{Cetin.}}{C^{32}H^{64}O^2} + KHO = \underset{\substack{\text{Cetyl-}\\\text{alcohol.}}}{C^{16}H^{34}O} + \underset{\substack{\text{Palmitate of}\\\text{potassium.}}}{C^{16}H^{31}KO^2}$$

In the same manner, cerotyl-alcohol is formed from Chinese-wax, and melissyl-alcohol from bees-wax.

$$\underset{\text{Chinese-wax.}}{C^{54}H^{108}O^2} + KHO = \underset{\text{Cerotyl-alcohol.}}{C^{27}H^{56}O} + \underset{\text{Cerotate of potassium.}}{C^{27}H^{53}KO^2}$$

Some of these alcohols have also been formed from the corresponding hydrocarbons C^nH^{2n}, *e.g.* common alcohol from olefiant gas, C^2H^4, and trityl-alcohol from tritylene, C^3H^6, by dissolving these gaseous hydrocarbons in strong sulphuric acid, and decomposing the resulting ethyl-sulphuric or trityl-sulphuric acid by distillation with water. Methyl-alcohol has been formed from marsh-gas, CH^4, by exposing that compound to the action of chlorine in sunshine, whereby chloride of methyl is obtained, and decomposing this body with aqueous potash (Berthelot, Compt. rend. xlv. 916):

$$CH^3Cl + KHO = CH^4O + KCl.$$

The first eight alcohols of the series are liquid at ordinary temperatures. Methylic and ethylic alcohols are mobile watery liquids; the others are more or less oily, the viscidity increasing with the atomic weight. Cetyl-alcohol is a solid fat: cerotylic and melissylic alcohols are waxy.

Oxidising agents convert these alcohols into aldehydes, $C^nH^{2n}O$, or acids, $C^nH^{2n}O^2$, in each case with elimination of one atom of water:

$$C^nH^{2n+2}O + O = C^nH^{2n}O + H^2O$$

and

$$C^nH^{2n+2}O + O^2 = C^nH^{2n}O^2 + H^2O$$

These changes take place on exposing the alcohols to the air, especially in contact with platinum-black, and more quickly on distilling them with a mixture of dilute sulphuric acid and chromate of potassium. The alcohols are also converted into fatty acids by heating them strongly in contact with soda-lime (a mixture of quick lime with caustic soda); *e.g.* amyl-alcohol thus treated yields valerate of sodium.

The alcohols of this series contain one atom of hydrogen replaceable by metals or compound radicles. Many of them, when treated with potassium or sodium, give off hydrogen, and form solid compounds containing 1 atom of the alkali-metal, *e.g.* ethylate of sodium, C^2H^5NaO. In this respect the alcohols partake of the nature of acids.—The compounds thus formed are easily decomposed, and are not easily obtained in a definite form.

On treating these potassium- or sodium-alcohols with the iodide of an alcohol-radicle, iodide of potassium or sodium is precipitated, and an *ether* is formed, that is to say, a compound derived from an alcohol by the substitution of an alcohol-radicle for the basic atom of hydrogen: thus ethylate of sodium with iodide of ethyl yields ethylic ether $(C^2H^5)^2O$, and with iodide of amyl, ethyl-amyl ether, $C^2H^5.C^5H^{11}.O$ (p. 76).

The alcohols are also converted into ethers by the action of strong sulphuric acid chloride of zinc, fluoride of boron, and other powerful dehydrating agents, at a certain temperature. The *ultimate* change is represented by the equation:

$$\underbrace{2\left(\left.\begin{matrix}C^nH^{2n+1}\\H\end{matrix}\right\}O\right)}_{\text{Alcohol.}} - H^2O = \underbrace{\left.\begin{matrix}C^nH^{2n+1}\\C^nH^{2n+1}\end{matrix}\right\}O}_{\text{Ether.}}$$

For the intermediate steps of the process see page 76. This particular change takes place only between certain limits of temperature, *e.g.* for the etherification of common alcohol by sulphuric acid, the limits are 140° and 160° C. At higher temperatures, a further dehydration takes place, and a hydrocarbon C^nH^{2n} is obtained:

$$C^nH^{2n+2}O - H^2O = C^nH^{2n}$$

e.g. common alcohol heated above 160° with strong sulphuric acid, yields olefiant gas C^2H^4.

With the greater number of acids, alcohols yield *compound ethers*; that is to say, salts in which the basic hydrogen of the acid is more or less replaced by the radicle of the alcohol. With monobasic acids, only neutral ethers are formed: thus common alcohol heated with strong acetic acid yields acetate of ethyl, with elimination of water:

$$\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O + \left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O = \left.\begin{matrix}C^2H^3O\\C^2H^5\end{matrix}\right\}O + H^2O$$

The formation of these ethers is greatly assisted by the presence of strong sulphuric or hydrochloric acid, to take up the water. They are commonly prepared either by distilling the alcohol with sulphuric acid, and a salt of the other acid (*e.g.* acetate of ethyl, by distilling alcohol with sulphuric acid and acetate of sodium), or by passing hydrochloric acid gas into an alcoholic solution of the acid. The former method is applicable to the more volatile ethers, the latter to those of higher boiling-point.

With dibasic and tribasic acids, the alcohols generally form *acid ethers* or *alcoholic acids*, that is to say, compounds in which only a portion of the basic hydrogen of the acid is replaced by the alcohol-radicle. Thus, when amyl-alcohol is mixed with sulphuric acid and the mixture kept cool, *amyl-sulphuric acid*, $\left.\begin{matrix}C^5H^{11}\\H\end{matrix}\right\}SO^4$ or $\left.\begin{matrix}(SO^2)''\\C^5H^{11}.H\end{matrix}\right\}O^2$ is produced:

$$\left.\begin{matrix}C^5H^{11}\\H\end{matrix}\right\}O \;+\; \left.\begin{matrix}H\\H\end{matrix}\right\}SO^4 = \left.\begin{matrix}C^5H^{11}\\H\end{matrix}\right\}SO^4 + \left.\begin{matrix}H\\H\end{matrix}\right\}O$$

In like manner, phosphoric acid and amyl-alcohol yield amyl-phosphoric acid, $PO^4.C^5H^{11}.H^2$.

Hydrochloric, hydrobromic, and hydriodic acids convert the alcohols of this series into chlorides, &c., of the alcohol-radicles, with elimination of water:

$$\left.\begin{matrix}C^nH^{2n+1}\\H\end{matrix}\right\}O + HCl = C^nH^{2n+1}\,Cl + H^2O$$

A similar transformation is effected by the chlorides, bromides, and iodides of phosphorus: *e.g.*

$$\underbrace{\left.\begin{matrix}C^5H^{11}\\H\end{matrix}\right\}O}_{\substack{\text{Amyl-}\\\text{alcohol.}}} + \underbrace{PCl^3.Cl^2}_{\substack{\text{Penta-}\\\text{chloride of}\\\text{phosphorus.}}} = \underbrace{C^5H^{11}Cl}_{\substack{\text{Chloride}\\\text{of amyl.}}} + HCl + \underbrace{POCl^3}_{\substack{\text{Oxychlo-}\\\text{ride of}\\\text{phosphorus.}}}$$

With the chlorides of acid radicles, the alcohols form compound ethers, hydrochloric acid being at the same time eliminated:

$$\underbrace{\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O}_{\substack{\text{Ethyl-}\\\text{alcohol.}}} + \underbrace{C^7H^5O.Cl}_{\substack{\text{Chloride of}\\\text{benzoyl.}}} = \underbrace{\left.\begin{matrix}C^7H^5O\\C^2H^5\end{matrix}\right\}O}_{\substack{\text{Benzoate}\\\text{of ethyl.}}} + HCl$$

Persulphide of phosphorus transforms the alcohols of this series into mercaptans (sulphur-alcohols):

$$5C^nH^{2n+2}\,O + P^2S^5 = 5C^nH^{2n+2}S + P^2O^5$$

2. Alcohols of the form $C^nH^{2n}O = \left.\begin{matrix}C^nH^{2n-1}\\H\end{matrix}\right\}O$ convertible by oxidation into acids of the form $C^nH^{2n-2}O^2$.

Only one term of this series is at present known, viz.: —

Allyl-alcohol or *Hydrate of Allyl*, $C^3H^6O = \left.\begin{matrix}C^3H^5\\H\end{matrix}\right\}O$.

This alcohol was discovered by Cahours and Hofmann in 1856. It is converted by oxidising agents into acrylic aldehyde or acrolein, C^3H^4O, and acrylic acid, $C^3H^4O^2$, and moreover exhibits all the transformations of the bodies of the preceding series (see ALLYL). It is probable that to every acid of the series $C^nH^{2n-2}O^2$ (angelic, terebic, oleic acid, &c), there corresponds an alcohol of the form $C^nH^{2n}O$. These alcohols are isomeric with the aldehydes of the preceding series; *e.g.* allyl-alcohol with propionic aldehyde.

3. Alcohols of the form $C^nH^{2n-2}O = \left.\begin{matrix}C^nH^{2n-3}\\H\end{matrix}\right\}O$. Only one alcohol of this kind is known, viz.:

Camphol, or *Bornean Camphor*, $C^{10}H^{18}O = \left.\begin{matrix}C^{10}H^{17}\\H\end{matrix}\right\}O$. It is a solid substance which, when distilled with anhydrous phosphoric acid, yields the hydrocarbon, $C^{10}H^{16} = C^{10}H^{18}O - H^2O$. It forms neutral ethers with stearic and benzoic acids.

4. Alcohols of the form $C^nH^{2n-6}O = \left.\begin{matrix}C^nH^{2n-7}\\H\end{matrix}\right\}O$, and corresponding to acids of the form $C^nH^{2n-8}O^2$. Three of these alcohols are known, viz.:

Benzyl-alcohol, or *Hydrate of Benzyl*, $C^7H^8O = \left.\begin{matrix}C^7H^7\\H\end{matrix}\right\}O$

Cumyl-alcohol, or *Hydrate of Cumyl*, $C^{10}H^{14}O = \left.\begin{matrix}C^{10}H^{13}\\H\end{matrix}\right\}O$

Sycoceryl-alcohol, or *Hydrate of Sycoceryl*, $C^{18}H^{30}\,O = \left.\begin{matrix}C^{18}H^{29}\\H\end{matrix}\right\}O$

Benzyl-alcohol was discovered by Cannizzaro in 1853; cumyl-alcohol by Kraut in 1854; these two alcohols are obtained by treating the corresponding aldehydes (bitter-almond oil and cuminol) with an alcoholic solution of potash:

$$\underbrace{2C^7H^6O}_{\text{Hydride of benzoyl.}} + KHO = \underbrace{C^7H^8O}_{\text{Benzyl-alcohol.}} + \underbrace{C^7H^5KO^2}_{\text{Benzoate of potassium.}}$$

Moreover, the aldehydes themselves may be formed from acids, by distilling a mixture of the calcium-salt of the acid with formate of calcium, thus:

$$\underbrace{\left.\begin{matrix}C^7H^5O\\Ca\end{matrix}\right\}O}_{\text{Benzoate of calcium.}} + \underbrace{\left.\begin{matrix}CO.H\\Ca\end{matrix}\right\}O}_{\text{Formate of calcium.}} = \underbrace{\left.\begin{matrix}C^7H^5O\\H\end{matrix}\right\}}_{\text{Hydride of of benzoyl.}} + \underbrace{\left.\begin{matrix}CO\\Ca^2\end{matrix}\right\}O^2}_{\text{Carbonate of calcium.}}$$

Hence it appears that these alcohols may be formed from the corresponding acids.

Benzylic and cumylic alcohols are liquids which volatilise without decomposition. They are converted into aldehydes and acids by the action of oxidising agents; they form compound ethers when treated with a mixture of sulphuric acid and other oxygen-acids (*e.g.* acetate of benzyl, $C^2H^3O^2.C^7H^7$, is formed by treating benzyl-alcohol with a mixture of sulphuric and acetic acids), and yield the chlorides of the corresponding radicles when treated with hydrochloric acid; thus chloride of benzyl, C^7H^7Cl is obtained by treating benzyl-alcohol with strong hydrochloric acid.

With sulphuric acid or chloride of zinc, they yield resinous masses, which are probably hydro-carbons analogous to olefiant gas: anhydrous boracic acid converts benzyl-alcohol into benzyl-ether $(C^7H^7)^2O$. They do not appear to form conjugated acids like ethyl-sulphuric acid. By caustic potash, at high temperatures, they are converted into the corresponding acids and hydrides of the alcohol-radicles; *e.g.*:

$$\underbrace{3(C^7H^7.H.O)}_{\text{Benzyl-alcohol.}} = \underbrace{C^7H^6O^2}_{\text{Benzoic acid.}} + \underbrace{2(C^7H^7.H)}_{\text{Hydride of benzyl.}} + H^2O$$

Sycoceryl-alcohol was discovered by Warren De la Rue and Hugo Müller, in 1859 (Proc. Roy. Soc. x. 298). It exists in the form of a natural acetic ether in the exudation from an Australian plant, the *Ficus rubiginosa.* This ether is readily obtained in beautiful crystals, and when treated with sodium-alcohol, yields acetic acid and sycocerylic alcohol, in feathery crystals resembling caffeine or asbestos. Treated with nitric acid, it yields an acid which appears to be sycocerylic acid; and with chromic acid, it yields a product which is probably the corresponding aldehyde.

5. Alcohols isomeric with the last, but differing from them in forming conjugated acids with sulphuric acid, phosphoric acid, &c., and in not being converted into acids and aldehydes by the action of oxidising agents. Two of these alcohols are known, viz.:

Phenyl-alcohol, or *Hydrate of Phenyl,* $C^6H^6O = \left.\begin{matrix}C^6H^5\\H\end{matrix}\right\}O$

Cresyl-alcohol, or *Hydrate of Cresyl,* $C^7H^8O = \left.\begin{matrix}C^7H^7\\H\end{matrix}\right\}O.$

The former was identified as an alcohol by Laurent, in 1841; the latter was discovered by Williamson and Fairlie, in 1854.

Both of these compounds occur among the products of the destructive distillation of coal, and are separated by fractional distillation. Phenyl-alcohol is also produced by the destructive distillation of salicylic acid:

$$C^7H^6O^3 = C^6H^6O + CO^2.$$

Phenyl-alcohol is solid and crystalline at ordinary temperatures, melts at 35°, and distils without decomposition at about 185°. Cresyl-alcohol is liquid at ordinary temperatures.

These alcohols are easily decomposed by potassium and sodium, like common alcohols, hydrogen being evolved, and compounds formed analogous to ethylate of potassium. They exhibit more decided acid characters than any of the preceding alcohols: phenyl-alcohol indeed is sometimes called *phenic* or *carbolic acid:* it forms a series of salts, called phenates or carbolates, containing 1 at. metal in place of the basic hydrogen. These alcohols are not converted into simple ethers or hydrocarbons by heating with sulphuric acid. Strong nitric acid converts them into nitro-acids, *e.g.* phenyl-alcohol into trinitrocarbolic or picric acid, $C^6H^3(NO^2)^3O$.

With pentachloride of phosphorus, they yield a chloride and a phosphate of the radicle together with hydrochloric acid: *e.g.*

$$\underbrace{4(C^6H^5.H.O)}_{\text{Hydrate of phenyl.}} + PCl^2.Cl^3 = \underbrace{PO^4(C^6H^5)^3}_{\text{Phosphate of phenyl.}} + \underbrace{C^6H^5Cl}_{\text{Chloride of phenyl.}} + 4HCl$$

With the chlorides of the acid radicles, they form compound ethers, thus:

$$\underbrace{C^6H^5.H.O}_{\text{Hydrate of phenyl.}} + \underbrace{C^7H^5O.Cl}_{\text{Chloride of benzoyl.}} = \underbrace{C^7H^5O^2.C^6H^5}_{\text{Benzoate of phenyl.}} + HCl$$

6. Alcohols of the form $C^nH^{2n-8}O = \left.\begin{matrix}C^nH^{2n-9}\\ H\end{matrix}\right\}O$. Two only of these bodies are known, viz.:

Cinnamic alcohol, *Hydrate of Cinnamyl*, or *Styrone*, $C^9H^{10}O = \left.\begin{matrix}C^9H^9\\ H\end{matrix}\right\}O$

Cholesterin . . . . . . $C^{26}H^{44}O = \left.\begin{matrix}C^{26}H^{43}\\ H\end{matrix}\right\}O$

Styrone is obtained by heating styracin (cinnamate of cinnamyl), with caustic alkalis; cholesterin is found in the bile and other products of the animal economy. Styrone is converted by oxidising agents into cinnamic aldehyde, C^9H^8O, and cinnamic acid, $C^9H^8O^2$, and forms with fuming sulphuric acid a conjugated acid, the barium-salt of which is soluble in water. Cholesterin heated with strong sulphuric acid gives up water and forms a resinous hydrocarbon, $C^{26}H^{42}$ (Zwenger, Ann. Ch. Pharm. lxv. 5). Heated to 200°, with acetic, butyric, benzoic, and stearic acids, it forms compound ethers, with elimination of water, thus:

$$\underbrace{\left.\begin{matrix}C^{18}H^{35}O\\ H\end{matrix}\right\}O}_{\text{Stearic acid.}} + \underbrace{\left.\begin{matrix}C^{26}H^{43}\\ H\end{matrix}\right\}O}_{\text{Cholesterin.}} = \underbrace{\left.\begin{matrix}C^{18}H^{35}O\\ C^{26}H^{43}\end{matrix}\right\}O}_{\text{Stearate of cholesterin.}} + H^2O$$

7. *Saligenin*, $C^7H^8O^2$, an alcohol of the salicyl-series, and *Anisic alcohol*, $C^8H^{10}O^2$, produced by the action of alcoholic potash on hydride of anisyl, $C^8H^7O^2.H$, are probably monatomic; if so, they must contain oxygen-radicles, their rational formulæ being $\left.\begin{matrix}C^7H^7O\\ H\end{matrix}\right\}O$ and $\left.\begin{matrix}C^8H^9O\\ H\end{matrix}\right\}O$; but they may also be diatomic alcohols, $\left.\begin{matrix}C^7H^6\\ H^2\end{matrix}\right\}O^2$ and $\left.\begin{matrix}C^8H^8\\ H^2\end{matrix}\right\}O^2$. Their reactions are not sufficiently known to decide the question.

B. **Diatomic Alcohols,** or **Glycols.** $C^nH^{2n+2}O^2 = \left.\begin{matrix}(C^nH^{2n})''\\ H^2\end{matrix}\right\}O^2$. These compounds, discovered by Wurtz, are derived from a double molecule of water, $\begin{matrix}H^2\\ H^2\end{matrix}O^2$, in which half the hydrogen is replaced by a diatomic radicle C^nH^{2n}. Four of these have been obtained, viz. *Ethylene-glycol*, or *Hydrate of Ethylene*, $C^2H^6O^2 = \left.\begin{matrix}(C^2H^4)''\\ H^2\end{matrix}\right\}O^2$, *Propylene-glycol*, $C^3H^8O^2$, *Butylene-glycol*, $C^4H^{10}O^2$, and *Amylene-glycol*, $C^5H^{12}O^2$. The simple name *glycol* is especially applied to the first of these, just as the term alcohol is especially applied to hydrate of ethyl, the most important of the monatomic alcohols.

Glycol is obtained by treating iodide of ethylene with acetate of silver, whereby diacetate of ethylene is formed:

$$\underbrace{C^2H^4I^2}_{\text{Iodide of ethylene.}} + \underbrace{\left.\begin{matrix}(C^2H^3O)^2\\ Ag^2\end{matrix}\right\}O^2}_{\text{2 at. acetate of silver.}} = \underbrace{\left.\begin{matrix}C^2H^4\\ (C^2H^3O)^2\end{matrix}\right\}O^2}_{\text{Diacetate of ethylene.}} + 2AgI,$$

and heating the distilled diacetate of ethylene with potash, whereby it is decomposed, like other compound ethers, yielding acetate of potassium and hydrate of ethylene:

$$\left.\begin{matrix}C^2H^4\\ (C^2H^3O^2)^2\end{matrix}\right\}O^2 + 2(KHO) = \left.\begin{matrix}C^2H^4\\ H^2\end{matrix}\right\}O^2 + \left.\begin{matrix}(C^2H^3O)^2\\ K^2\end{matrix}\right\}O^2$$

It was discovered by Wurtz in 1856. The other bodies of the series are obtained by similar processes. They are oily liquids, which distil without decomposition. They contain two atoms of basic hydrogen, one or both of which may be replaced by metals or other radicles.

Glycol treated with sodium yields *monosodic glycol*, $C^2H^4(NaH)O^2$, and this compound, fused with excess of sodium, yields *disodic glycol*, $C^2H^4Na^2O^2$. By treating monosodic glycol with iodide of ethyl, the product with potassium, and this product again with iodide of ethyl, the compounds $C^2H^4(C^2H^5.H)O^2$, $C^2H^4(C^2H^5.K)O^2$, and $C^2H^4(C^2H^5)^2O^2$, are successively obtained. The last is isomeric with acetal, but not identical with it (p. 3), inasmuch as it boils at a temperature 20° below that compound.

Dehydrating agents, such as sulphuric acid and chloride of zinc, do not act upon the glycols in the same manner as upon the corresponding monatomic alcohols. Ethyl-alcohol, $C^2H^5.H.O$, acted upon by sulphuric acid, or chloride of zinc, at certain temperatures, is converted into ether, $(C^2H^5)^2O$, a second atom of ethyl being introduced in place of the remaining hydrogen. If glycol were acted on by these reagents in the same manner, the result would be a glycolic ether containing $(C^2H^4)^2O^2$. Instead of this, the change which takes place is a simple abstraction of water, and the resulting compound is *aldehyde*, C^2H^4O, a body of isomeric composition, but only half the atomic weight:

$$C^2H^6O^2 - H^2O = C^2H^4O.$$

Similar results are obtained with the other glycols. The aldehydes are isomeric with the ethers of the diatomic alcohols (see ETHERS, and ETHYLENE, OXIDE OF); and their mode of formation from these alcohols differs from the etherification of the monatomic alcohols in the same manner as the conversion of dibasic acids into anhydrides differs from that of monobasic acids,—the latter being converted into anhydrides by duplication of the radicle: *e. g.* acetic acid = $C^2H^3O.H.O$; acetic anhydride = $(C^2H^3O)^2O$, whereas dibasic acids pass to the state of anhydrides by simple abstraction of water, *e. g.* $SO^4H^2 - H^2O = SO^3$. (Wurtz, Compt. rend. xlvii. 346.)

By treating diatomic alcohols, first with hydrochloric acid and afterwards with potash, compounds are obtained isomeric with the aldehydes, and resembling them in some of their properties, but differing in others; thus, ethylene-glycol, heated in a sealed tube with hydrochloric acid, yields *monochlorhydric glycol*, C^2H^5ClO, a compound intermediate between glycol and chloride of ethylene, $C^2H^4Cl^2$, and formed from glycol by the substitution of Cl for 1 atom of peroxide of hydrogen:

$$C^2H^4.H^2O^2 + HCl = C^2H^4.HO.Cl + H^2O;$$

and this compound, treated with potash, yields oxide of ethylene, a body isomeric with acetic aldehyde:

$$C^2H^4.HO.Cl + KHO = C^2H^4O + H^2O + KCl.$$

This oxide of ethylene resembles aldehyde in being miscible with water, and in forming a crystalline compound with acid sulphite of sodium; but differs from it by boiling at a lower temperature, and by not forming a crystalline compound with ammonia. Similar results are obtained with propylene-glycol. (Wurtz, Compt. rend. xlviii. 100.)

The glycols corresponding to the other series of monatomic alcohols, have not yet been obtained; but several diatomic compound ethers containing benzylene, C^7H^6, have been produced, viz. the acetate, valerate, and benzoate, $C^7H^6.(C^2H^3O)^2.O^2$, &c.; the methylate, ethylate, and amylate, $C^7H^6.(CH^3)^2.O^2$, &c.; the sulphate, $SO^4.C^7H^6$, and the succinate, $C^7H^6.C^4H^4O^2.O^2$. The diatomic alcohol, $C^7H^6.H^2O^2$, corresponding to those compound ethers, has not yet been obtained, not being produced when the ethers are decomposed by alkalis. (W. Wicke, Ann. Ch. Pharm. cii. 363.)

C. **Triatomic Alcohols, or Glycerins.** The general formula of these compounds is $\left.\begin{matrix}C^nH^{2n-1}\\H^3\end{matrix}\right\}O^3$, the radicle C^nH^{2n-1} being equivalent to three atoms of hydrogen. One term of the series has long been known, viz. ordinary glycerin, $C^3H^8O^3 = \left.\begin{matrix}C^3H^5\\H^3\end{matrix}\right\}O^3$, the sweet oily liquid obtained in the saponification of fats. It was first shown to be a triatomic alcohol by Berthelot, in 1853. (Compt. rend. xxxvii. 398.)

The neutral fats of the animal body, stearin, palmitin, olein, &c., consist of glycerin, in which three atoms of hydrogen are replaced by acid radicles; and by heating glycerin with acids in different proportions, a large number of compounds may be formed, in which $\frac{1}{3}$, $\frac{2}{3}$, or the whole of the replaceable hydrogen is thus replaced, the formation of these compounds being accompanied by the elimination of 1, 2, or 3 atoms of water. Thus, with stearic acid, $C^{18}H^{36}O^2$, the following compounds are obtained:

Monostearin $= C^{21}H^{42}O^4 = C^3H^8O^3 + C^{18}H^{36}O^2 - H^2O = \left.\begin{matrix}(C^3H^5)'''\\H^2.C^{18}H^{35}O\end{matrix}\right\}O^3.$

Distearin $= C^{39}H^{76}O^5 = C^3H^8O^3 + 2C^{18}H^{36}O^2 - 2H^2O = \left.\begin{matrix}(C^3H^5)'''\\H.(C^{18}H^{35}O)^2\end{matrix}\right\}O^3$

Tristearin (natural stearin) $= C^{57}H^{110}O^6 = C^3H^8O^3 + 3C^{18}H^{36}O^2 - 3H^2O = \left.\begin{matrix}(C^3H^5)'''\\(C^{18}H^{35}O)^3\end{matrix}\right\}O^3.$

Precisely similar actions take place on heating glycerin with hydrochloric, hydrobromic, or hydriodic acid; but to refer the resulting compounds to the same type, it is best to write the formula of glycerin thus: $C^3H^5(HO)^3$, representing it as a compound of glyceryl with 3 at. peroxide of hydrogen: then the compounds just mentioned may be represented as glycerin in which 1, 2, or 3 at. peroxide of hydrogen are replaced by Cl, Br, I, &c. Thus:

Monochlorhydrin $= C^3H^7ClO^2 = C^3H^8O^3 + HCl - H^2O = C^3H^5Cl(HO)^2$
Dichlorhydrin $= C^3H^6Cl^2O = C^3H^8O^3 + 2HCl - 2H^2O = C^3H^5Cl^2(HO)$
Trichlorhydrin $= C^3H^5Cl^3 = C^3H^8O^3 + 3HCl - 3H^2O$
Bromhydrodichlorhydrin $= C^3H^5Cl^2Br = C^3H^8O^3 + 2HCl + HBr - 3H^2O$.

The chlorhydrins and bromhydrins are likewise produced by treating glycerin with either of the bromides or chlorides of phosphorus. (See GLYCERIN.)

By treating glycerin with the chloride of an acid radicle, or by passing hydrochloric acid gas into a solution of glycerin in the corresponding acid, compounds are formed which may be regarded as glycerin, in which the peroxide of hydrogen is replaced partly by chlorine and partly by the peroxide of the acid radicle; thus with acetic acid [$Ac = C^2H^3O$]:

Acetochlorhydrin $= C^5H^9ClO^3 = C^3H^8O^3 + C^2H^4O^2 + HCl - 2H^2O = C^3H^5.Cl(AcO)(HO)$.
Diacetochlorhydrin $= C^7H^{11}ClO^4 = C^3H^8O^3 + 2C^2H^4O^2 + HCl - 3H^2O = C^3H^5.Cl(AcO)^2$
Acetodichlorhydrin $= C^5H^6Cl^2O^2 = C^3H^8O^3 + C^2H^4O^2 + 2HCl - 3H^2O = C^3H^5.Cl^2AcO$.

(For further details, see ACETINS, p. 25.)

All these compounds, when heated with caustic alkalis, or with metallic oxides and water, reproduce the acid and the glycerin; thus stearin heated with caustic potash, yields glycerin and stearate of potassium:

$$\left.\begin{matrix}C^3H^5\\(C^{18}H^{35}O)^3\end{matrix}\right\}O^3 + 3KHO = \left.\begin{matrix}C^3H^5\\H^3\end{matrix}\right\}O^3 + 3\left(\left.\begin{matrix}C^{18}H^{35}O\\K\end{matrix}\right\}O\right)$$

Glycerin may also be formed synthetically in a similar manner to glycol, viz. by heating tribromhydrin, $C^3H^5Br^3$, with acetate of silver, whereby triacetin, $C^3H^5Ac^3O^3$ is formed, and heating this compound with solution of caustic baryta. The other glycerins have not yet been obtained in the free state, but the *acetate of ethyl-glycerin* $(C^2H^3)'''Ac^3O^3$ appears to be obtained, together with glycol, by the action of iodide of ethylene on acetate of silver.

D. **Alcohols not included in any of the preceding groups.**—Berthelot has shown that a considerable number of substances, not usually classed as alcohols, nevertheless possess one essential character of those bodies, viz. that they unite with acids, producing neutral compounds, the formation of which is attended with elimination of water; and these compounds, when heated with alkalis, reproduce the substances from which they have been formed. The bodies in question are chiefly of a saccharine nature, viz. *Mannite*, $C^6H^{12}O^5.H^2O$, the sugar of manna; *Dulcin*, $C^6H^{12}O^5.H^2O$, a saccharine substance from an unknown plant, brought from Madagascar; *Pinite*, $C^6H^{12}O^5$, a sugar from the *Pinus lambertiana*, a tree growing in California; *Quercite*, $C^6H^{12}O^5$, the sugar of acorns; *Erythromannite*, *Erythroglucin*, or *Phycite*, $C^6H^{14}O^6$, a sugar obtained from certain lichens, and from the *Protococcus vulgaris*.—*Orcin*, $C^7H^8O^2$, a sweet crystalline substance, existing in the lichens which yield archil and litmus; *Trehalose*, $C^6H^{10}O^5$, also a kind of sugar; *Glucose*, $C^6H^{12}O^6$, and *Meconin*, $C^{10}H^{10}O^4$, an acrid crystallisable substance, obtained from opium. The following are examples of the compounds formed:

$$\underset{\text{Mannitan.}}{C^6H^{12}O^5} + \underset{\text{Acetic acid.}}{2C^2H^4O^2} - 2H^2O = C^{10}H^{16}O^7$$

$$\underset{\text{Mannitan.}}{C^6H^{12}O^5} + \underset{\text{Stearic acid.}}{4C^{18}H^{36}O^2} - 2H^2O = C^{78}H^{152}O^{11}$$

$$\underset{\text{Mannitan.}}{C^6H^{12}O^5} + \underset{\text{Stearic acid.}}{6C^{18}H^{36}O^2} - 6H^2O = C^{114}H^{216}O^{11}$$

$$\underset{\text{Phycite.}}{C^6H^{14}O^6} + \underset{\text{Benzoic acid.}}{2C^7H^6O^2} - 2H^2O = C^{20}H^{22}O^8 \quad (?)$$

$$\underset{\text{Phycite.}}{C^6H^{14}O^6} + \underset{\text{Benzoic acid.}}{6C^7H^6O^2} - 6H^2O = C^{48}H^{38}O^{12} \quad (?)$$

$$\underset{\text{Glucose.}}{C^6H^{12}O^6} + \underset{\text{Stearic acid.}}{2C^{18}H^{36}O^2} - 3H^2O = C^{42}H^{78}O^7$$

$$\underset{\text{Meconin.}}{C^{10}H^{10}O^4} + \underset{\text{Stearic acid.}}{2C^{18}H^{36}O^2} - 2H^2O = C^{46}H^{78}O^6.$$

The compounds formed by all these bodies, excepting the last two, with acids, readily yield the original saccharine substance and the acid. The compounds formed with glucose are not very definite, and not easily decomposed; but when treated with dilute sulphuric acid, they yield the original acid and a fermentable sugar, which reduces copper salts. (Berthelot, Compt. rend. xli. 452; xlvii. 262.)

ALDEHYDE. $C^2H^4O = C^2H^3O.H.$ [or $C^4H^4O^2 = C^4H^3O.HO$]. *Acetic aldehyde, Hydride of Acetyl* (Gm. viii. 274; xiii. 437; Gerh. i. 658).—A volatile liquid produced by the oxidation and destructive distillation of alcohol and other organic compounds. It was first obtained in an impure state by Döbereiner, who called it *Light oxygen ether*, and was afterwards prepared pure and thoroughly examined by Liebig (Ann. Ch. Pharm. xiv. 133; xxxvi. 376). The name *aldehyde* is an abbreviation of *alcohol dehydrogenatum*, inasmuch as the compound may be regarded as alcohol deprived of two atoms of hydrogen.

Formation.—1. In the oxidation of alcohol, either by slow combustion in contact with platinum-black, chromic oxide, &c., or by the action of chromic acid, nitric acid, chlorine water, or a mixture of sulphuric acid and peroxide of manganese (see ALCOHOL, p. 74).—2. When the vapour of alcohol or ether is passed through a tube heated to dull redness; also in the slow combustion of ether.—3. In the decomposition of acetate of ethyl, and probably also of other ethylic ethers, by a mixture of sulphuric acid and acid chromate of potassium.—4. By heating acetal with glacial acetic acid to between 150° and 200° C. for two days. Acetic ether and alcohol are formed at the same time, and on distilling the mixture, aldehyde passes over below 60°:

$$\underbrace{C^6H^{14}O^2}_{\text{Acetal.}} + \underbrace{C^2H^4O^2}_{\text{Acetic acid.}} = \underbrace{C^2H^4O}_{\text{Aldehyde.}} + \underbrace{C^4H^8O^2}_{\text{Acetic ether.}} + \underbrace{C^2H^6O}_{\text{Alcohol.}}$$

also by heating acetal with acetic anhydride:

$$C^6H^{14}O^2 + C^4H^6O^3 = C^2H^4O + 2C^4H^8O^2.$$

A few drops of liquid are also obtained boiling above 150°, and probably consisting of a compound of aldehyde with acetic anhydride (Beilstein, Compt. rend. xlviii. 1121).—5. By heating ethyl-sulphuric acid or one of its salts with a mixture of sulphuric acid and peroxide of manganese. This formation of aldehyde is said to take place under circumstances which altogether preclude any previous formation of alcohol (Jacquemin and Liès-Bodard, l'Institut, 1857, p. 407).—6. When hemp-oil is passed through a gun-barrel heated to low redness, a liquid is formed containing a large quantity of aldehyde, together with alhehydic or lampic acid (Hess).—7. By the dry distillation of lactic acid, lactic anhydride, and lactates with weak bases, such as lactate of copper, carbonic oxide being given off at the same time:

$$\underbrace{C^6H^{12}O^6}_{\text{Lactic acid.}} = \underbrace{2C^2H^4O}_{\text{Aldehyde.}} + 2CO + 2H^2O.$$

8. Lactic acid and the lactates also yield considerable quantities of aldehyde when distilled with sulphuric acid and peroxide of manganese (Städeler, Ann. Ch. Pharm. lxxix. 333).—9. In the decomposition of animal albumin, fibrin, casein, and gelatin by a mixture of sulphuric acid and peroxide of manganese, or bichromate of potassium (Guckelberger), also of vegetable fibrin by sulphuric acid and peroxide of manganese (Keller).—10. By the dry distillation of a mixture of acetate and formate of calcium in equal numbers of atoms (Limpricht. See ALDEHYDES, p. 111; also ACETONES, p. 31).

$$\underbrace{C^2H^3CaO^2}_{\text{Acetate of calcium.}} + \underbrace{CHCaO^2}_{\text{Formate of calcium.}} = \underbrace{C^2H^4O}_{\text{Aldehyde.}} + \underbrace{CO^3Ca^2}_{\text{Carbonate of calcium.}}.$$

Preparation.—1. Two pts. of 80 per cent. alcohol are mixed with 3 pts. peroxide of manganese, 3 pts. oil of vitriol and 2 pts. water, and distilled into a receiver kept at a very low temperature. The mixture is gently heated till it begins to froth slightly, and the distillation is interrupted as soon as the liquid which passes over begins to redden litmus, which it does when the distillate amounts to 3 pts. The distillate, consisting of aldehyde, alcohol, &c., is mixed with an equal weight of chloride of calcium, and distilled (the receiver being constantly kept very cold), till 1½ pt. has passed over, and this distillate is again rectified with an equal weight of chloride of calcium till ¾ pt. has passed over. This last portion is anhydrous, but contains alcohol and certain compound ethers as well as aldehyde. To purify it, 1 vol. is mixed with 2 vol. ether, the mixture surrounded with cold water, and dry ammoniacal gas passed into it to saturation; the gas is absorbed rapidly and with great evolution of heat, and the aldehyde separates out in crystals of aldehyde-ammonia. These crystals are washed three times with absolute ether and dried as above. (Liebig.)

2. A mixture of 1 pt. 80 per cent. alcohol and 2 pts. water is saturated with chlorine gas (being kept cool all the while), and the liquid distilled, as soon as it has lost the odour of chlorine, till $\frac{1}{20}$ has passed over. That which distils over afterwards is alcohol, which may be collected in a separate receiver and again treated with chlorine as above. The first distillate is again freed from water by repeated distillation so far as to admit of its being saturated with ammonia as above, and yields a very large crop of crystals. (Liebig.)

3. One part of alcohol of sp. gr. 0·842 and 1 pt. of bichromate of potassium are introduced into a capacious tubulated retort and 1⅓ pt. oil of vitriol admitted by drops through the tubulus. The heat evolved by the chemical action which ensues is sufficient to begin the distillation, but towards the end, heat must be applied from without. A large quantity of carbonic acid gas is evolved, and the aldehyde condenses in the well cooled receiver, contaminated with only a small quantity of acetic acid and other substances, so that the distillate may be immediately mixed with ether, and ammoniacal gas passed through it as above (W. and R. Rodgers, J. pr. Chem. xl. 248). The modes of formation 5, 6, and 8, above given, may also be advantageously used for the preparation of aldehyde.

To obtain the pure anhydrous aldehyde from the aldehyde-ammonia formed by either of these processes, a solution of 2 pts. of the aldehyde-ammonia in 2 pts. water, is distilled in a water-bath at a gentle but increasing heat, with a mixture of 3 pts. sulphuric acid and 4 pts. water, the distillation being interrupted as soon as the water in the bath begins to boil, and the receiver kept as cold as possible. The hydrated aldehyde which passes over is dried by contact with coarse lumps of chloride of calcium in a well closed vessel, and then rectified in a water-bath, at a temperature not exceeding 30°.

Properties.—Aldehyde is a thin, transparent, colourless liquid, having a pungent suffocating odour. Its specific gravity is 0·80002 at 0° (Kopp); 0·80551 at 0° (Pierre). It boils at 20·8° when the barometer stands at 760 mm. (Kopp); at 22°, with the barometer at 758·2 mm (Pierre). Vapour-density 1·532 (Liebig); (by calculation, 1·520, for a condensation to 2 vol.) It does not redden litmus, even when it is dissolved in water or alcohol.

Aldehyde may be regarded either as the *hydride of acetyl*, $C^2H^3O.H$, or as the *hydrate* or *hydrated oxide of vinyl*,  $\left.\begin{matrix}C^2H^3\\H\end{matrix}\right\}O$. Its chemical reactions may for the most part be explained equally well on either hypothesis; but according to the recent observations and calculations of Kopp, the formula $C^2H^3O.H$, is most in accordance with the observed atomic volume of aldehyde, which is between 56·0 and 56·9, the calculated atomic volume being 56·2, as deduced from the first formula, and 51·8 as deduced from the second. (See ATOMIC VOLUME: also Graham's Chemistry, 2nd Ed. vol. ii. p. 581.)—Aldehyde is isomeric, but not identical, with the oxide of ethylene, $C^2H^4.O$, recently discovered by Wurtz.

Aldehyde mixes in all proportions with *water*, *alcohol*, and *ether*. A mixture of 1 pt. aldehyde and 3 pts. water boils at 37°. Chloride of calcium added to the aqueous solution separates the aldehyde, which then rises to the surface.

Aldehyde dissolves *sulphur* and *phosphorus*, also *iodine*, forming a brown solution.

Dry sulphurous acid gas passed into anhydrous aldehyde surrounded with cold water, is rapidly absorbed, 11 pts. of aldehyde absorbing 9 pts. of the gas, with increase of volume. The absorption-coefficient of aldehyde for sulphurous acid gas is 1·4 times as great as for alcohol, and 7 times as great as for water. (Geuther and Cartmell, Ann. Ch. Pharm. cxi. 17.)

Decompositions.—1. Aldehyde is very inflammable, and burns with a blue flame.—2. When kept in close vessels, it is often converted into a less volatile liquid, or into two crystalline bodies, which are isomeric modifications of aldehyde (p. 109).—3. In vessels containing *air*, it absorbs oxygen, and is converted into acetic acid; the action is greatly accelerated by the presence of platinum black.—4. *Chlorine-water* and *nitric acid* also convert aldehyde into acetic acid.—5. By strong *sulphuric acid*, it is thickened and blackened, also by *phosphoric anhydride*.—6. When an aqueous or alcoholic solution of aldehyde is heated with *potash*, it becomes yellowish and turbid, and a red-brown resinous mass, the *resin of aldehyde*, separates on the surface, the liquid at the same time emitting a spirituous and disagreeably pungent odour. The solution is afterwards found to contain formate and acetate of potassium. This is the most characteristic reaction of aldehyde.—7. When vapour of aldehyde is passed over red-hot *potash-lime*, acetate of potassium is formed and hydrogen evolved:

$$C^2H^4O + KHO = C^2H^3KO^2 + 2H.$$

8. *Potassium* (or *sodium*) acts on aldehyde in the same manner as on alcohol, hydrogen being evolved and aldehydate of potassium, C^2H^3KO, produced.—9. When an

aqueous solution of aldehyde is heated with *oxide* or *nitrate of silver*, mixed with a small quantity of *ammonia*, the silver is reduced, forming a beautiful specular coating on the side of the vessel, and acetate of silver is formed in the solution. This reaction affords an extremely delicate test for aldehyde.—10. *Chlorine gas* in contact with aldehyde, both being dry, decomposes part of the aldehyde, forming chloride of acetyl, which then unites with the undecomposed aldehyde, forming the compound, $C^2H^4O.C^2H^3OCl$.—11. When dry *hydrochloric acid gas* is passed into anhydrous aldehyde surrounded by a freezing mixture, the gas is absorbed, and the liquid separates into two layers, the lower consisting of water saturated with hydrochloric acid, and the upper of *oxychloride of ethylidene*, $C^4H^8Cl^2O$ (A. Lieben, Compt. rend. xlvi. 662):

$$2C^2H^4O + 2HCl = C^4H^8Cl^2O + H^2O.$$

According to Geuther and Cartmell (Ann. Ch. Pharm. cxii. 13; Proc. Roy. Soc. x. 110) the first product of the action is the body, $C^6H^{12}Cl^2O^2$, which, when gently heated in an atmosphere of carbonic acid, splits up into aldehyde, C^2H^4O, and $C^4H^8Cl^2O$. The compound $C^6H^{12}Cl^2O^2$, may be regarded as a triple molecule of aldehyde ($C^6H^{12}O^3$), having one atom O replaced by Cl^2.—12. Aldehyde mixed with twice its bulk of absolute alcohol, and saturated in the cold with hydrochloric acid gas, yields the compound C^4H^9ClO, which, when treated with ethylate of sodium, forms acetal (p. 3).—13. With *pentachloride of phosphorus*, aldehyde yields chloride of ethylidene, $C^2H^4Cl^2$, and with *pentabromide of phosphorus* it yields bromide of ethylidene, $C^2H^4Br^2$, which is converted by ethylate of sodium into acetal (p. 4).—14. *Chlorocarbonic oxide* (phosgene gas) converts aldehyde into chloride of vinyl, C^2H^3Cl, with evolution of hydrochloric acid and carbonic anhydride. (Harnitz Harnitzky, Ann. Ch. Pharm. cxi. 192.)

$$C^2H^4O + COCl^2 = C^2H^3Cl + HCl + CO^2.$$

15. *Hydriodic acid* gas appears to act upon aldehyde in the same manner as hydrochloric acid, but the product is very unstable.—16. When aqueous aldehyde is saturated with *hydrosulphuric acid gas*, a viscid oil is formed, consisting of *hydrosulphate of acetyl-mercaptan:* $C^{12}H^{26}S^7 = SH^2.6C^2H^4S$. On treating this oil with strong hydrochloric or sulphuric acid, hydrosulphuric acid escapes, and a white crystalline mass remains, consisting of *acetyl-mercaptan*, C^2H^4S, a compound related to aldehyde, in the same manner as ethyl-mercaptan, C^2H^6S, to alcohol.—17. *Cyanic acid* vapour evolved from cyanuric acid is quietly absorbed by anhydrous aldehyde at 0°; but even at ordinary temperatures the mixture becomes heated, gives off carbonic anhydride, and ultimately froths up and solidifies into a mass consisting of *trigenic acid*, $C^4H^7N^3O^2$, together with small quantities of cyamelide, aldehyde-ammonia, and other products (Liebig and Wohler):

$$C^2H^4O + 3CNHO = C^4H^7N^3O^2 + CO^2.$$

ALDEHYDATES.—Aldehyde may be regarded as a monobasic acid, inasmuch as it contains one atom of hydrogen replaceable by metals. Thus, when potassium is gently heated with aldehyde, hydrogen is evolved, and aldehydate of potassium, C^2H^3KO, produced: and by evaporation in vacuo this salt may be obtained in the solid state.—Aldehydate of silver, C^2H^3AgO, is produced when oxide of silver is heated with aldehyde and ammonia. The most important of these salts is the ammonium-salt:

Aldehydate of Ammonium, Aldehyde-ammonia, Acetyl-ammonium, $C^2H^4O.NH^3 = C^2H^3O.NH^4$, or *Oxide of Vinyl and Ammonium*, $C^2H^3.NH^4.O$.—Ammoniacal gas passed into pure aldehyde combines with it, giving off heat, and forming a white crystalline mass. If the aldehyde be previously mixed with ether, the compound separates in distinct crystals; the finest are obtained by mixing a concentrated alcoholic solution of aldehyde-ammonia with ether (Liebig).—The crystals are acute rhombohedrons with terminal edges of about 85°, often truncated with the faces of another rhombohedron (G. Rose); they are transparent, colourless, shining, strongly refractive, of the hardness of common sugar, and very friable. The compound melts between 70° and 80° C., and distils unaltered at 100°. In the state of vapour or in aqueous solution, it reddens turmeric paper. Its odour is ammoniacal, but has likewise the character of turpentine (Liebig).—It dissolves very easily in water, less easily in alcohol and ether.

Aldehyde-ammonia is very inflammable. In contact with the air, especially if also exposed to light, it becomes yellow, and acquires an odour resembling that of burnt animal substances. By distillation it may again be obtained in the colourless state, and leaves a brown residue, which is soluble in water, and contains acetate of ammonium and another ammoniacal salt. Even the weaker acids, such as acetic acid, separate the aldehyde from the compound. Sulphuric acid and potash act upon it in the same manner as upon aldehyde. Its aqueous solution, digested with oxide of silver, reduces part of this oxide and dissolves the rest, forming aldehydate and acetate of silver mixed with ammonia, from which the oxide of silver is precipitated by baryta-water, and reduced when the liquid is heated, while acetate of barium remains in solution.

Aldehyde-ammonia treated with hydrosulphuric acid yields *thialdine*, $C^6H^{13}NS^2$:

$$3(C^2H^3O.NH^4) + 3H^2S = C^6H^{13}NS^2 + (NH^4)^2S + 3H^2O.$$

Similarly, with hydroselenic acid, it yields *selenaldine*, $C^6H^{13}NSe^2$. With bisulphide of carbon it forms *carbothialdine*:

$$\underbrace{2(C^2H^3O.NH^4)}_{\text{Aldehyde-ammonia.}} + CS^2 = \underbrace{C^5H^{10}N^2S^2}_{\text{Carbothialdine.}} + 2H^2O$$

Aldehyde-ammonia heated with hydrocyanic and hydrochloric acids yields *alanine:*

$$\underbrace{C^2H^4O.NH^3}_{\text{Aldehyde-ammonia.}} + \underbrace{CNH}_{\text{Hydrocyanic acid.}} + H^2O + HCl = \underbrace{C^3H^7NO^2}_{\text{Alanine.}} + NH^4Cl.$$

But when a mixture of aldehyde-ammonia and hydrocyanic acid, with sufficient hydrochloric acid to give it a distinct acid reaction, is left to itself for some time, in a closed vessel, especially in sunshine, colourless needle-shaped crystals are formed, consisting of *hydrocyanaldine*, $C^9H^{12}N^4$:

$$3(C^2H^4O.NH^3) + 3CNH + 2HCl = C^9H^{12}N^4 + 2NH^4Cl + 3H^2O.$$

Aldehyde-ammonia heated in a sealed tube to 120° C. is decomposed, and yields two layers of liquid, the upper consisting chiefly of aqueous ammonia, with small quantities of other volatile bases, while the lower, which remains behind on distilling at 200°, contains a substance which has the composition $C^{10}H^{15}NO$, and may be regarded as an *aldehydate of tetravinylium:* $=C^2H^3O.N(C^2H^3)^4$. Its formation is represented by the equation:

$$5(C^2H^3O.NH^4) = C^{10}H^{15}NO + 4NH^3 + 4H^2O.$$

By treating this compound with baryta-water, the group C^2H^3O is replaced by HO. and *hydrate of tetravinylium* is formed.

$$C\,H^3O.N(C^2H^3)^4 + BaHO = C^2H^3O.Ba + N(C^2H^3)^4.H.O.$$

(Babo, J. pr. Chem. lxxii. 88; Chem. Gaz. 1858, 136.)

Concentrated aqueous solutions of aldehyde-ammonia and nitrate of silver yield, when mixed, a fine-grained white precipitate, probably consisting of $NO^3Ag.2(C^2H^3O.NH^4)$. It dissolves very sparingly in alcohol, easily in water.

Sulphite of Aldehyde-ammonia, or *Sulphite of Vinyl-ammonium*, $C^2H^3(NH^4)O.SO^2 = (C^2H^3.NH^4).SO^3$.—Sulphurous acid gas passed into a solution of aldehyde-ammonia in absolute alcohol is rapidly absorbed; and if the liquid be kept cool, sulphite of aldehyde-ammonia is deposited in small white prisms, which may be washed with alcohol and dried in vacuo. This compound is isomeric with taurin, $C^2H^7NO^3S$—a substance produced by the metamorphosis of a sulphur-acid contained in the bile—but possesses very different properties. It is soluble in water and in aqueous alcohol, very sparingly in absolute alcohol. The crystals decompose slowly in the air at ordinary temperatures, turn brown and lose weight at 100°, and are completely decomposed at higher temperatures, leaving a spongy carbonaceous residue. Acids decompose them, liberating aldehyde and sulphurous anhydride. When strongly heated with potash-lime, they give off ethylamine (Gössmann, Ann. Ch. Pharm. xci. 122), or rather perhaps dimethylamine:

$$C^2H^3.NH^4.SO^3 + KHO = C^2H^7N + SO^4.HK.$$

COMPOUND OF ALDEHYDE WITH ACETIC ANHYDRIDE, $C^6H^{10}O^4 = C^4H^6O^3.C^2H^4O$.—When 1 at. acetic anhydride and 1 at. pure aldehyde are heated together in a sealed tube to 180° C. for about 12 hours, they unite and form a liquid compound which may be freed from unaltered aldehyde and acetic anhydride by fractional distillation, further purified by washing the portion which passes over above 140° with hot water, and dehydrated over chloride of calcium. It then boils at 168°. It has an alliaceous odour and slight acid reaction, probably arising from decomposition during distillation. Heated with hydrate of potassium, it yields acetate of potassium, giving off the peculiar odour of aldehyde when similarly treated. This reaction distinguishes the compound from Wurtz's acetate of ethylene (acetate of glycol), $C^2H^4(C^2H^3O)^2.O^2$ with which it is isomeric: for that compound heated with caustic alkalis, yields hydrate of ethylene (glycol), without any odour of aldehyde. (Geuther, Ann. Ch. Pharm. cvi. 249.)

Aldehyde appears to form similar compounds with *benzoic* and *succinic anhydrides*.

Compound of Aldehyde with Chloride of Acetyl, $C^4H^7ClO^2 = C^2H^4O.C^2H^3OCl$. —Chloride of acetyl and aldehyde heated together to 100° for three hours in a sealed tube, unite and form a liquid which distils completely between 90° and 140° C. and yields by fractional distillation a considerable quantity of liquid, boiling between 120° and 124°. This liquid is lighter than water; is very slowly decomposed by cold water, more quickly by hot water; and dissolves easily in dilute potash, forming chloride and acetate of potassium, and yielding free aldehyde which is partly resinised by the potash. Moist oxide of silver also decomposes it, forming chloride and acetate of silver. (Maxwell Simpson, Compt.-rend. xlvii. 174.)

The same compound is produced, according to Wurtz (Ann. Ch. Phys. [3] xliv. 58), together with chloride of acetyl, by introducing perfectly dry aldehyde into a large vessel filled with dry chlorine. Its formation is due to the union of the chloride of acetyl first produced with the remaining aldehyde (compare p. 106). Wurtz, however, regards it as a double molecule of aldehyde ($C^4H^8O^2$), having 1 at. H replaced by chlorine.

Modifications of Aldehyde.—Aldehyde is susceptible of four isomeric modifications, two liquid and two solid.

a. Liquid modifications.—1. Pure aldehyde sealed up in a tube changes in the course of a few weeks into a liquid, which has a pleasant ethereal odour, boils at about 81°, and no longer forms a resin with potash; it may be exposed to the air without oxidising, and floats on water without mixing. (Liebig)

2. Pure aldehyde mixed with about half its bulk of water and a trace of sulphuric or nitric acid, and cooled to 0° C., changes into a liquid which is no longer miscible with water, and after being purified by agitation with water, and rectification over chloride of calcium, boils at 125°. It has a peculiar aromatic burning taste, and is soluble in alcohol and ether, sparingly also in water. Its vapour-density is 4·583, which for a condensation to 2 volumes, corresponds to the formula $C^6H^{12}O^3$. When left to itself, or in contact with water, it readily changes into an acid, and then becomes miscible with water; occasionally also crystals separate from it at the same time. When heated with a small quantity of sulphuric or nitric acid, it is converted into ordinary aldehyde. (Weidenbusch, Ann. Ch. Pharm. lxvi. 155.)

b. Solid modifications.—1. *Solid and fusible Elaldehyde.*—Anhydrous aldehyde, enclosed in a tube, together with pieces of chloride of calcium, for two months in winter, yielded long transparent prisms, which, however, disappeared again after a fortnight, so completely that not a trace of them could be perceived in the liquid.—These crystals melt at + 2° C., forming a liquid which solidifies at 0°, and boils at 94°, giving off a vapour whose density is 4·5157. In the fused state, this substance has an ethereal odour; more agreeable and less pungent than that of aldehyde; its taste is somewhat burning. Its burns with a blue flame; its vapour passed through a red-hot tube yields a combustible gaseous mixture, and a small quantity of a liquid having an empyreumatic odour. Oil of vitriol blackens the crystals slowly in the cold, immediately when heated. The crystals may be heated with potash-ley for some time without becoming coloured, and solidify again on the surface as the liquid cools. When heated with aqueous nitrate of silver, they throw down the silver in the form of a grey powder, not as a specular coating. When dissolved in ether, they do not absorb ammoniacal gas but remain unaltered. (Fehling, Ann. Ch. Pharm. xxvii. 319.)

Geuther and Cartmell (Ann. Ch. Pharm. cxi. 16) have obtained a similar modition, by saturating common aldehyde with sulphurous acid gas, dissolving the resulting liquid in water, saturating the acid with chalk, distilling, and treating the distillate with potash, which separates the remaining common aldehyde in the resinous form, and leaves the modified aldehyde in the form of a clear liquid, which boils at 124° C., like the modification obtained by Weidenbusch, and solidifies at 10°, starting into crystals which also begin to melt at 10°.

2. *Solid and infusible Metaldehyde.*—Anhydrous aldehyde kept for some time in a sealed tube or well stoppered bottle, frequently deposits transparent, colourless, four-sided prisms, which traverse the whole liquid like a network. The crystals remain solid at 100° C., but at a stronger heat sublime undecomposed, in the form of transparent, colourless, shining, rather hard needles, which are easily pulverised, inodorous, combustible, scarcely at all soluble in water, but easily soluble in alcohol and ether (Liebig).—Fehling, by exposing pure aldehyde to the cold of winter for several weeks, once obtained the same crystals, mixed, however, with a larger quantity of the crystals *b*. They are hard and easy to pulverise; at 120° they sublime without previous fusion. When they are suffered to evaporate in the air, the vapour condenses in fine snowy flakes (Liebig). Heated for some time to 180° in sealed tubes they are reconverted into ordinary aldehyde. (Geuther, Ann. Ch. Pharm. cvi. 252.)

Aldehyde-resin.—A resinous body obtained by heating aldehyde with potash, either in aqueous or in alcoholic solution, especially the latter. It is also formed in solutions of the alkalis in alcohol, and in acetal, when kept for a long time. According to Weidenbusch (Ann. Ch. Pharm. lxvi. 153) it is a substance of a fiery orange colour which is reduced by drying at 100°, to a powder, having a paler tint. It dissolves in alcohol and ether, sparingly in water, scarcely at all in alkalis, partially in strong sulphuric acid, from which it is precipitated by water. When purified as completely as possible, it contains 76·4 per cent. of carbon, and 8·0 per cent. of hydrogen: its formation is accompanied by that of acetic, formic and acetylous [?] acid; at the same time a pungent odour is evolved, proceeding from a peculiar substance which adheres obstinately to the resin. This substance is oily and volatile when first produced, but soon thickens, even when alone and still more quickly under the influence of nitric acid, and is converted into a golden-yellow, viscid resin, which smells like cinnamon, dissolves in alcohol and ether, and sparingly in water, and is different from the true aldehyde-resin.

ALDEHYDES. A class of organic compounds intermediate between alcohols and acids. They are derived from alcohols by abstraction of 2 atoms of hydrogen, and are converted into acids by addition of 1 atom of oxygen: thus in the fatty acid series:

$$\underbrace{C^nH^{2n+2}O}_{\text{Alcohol.}} - H^2 = \underbrace{C^nH^{2n}O}_{\text{Aldehyde.}}, \text{ and } \underbrace{C^nH^{2n}O}_{\text{Aldehyde.}} + O = \underbrace{C^nH^{2n}O^2}_{\text{Acid.}}$$

Aldehydes may be regard d as derivatives: 1. Of a molecule of hydrogen HH, half the hydrogen being replaced by an oxygen-radicle: *e.g.* benzoic aldehyde or bitter-almond oil, $C^7H^6O = C^7H^5O.H.$—2. Of a molecule of water, half the hydrogen being replaced by a monatomic hydrocarbon, *e. g.* benzoic aldehyde = $\left.\begin{matrix}C^7H^5\\H\end{matrix}\right\}O$; acetic aldehyde = $\left.\begin{matrix}C^2H^3\\H\end{matrix}\right\}O$.—3. Of a molecule of water, in which the whole of the hydrogen is replaced by a diatomic hydrocarbon: *e. g.* acetic aldehyde = $(C^2H^4.)''O$. According to this last view, which is strongly corroborated by the action of sulphuric acid and chloride of zinc upon glycol (p. 102), the aldehydes are isomeric with the ethers or anhydrides of the diatomic alcohols, and are related to them in the same manner as the dibasic anhydrides to the dibasic acids; thus

Type	H^4O^2	Type	H^2O
Sulphuric acid	$\left.\begin{matrix}SO^2\\H^2\end{matrix}\right\}O^2$	Sulphuric anhydride	$SO^2.O$
Glycol	$\left.\begin{matrix}C^2H^4\\H^2\end{matrix}\right\}O^2$	Aldehyde	$C^2H^4.O.$

The following are the aldehydes at present known.

1. Aldehydes of the form $C^nH^{2n}O = \left.\begin{matrix}C^nH^{2n-1}\\H\end{matrix}\right\}O = C^{2n}H^{2n-1}O.H.$

Acetic aldehyde	C^2H^4O	Caprylic aldehyde [?]	$C^8H^{16}O$
Propionic ,,	C^3H^6O	Enodic ,,	$C^{11}H^{22}O$
Butyric ,,	C^4H^8O	Lauric ,,	$C^{12}H^{24}O$
Valeric ,,	$C^5H^{10}O$	Palmitic ,,	$C^{16}H^{32}O$
Œnanthylic ,,	$C^7H^{14}O$		

2. Aldehyde of the form $C^nH^{2n-2}O = \left.\begin{matrix}C^nH^{2n-3}\\H\end{matrix}\right\}O = C^nH^{2n-3}O.H.$

Acrylic aldehyde, or Acrolein, C^3H^4O.

3. Aldehyde of the form $C^nH^{2n-4}O = \left.\begin{matrix}C^nH^{2n-5}\\H\end{matrix}\right\}O = C^nH^{2n-5}O.H$

Campholic aldehyde, or Camphor, $C^{10}H^{16}O$.

4. Aldehydes of the form $C^nH^{2n-8}O = \left.\begin{matrix}C^nH^{2n-9}\\H\end{matrix}\right\}O = C^nH^{2n-9}O.H.$

Benzoic aldehyde, or Bitter-almond oil, C^7H^6O.
Cuminic aldehyde, or Oil of Cumin, $C^{10}H^{12}O$.

5. Aldehyde of the form $C^nH^{2n-10}O = \left.\begin{matrix}C^nH^{2n-11}\\H\end{matrix}\right\}O$, or $C^nH^{2n-11}O.H.$

Cinnamic aldehyde, or Oil of Cinnamon, C^9H^8O.

6. Aldehydes of the form $C^nH^{2n-8}O^2 = \left.\begin{matrix}C^nH^{2n-9}O\\H\end{matrix}\right\}O$, or $C^nH^{2n-9}O^2.H.$

Salicylic aldehyde, or Salicylous acid, $C^7H^6O^2$.
Anisylic aldehyde, or Anisylous acid, $C^8H^8O^2$.

The aldehydes corresponding to known alcohols may all be formed from those alcohols by oxidation, either by exposure to the air in contact with platinum-black, or by distillation with a mixture of dilute sulphuric acid and peroxide of manganese or acid chromate of potassium. Aldehydes may also be prepared from the corresponding acids by a general process, viz. by distilling a mixture of the barium-salt of the acid with an equivalent quantity of formate of barium, thus:

$$\underbrace{\left.\begin{matrix}C^7H^5O\\ Ba\end{matrix}\right\}O}_{\text{Benzoate of barium.}} + \underbrace{\left.\begin{matrix}CHO\\ Ba\end{matrix}\right\}O}_{\text{Formate of barium.}} = \underbrace{\left.\begin{matrix}C^7H^5O\\ H\end{matrix}\right\}}_{\text{Hydride of benzoyl.}} + \underbrace{\left.\begin{matrix}CO\\ Ba^2\end{matrix}\right\}O^2}_{\text{Carbonate of barium.}}$$

(**Limpricht**, Ann. Ch. Pharm. xcvii. 368; **Piria**, Ann. Ch. Phys. [3] xlviii. 113). This process is a particular case of Williamson's method of producing compound acetones (p. 31).

Several aldehydes, as benzoic, acetic, propionic, butyric, &c. are produced by the distillation of albumin, fibrin, casein, and gelatin with peroxide of manganese and sulphuric acid. Some are formed in the destructive distillation of organic acids, as acetic aldehyde from lactic acid, œnanthylic aldehyde from ricinolic acid. Caprylic aldehyde is said by some chemists to be produced (together with the corresponding alcohol), by distilling ricinolic acid with excess of potash. According to **Bouis** (Compt. rend. xli. 603), a new acid, $C^{10}H^{18}O^2$, is formed at the same time:

$$\underbrace{C^{18}H^{34}O^3}_{\text{Ricinolic acid.}} = \underbrace{C^8H^{16}O}_{\text{Caprylic aldehyde.}} + C^{10}H^{18}O^2.$$

But according to **Malaguti** (Cimento, iv. 401), the acid formed is sebacic acid thus:

$$\underbrace{C^{18}H^{34}O^3}_{\text{Ricinolic acid.}} + 2O = \underbrace{C^8H^{16}O}_{\text{Caprylic aldehyde.}} + \underbrace{C^{10}H^{18}O^4}_{\text{Sebacic acid.}}$$

This decomposition is supposed to take place simultaneously with that by which octylic (caprylic) alcohol is produced (p. 97). The aldehyde might indeed be produced by oxidation of the alcohol. According to **Städeler**, on the other hand (J. pr. Chem. lxxxiii. 241), the product $C^8H^{16}O$ thus formed is not caprylic aldehyde, but methyl-œnanthyl, $CH^3.C^7H^{13}O$, a body isomeric with it (p. 97).

Many aldehydes are obtained directly from plants, either existing ready formed in the plants, or being given off as volatile oils on distilling the plants with water. Thus, benzoic aldehyde constitutes the essential part of bitter-almond oil, cinnamic aldehyde of cinnamon oil, cuminic aldehyde of Roman cumin oil, and salicylic aldehyde or salicylous acid, of oil of spiræa. Oil of rue consists principally of euodic aldehyde, mixed with a small quantity of lauric aldehyde (C. G. **Williams**, Proc. Roy. Soc. ix. 167). It was formerly supposed to be capric aldehyde. Benzoic aldehyde is also produced by the action of nascent hydrogen (evolved by the action of zinc on hydrochloric acid) on cyanide of benzoyl, hydrocyanic being formed at the same time:

$$C^7H^5O.Cy + HH = C^7H^5O.H + CyH.$$

This mode of formation corresponds with the representation of aldehydes as hydrides of acid radicles.

All the known aldehydes (except palmitic aldehyde, which is a fatty solid) are liquids, which volatilise without decomposition. They are very prone to oxidation, being converted into acids more or less quickly by mere exposure to the air. In consequence of this tendency to oxidation, they easily reduce the oxides of the noble metals (see p. 106). Many aldehydes are converted by hydrate of potassium, especially in alcoholic solution, into the corresponding alcohols, and the potassium-salt of the corresponding acid: thus, with bitter almond oil:

$$\underbrace{2C^7H^6O}_{\text{Benzoic aldehyde.}} + KHO = \underbrace{C^7H^8O}_{\text{Benzyl-alcohol.}} + \underbrace{C^7H^5KO^2}_{\text{Benzoate of potassium.}}$$

Cuminic aldehyde and anisylic aldehyde are decomposed in like manner. The aldehydes of the first series (corresponding to the fatty acids) and acrylic aldehyde, are not decomposed in this manner: acetic aldehyde treated with potash yields acetate and formate of potassium and a brown resinous mass.

All aldehydes form definite, and for the most part crystalline, compounds with the acid sulphites of the alkali-metals, *e. g.* bitter-almond oil with acid sulphite of sodium,

$C^7H^6O.SO^3NaH = \left.\begin{matrix}C^7H^5\\Na\end{matrix}\right\}SO^3 + H^2O = \left.\begin{matrix}SO\\Na.C^7H^5\end{matrix}\right\}O^2 + H^2O$. These compounds are for the most part soluble in water and alcohol, but insoluble in saturated solutions of the alkaline bisulphites. Hence by shaking a liquid containing an aldehyde with excess of such a saturated solution, the aldehyde may be completely separated in the form of a crystalline compound. This is an excellent method of purifying those volatile oils which have the constitution of aldehydes. The acid sulphites of potassium and sodium are, generally speaking, the best adapted for this purpose, as the compounds which they form with the aldehydes are much less soluble in the solution of the sulphite than the corresponding ammonium-compounds, and therefore crystallise more readily. From all these compounds, the aldehyde may be set free by the action of the stronger acids, or by neutralisation with an alkaline carbonate, and may then be obtained in the pure state by distillation.

The aldehydes of the first series combine with ammonia, forming crystalline compounds like aldehyde-ammonia, $C^2H^4O.NH^3$, (p. 106), and valeral-ammonia, $C^5H^{10}O.NH^3$. These compounds treated with sulphuretted hydrogen yield sulphur-bases, like thialdine, $C^6H^{13}NS^2$, and valeraldine, $C^{15}H^{31}NS^2$, thus:

$$3(C^5H^{10}O.NH^3) + 3H^2S = C^{15}H^{31}NS^2 + (NH^4)^2S + 3H^2O.$$

Heated with hydrocyanic and hydrochloric acids, they yield bases similar to the last, but containing oxygen in place of sulphur: *e. g.*:

$$C^5H^{10}O.NH^3 + CNH + ClH + H^2O = \underbrace{C^6H^{13}NO^2}_{\text{Leucine.}} + NH^4Cl.$$

Acrylic aldehyde appears also to combine directly with ammonia, forming a white amorphous compound.

The remaining aldehydes yield with ammonia peculiar amides called hydramides, the formation of which is attended with elimination of 3 atoms of water, *e. g.*

$$\underbrace{3(C^7H^6.O)}_{\substack{\text{Benzoic}\\\text{aldehyde.}}} + N^2H^6 = \underbrace{N^2(C^7H^6)^3}_{\substack{\text{Hydrobenza-}\\\text{mide.}}} + 3H^2O$$

$$\underbrace{3(C^7H^6O^2)}_{\substack{\text{Salicylic}\\\text{aldehyde.}}} + N^2H^6 = \underbrace{N^2(C^7H^6O)^3}_{\text{Salhydramide.}} + 3H^2O$$

Aldehydes also combine with anhydrous acids (anhydrides), forming compounds which are isomeric, but not identical with the diacid glycol-ethers. Thus acetic aldehyde unites with anhydrous acetic acid, forming the compound, $C^2H^4O.C^4H^6O^3$, isomeric with acetate of ethylene, $C^2H^4.(C^2H^3O)^2.O^2$;—also with anhydrous benzoic and succinic acids. Valeral forms with anhydrous acetic, and benzoic acids, the componnds $C^5H^{10}O.C^4H^6O^3$ and $C^5H^{10}O.C^{14}H^{10}O^3$, isomeric with acetate and benzoate of amylene, $C^5H^{10}.(C^2H^3O)^2.O^2$ and $C^5H^{10}.(C^7H^5O)^2.O^2$. These compounds heated with caustic alkalis yield acetates, benzoates, &c., of the alkali-metals, and reproduce the original aldehydes, whereas the acetates, benzoates of ethylene, amylene, &c., under the same circumstances, yield glycols, or hydrates of ethylene, amylene, &c. (Geuther, Ann. Ch. Pharm. cvi. 249; Guthrie u. Kolbe, ibid. cix. 296.)

The calcium and barium-salts of certain monobasic organic acids, butyric and valeric acids, for example, yield by dry distillation, together with acetones (p. 31), compounds isomeric with the aldehydes, but distinguished from them by not combining with ammonia: these compounds are called *butyral*, *valeral*, &c. (Chancel, J. Pharm. [3] vii. 143; Limpricht, Ann. Ch. Pharm. xc. 111.)

Many of the aldehydes are susceptible of polymeric transformations. Acetic aldehyde exhibits three or four such modifications (p. 108); and benzoic aldehyde is very apt to pass into the solid substance benzoin, $C^{14}H^{12}O^2$.

The acetones or ketones are aldehydes in which the basic atom of hydrogen is replaced by an alcohol-radicle, thus:

$$\text{Acetone} = \left.\begin{matrix}C^2H^3\\C\,H^3\end{matrix}\right\}O = \left.\begin{matrix}C^2H^3O\\CH^3\end{matrix}\right\}$$

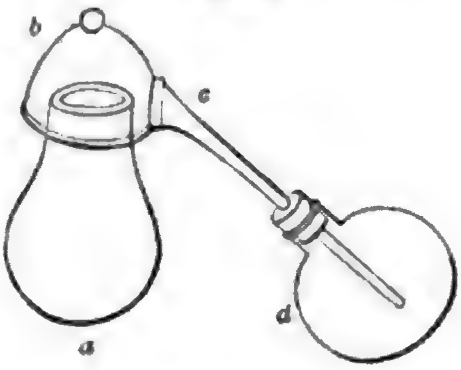
$$\text{Valerone} = \left.\begin{matrix}C^5H^9\\C^4H^9\end{matrix}\right\}O = \left.\begin{matrix}C^5H^9O\\C^4H^9\end{matrix}\right\}$$

$$\text{Valeracetone} = \left.\begin{matrix}C^5H^9\\CH^3\end{matrix}\right\}O = \left.\begin{matrix}C^5H^9O\\CH^3\end{matrix}\right\} \text{ or } \left.\begin{matrix}C^2H^3\\C^4H^9\end{matrix}\right\}O = \left.\begin{matrix}C^2H^3O\\C^4H^9\end{matrix}\right\}$$

ALDIDE. The generic name applied by L. Gmelin, in his Handbook, to the aldehydes, the latter term being by him restricted to acetic aldehyde. In Gmelin's system, the term includes several organic anhydrides and other compounds not generally regarded as aldehydes. (Handb. vii. 192.)

ALEMBIC. An apparatus for distillation, much used by the older chemists. It consists of a body *a*, to which is adapted a head *b*, of conical shape, and having its external circumference or base depressed lower than the neck, so that the vapours which rise and are condensed against the sides, run down into the circular channel formed by its depressed part, whence they pass through the nose or beak *c*, into the receiver *d*. The alembic is now scarcely used in the laboratory, being superseded by the retort, which is simpler and less expensive. Nevertheless, the alembic has its advantages. In particular the residues of distillations may be easily cleared out of the body *a*; and in experiments of sublimation, the head is very convenient to receive the dry products, while the more volatile portions pass over into the receiver. Glass alembics are now used in some manufactories of sulphuric acid for effecting the final concentration of the acid.

Fig. 4.



ALEMBROTH-SALT. A name given by the alchemists to one of the double chlorides of mercury and ammonium, $2(NH^4Cl.HgCl) + H^2O$, also called *Salt of wisdom*.

ALEXANDRITE. (See CHRYSOBERYL.)

ALGAROTH (Powder of). The alchemical name for the oxychloride of antimony, produced by throwing the chloride (butter of antimony) into water.

ALGERITE.—A hydrated silicate of alumina, occurring in New Jersey, and crystallising, sometimes in right, sometimes in oblique prisms. The following analyses of it have been given by Hunt and Crossley:

Silica	52·16	52·00
Alumina	26·08	25·42
Sesquioxide of Iron	1·94	1·54
Magnesia	1·21	5·39
Potash	10·69	10·38
Water	7·92	5·27
	100	100·00

ALIMENTARY SUBSTANCES. (See NUTRITION.)

ALISMIN. An acrid, bitter extract, probably a mixture of several compounds, obtained from the water-plaintain (*Alisma Plantago*) (Jach, Repert. Pharm. iv. 174; vi. 246.)

ALIXIA-CAMPHOR. A crystalline substance, sometimes deposited on the inner surface of the bark of *Alixia aromatica*. The crystals are white and capillary, with a slight aromatic taste and the agreeable odour of the plant. They sublime undecomposed between 70° and 80°C., but at higher temperatures they melt and form a brown substance. They are insoluble in cold, but soluble in warm water, forming a neutral solution, which deposits the crystals unaltered; so likewise does the distillate obtained from this solution. They dissolve readily in alcohol of 80 per cent., in ether, oil of turpentine, caustic potash, carbonate of potassium, and caustic ammonia. Nitric acid of sp. gr. 1·2 does not dissolve, but merely colours them yellow. (Handwört. d. Chem. i. 431.)

ALIZARIC ACID. Obtained by Schunck by the action of nitric acid on alizarin, and shown by Wolff and Strecker to be identical with Laurent's phthalic acid (which see.)

ALIZARIN. $C^{10}H^6O^3 + 2H^2O$ [or $C^{20}H^6O^6 + 4HO$]. *Lizaric acid.*—A red colouring matter obtained from madder. It was first prepared by Robiquet and Colin (Ann. Ch. Phys. [2] xxxiv. 225), who obtained it by digesting pounded madder with water at 15° or 20° C., exhausting the gelatinous extract thereby obtained with alcohol, and treating the alcoholic solution, after concentration, with dilute sulphuric acid. A precipitate was thereby obtained, which, when washed, dried, and sublimed, yielded alizarin in long, brilliant needles, having the red colour of native chromate of lead. Alizarin is identical with Runge's *madder-red* (J. pr. Chem. v. 362), and with the somewhat impure *matière colorante rouge*, obtained from madder by Persoz and Gaultier de Claubry (Ann. Ch. Phys. [2] xlviii. 69), and has been prepared in the pure state by Schunck (Ann. Ch. Pharm. lxvi. 174), by Debus (ibid. lxv. 351), and by Wolff and Strecker (ibid. lxxv. 1). It appears not to exist ready formed in madder, but to be produced by the decomposition of rubian and ruberythric acid. (See MADDER.)

Preparation according to Wolff and Strecker.—Madder is exhausted with boiling water; the decoction is precipitated by sulphuric acid; and the washed precipitate while yet moist, is boiled with a concentrated solution of alumina in hydrochloric acid, which dissolves the colouring matters, and leaves a dark brown residue. The solution mixed with hydrochloric acid deposits red flakes, consisting of alizarin, more or less contaminated with purpurin and resinous matters. This precipitate is dissolved in alcohol, or in dilute ammonia, and the solution is treated with hydrate of alumina, which unites with the colouring matters; and the alumina-compound thus formed is boiled with carbonate of soda, which dissolves the purpurin and leaves the alizarin in combination with the alumina. Lastly, this compound, after being freed from resinous matters by digestion in ether, is decomposed by hot hydrochloric acid which dissolves the alumina; and the alizarin thus separated is washed, dried by simple exposure to the air, and purified by repeated crystallisation from alcohol.

According to Schwartz (Bull. de la Soc. industr. de Mulhouse, 1856, No. 135), the purest alizarin is obtained by subliming on paper an alcoholic extract of madder having at least 35 times the colouring power of the root itself. According to Plessy and Schützenberger (Compt. rend. xliii. 167), when an extract of madder prepared with wood-spirit, is triturated with a tenfold quantity of water, and heated to 250° in a closed vessel, the water on cooling becomes filled with crystals of alizarin; and the fused extractive mass remaining at the bottom of the vessel, yields, when again treated in the same manner, an additional quantity of very pure alizarin.

Anderson, by treating opianic acid ($C^{10}H^{10}O^{5}$ = alizarin + $2H^{2}O$) with sulphuric acid, obtained a colouring matter (probably alizarin), which yielded all the madder colours with alumina and iron mordants. (Edinb. Phil. Trans. xxi. 1, 204.)

Alizarin in the anhydrous state forms red prisms, inclining more or less to yellow, according to the size of the crystals. It combines with 2 at. water, forming scaly crystals like mosaic gold. These crystals give off their water at 100 °C., becoming opaque and of a darker colour. At 215° the compound sublimes, yielding a crystalline sublimate of the same composition as alizarin dried at 100°; nevertheless a considerable quantity of charcoal is always left behind.

The following are the mean results of the analyses of alizarin dried between 100° and 120° or sublimed:

	Calculation.		Robiquet.	Schunck.	Debus.	Rochleder.
10 C . .	120	68·96	69·72	69·4	68·96	67·93
6 H . .	6	3·45	3·74	4·0	3·78	3·77
3 O . .	48	27·59	26·54	26·6	27·26	28·30
$C^{10}H^{6}O^{3}$	174	100·00	100·00	100·0	100·00	100·00

Shunck assigns to crystallised alizarin the formula $C^{14}H^{5}O^{4} + 2HO$. According to the formula $C^{10}H^{6}O^{3}$, alizarin is closely related to Laurent's chloronapthalic acid, $C^{10}H^{5}ClO^{3}$. The latter, when boiled with nitric acid, yields phthalic and oxalic acid, like alizarin (*vid. inf.*).

Alizarin dissolves but sparingly in water, even at the boiling heat; but according to Plessy and Schützenberger (*loc. cit.*) its solubility is much increased by heating to higher temperatures in close vessels, 100 pts. of water dissolve 0·034 pt. of alizarin at 100° C.; 0·035 at 150°; 0·82 at 200°; 1·70 at 225°; and 3·16 pts. at 250°.

Alcohol and ether dissolve it, forming yellow solutions. It is not decomposed by hydrochloric acid. Strong sulphuric acid dissolves it, forming a brown solution from which the alizarin is precipitated by water in orange-coloured flakes. Nitric acid at the boiling heat dissolves it, with evolution of red vapours, forming phthalic acid and probably also oxalic acid (Wolff and Strecker):

$$\underbrace{C^{10}H^{6}O^{3}}_{\text{Alizarin.}} + H^{2}O + 4O = \underbrace{C^{8}H^{6}O^{4}}_{\text{Phthalic acid.}} + \underbrace{C^{2}H^{2}O^{4}}_{\text{Oxalic acid.}}$$

It is also converted into phthalic acid by boiling with ferric chloride or nitrate (Schunck). Chlorine converts it, when suspended in water, into a yellow substance which dissolves in alkalis without much colour, and yields a colourless sublimate when heated.

Alizarin dissolves in caustic alkalis and in alkaline carbonates, forming deep purple solutions, from which it is precipitated by acids in orange-coloured flakes. The ammoniacal solution gives off all its ammonia by evaporation, and forms with the chlorides of barium and calcium purple precipitates which become nearly black when dry. The potash solution is completely decolorised by lime-water, a precipitate being formed containing $2C^{10}H^{6}O^{3}.3CaHO$, or $2C^{20}H^{6}O^{6}.3(CaO,HO)$. With baryta, in a similar manner, two compounds are formed, viz. $2C^{10}H^{6}O^{3}.3BaHO$ and $C^{10}H^{6}O^{3}.2BaHO$. Alumina decolorises an alcoholic solution of alizarin, forming a beautiful red lake. An ammoniacal solution of alizarin forms with salts of magnesium, iron, copper, and silver, purple precipitates with a red or bluish iridescence. The silver precipitate becomes reduced after some time. The alcoholic solution of alizarin forms with an alcoholic solution of acetate of lead, a purple precipitate containing $4C^{10}H^{5}PbO^{3}.3Pb^{2}O$, or $2C^{20}H^{5}PbO^{6}.3PbO$, according to Schunck, and $3C^{10}H^{6}O^{3}.2Pb^{2}O$, according to Debus.

ALIZITE. (See PIMELITE.)

ALKALI. *Alcali*, *Laugensalz*. The word *alkali* is used in various senses. In its most restricted, but most usual sense, it is applied to four substances only: hydrate of potassium (potash), hydrate of sodium (soda), hydrate of lithium (lithia), and hydrate of ammonium (which may be supposed to exist in the aqueous solution of ammonia). In a more general sense, it is applied to the hydrates of the so-called *alkaline earths* (baryta, strontia, and lime), and to a large number of organic substances both natural and artificial, which are more fully described in the articles ALKALOIDS and AMMONIUM-BASES. The first four bodies are sometimes spoken of as *alkalis proper*, when it is wished specially to distinguish them from the other alkalis.

As the individual alkalis are described with sufficient detail in the articles specially devoted to each, we shall confine this article to a discussion of those properties which they all possess in common; in order, as far as possible, to define the essential nature of alkalinity, and to point out upon what grounds this or that particular body is classed as an alkali. These objects will probably be best attained by tracing the most important of the successive steps by which the word alkali, which was at first the name of a single substance, has come to be the generic name of an indefinite number of bodies.

The term alkali was first used in chemistry to designate the soluble part of the ashes of plants, especially of sea-weed (carbonates of sodium and potassium). It was, however, soon extended to several similar substances which were obtained by other processes: for instance, to salt of tartar, and to carbonate of potassium obtained by heating nitre with charcoal. The substances obtained by these processes, and by others of like nature, were regarded as identical, or at most, as mere varieties of the same substance. Alkali was, therefore, not yet used as a generic name, but as the specific name of a particular substance. The character which was chiefly depended upon for distinguishing alkali from other substances was the property of effervescing with acids. This property was supposed to be characteristic of, and essential to, alkaline bodies, till after the middle of the 18th century. Another property of alkali which was early observed was its opposition to acids, and power of destroying their most distinctive characters. On account of its possessing these properties, carbonate of ammonium, which had been known since the thirteenth century, was, from the beginning of the seventeenth century, regarded as a kind of alkali. The power of alkali to change many vegetable colours was recognised at a later period than the properties above mentioned, but was well known to Boyle, who also knew that colours which had been thus altered could be restored by acids.

It was first clearly established in 1736, by Duhamel, that there existed two essentially distinct kinds of fixed alkali. From this time, three kinds of alkali were recognised, — vegetable alkali, mineral alkali, and volatile alkali, corresponding respectively to potash, soda, and ammonia, or to their carbonates.

We have already said that, far on in the eighteenth century, the power of effervescing with acids was regarded as an essential property of alkalis. Boyle had indeed observed, in 1684, that volatile alkali could be obtained by distillation over quick lime in a condition in which it no longer effervesced with acids, although it retained all its other usual properties. But, notwithstanding isolated observations of this kind, non-effervescing alkalis were regarded rather as subordinate varieties of the ordinary alkalis than as essentially different substances.

Moreover, it was known at a very early date, that quick lime altered some of the properties of alkali. This alteration was expressed by calling alkali, which had not been acted on by lime, *mild*, and alkali which had been so acted on, *caustic*. The effect of the lime was ascribed by Basil Valentine (latter half of the fifteenth century) to heat ("die Hitze aus dem lebendigen Kalk") which it imparted to the alkali. And the idea that lime in burning combined with an active principle — "matter of fire" — which it gave out again partially to water (when slaked), and completely to alkali, remained long dominant. Van Helmont (circ. 1640) regarded the substance taken up by lime as a kind of sulphuric acid, whence the heat evolved in the action of water on quick lime. Meyer, as recently as 1764, supposed the lime-salt of a peculiar acid, *acidum pingue*, to be formed during the burning of lime, and that when this salt was treated with a mild alkali, a corresponding alkaline salt (caustic alkali) was obtained. The greasy feel of the caustic alkalis suggested the name of the acid which Meyer supposed them to contain.[*]

---

[*] It is a remarkable illustration of the change which takes place in the ideas attached to the same word, that both Van Helmont and Meyer should have attributed what we consider an exaltation of the *alkaline* property to the agency of an *acid*. (See ACIDS, p. 40.)

The true nature of the difference between caustic and mild alkalis was discovered by Black in 1755. Black's investigation of this subject occupies so important a place in the history of general chemical theory, that it is worth while to consider a little in detail his experiments and the conclusions he derived from them.

His first observation was that quick lime, when deadened by exposure to air, became heavier, not lighter, as was to be expected, if the change which took place consisted in the escape of *fire-matter*. He made a similar observation in the case of magnesia (a substance which he had previously found to be distinct from lime). He found further that magnesia, in the state in which it effervesces with acids, lost considerably in weight when calcined, and that it then no longer effervesced with acids, although it formed with them salts exactly similar to those of effervescing magnesia. In order to find out what was the substance which effervescing magnesia lost when calcined, he repeated the calcination in a retort connected with a well cooled receiver. In this experiment, he obtained nothing but a small quantity of water; it occurred to him, however, that a gas might have escaped, and that this gas might be the same as that which is evolved during the solution of *magnesia alba* (effervescing magnesia) in acids. Following out this supposition, he came to the conclusion that the effervescing magnesia which is precipitated by a mild alkali from a solution of calcined (not effervescing) magnesia in acid, could obtain the gas, which caused it to effervesce when dissolved, from no source except the alkali. Hence he concluded further that the mild alkalis contain the same gas as is expelled from *magnesia alba* by calcination; that, when they combine with acids, this gas is separated and causes effervescence; and that, when a magnesia salt is precipitated by a mild alkali, the gas leaves the latter and unites with the magnesia, in combination with which it is precipitated. These conclusions were verified by the following quantitative experiment. A weighed quantity of *magnesia alba* was calcined; it then dissolved in sulphuric acid without effervescence. The solution was precipitated by mild vegetable alkali (carbonate of potassium), the precipitate washed, dried, and weighed: its weight was almost exactly the same as that of the original *magnesia alba*, and it behaved in every respect like that substance. On a further examination of the gas, which is expelled by acids from the mild alkalis and lime, and from *magnesia alba*, Black found it to be the same as that which is formed during fermentation, and gave it the name *fixed air*.

From the sum of his observations, Black deduced the following general conclusions. The effervescing earths and alkalis contain fixed air, which can be expelled from the former by heat, though not from the latter, but which is expelled from both by acids; the alkalis and earths are caustic when they contain no fixed air, and therefore their causticity does not depend on the presence of any peculiar constituent, but is a property possessed by them in a state of purity; quick lime renders the alkalis caustic, not by imparting to them any principle of causticity, but by the removal from them of fixed air; lastly fixed air partially neutralises the alkalis by combining with them, insomuch as it destroys their causticity.

Two of the most important effects which the adoption of Black's theory had upon the received ideas of alkalinity were that it caused chemists to perceive (which they had not done before), a necessary opposition between the causticity of an alkali and its power of effervescing with acids, and caused the term alkali to be transferred from the carbonated to the caustic alkalis.

Besides the substances to which the name alkali was first given, it was soon perceived that certain kinds of earth possessed, in some degree, alkaline properties; that is to say, the power of effervescing when acted on by acids, and of neutralising their acid properties. Earths which possessed these qualities were called *terræ absorbentes*, or *terræ alcalinæ*, and were long supposed to owe their peculiarities to the presence of alkali as one of their constituents.

It is not easy to make any precise statement as to the degree of similarity or of difference which was supposed to exist between these bodies and alkali proper. The difficulty arises partly from the fact, that, until they had acquired some idea of the principles of chemical analysis, chemists had no sure means of ascertaining the identity or individuality of chemical substances, and hence often called different bodies by the same name, or, on the other hand, gave different names to the same substance when obtained by different processes; partly also, from the word alkali having been used formerly as now in various senses: by Lemery, for instance, to include all substances which effervesce with acids; by Stahl, to include all those which neutralise acids; by many others, however, to denote none but the substances now known as the alkaline carbonates. This uncertainty in the use of the word is not surprising, when we remember that our present more extensive knowledge does not enable us to point out any one difference of fundamental importance between the alkalis and the alkaline earths. The different solubility in water of their carbonates probably furnishes a more exact distinction than any other single property. This character was pointed out by

Duhamel in 1736, as a generic difference. He distinguished earths from alkalis by the property which the latter have of precipitating the former from their solutions, and the alkaline earths from others by their capability of completely neutralising acids. These distinctions have, for the most part, been ever since retained.

It is not necessary to discuss with much detail early ideas relating to the ultimate constitution of the alkalis and alkaline earths. A similarity of constitution between the earths and metallic calces was soon suspected; in consequence of which Neumann, before the middle of the eighteenth century, endeavoured to get a metal from quick lime. By the later phlogistic chemists, both alkalis and earths were, like metallic calces, regarded as simple bodies. Lavoisier, though he regarded metallic calces as compounds, continued to class the alkalis and earths among elementary bodies, inasmuch as there was no known means of decomposing them. He considered it probable, however, that they contained oxygen, and suggested that the earths might be oxides of metals which had a greater affinity for oxygen than carbon, and therefore could not be reduced. Many attempts were made by Lavoisier's followers to verify these suppositions; but their uniform failure seemed almost to have proved the elementary nature of the bodies in question, when, in 1807, Sir Humphry Davy succeeded in reducing potash and soda by the galvanic current. The composition of volatile alkali (ammonia), was approximately ascertained by Berthollet in 1785. After the discovery of oxygen in the fixed alkalis, it was long supposed by Davy and Berzelius that ammonia also contained oxygen. The idea that aqueous ammonia contained the oxide of a compound metal, which likewise existed in the ammonia-salts, was suggested by Berzelius in 1820. (See AMMONIUM.)

In the present state of chemical theory, the relations of the alkalis to other substances lead to the representation of them as hydrates, or as water in which half the hydrogen is replaced by a metal, or compound radicle. (See TYPES.)

The earliest addition made by modern chemistry to the old list of alkalis was morphia, discovered in opium by Sertürner in 1805, but first fully described by him in 1817. This was the first organic alkali, or alkaloid which became known; but, when the general attention of chemists was directed to its existence, it was soon found to be one of a very numerous class of compounds (see ALKALOIDS). Of late years, a large number of bodies, possessing many points of resemblance to the natural alkaloids have been obtained by artificial processes. The constitution of these artificial alkalis is similar to that of hydrate of ammonium: they represent hydrate of ammonium in which hydrogen is replaced by an electro-positive radicle (in most cases a hydrocarbon), (see AMMONIUM-BASES), or in which nitrogen is replaced by phosphorus, arsenic, or antimony.

The following properties are common to the mineral alkalis and to many of the organic alkalis.

(1) They are more or less soluble in water, the alkalis proper much more so than the alkaline earths. (2) They neutralise completely the strongest acids, and with weak acids form salts possessing in some degree, alkaline properties. (3) Their aqueous solutions exert a caustic or corrosive action on vegetable and animal substances; (4) precipitate the heavy metals from most of their acid solutions as hydrates or as oxides; (5) and alter the tint of many colouring matters; for instance, they turn litmus, which has been reddened by acid, blue, they turn turmeric brown, and syrup of violets and infusion of red cabbage, green. The extent to which the various alkalis dissolve in water appears to determine the degree in which they possess the last three properties (3, 4, 5), the most soluble possessing them in a greater degree than the rest. The action on colouring matters appears to belong to all metallic hydrates which are soluble in water, and is possessed by the hydrates of lead, silver, and mercury, in a degree corresponding to their slight solubility.

(For further historical details concerning alkalis and alkaline earths, see Kopp, Geschichte der Chemie, vols. iii. and iv.). — G. C. F.

ALKALIMETRY is the determination of the amount of real alkali in alkaline mixtures and liquids, such as the commercial carbonates of potassium and sodium, (commonly called potash and soda), in wood-ashes, solutions of caustic and carbonated alkalis, &c. This estimation, like that of the strength of acids, may be made either by volumetric or by weight-analysis.

The volumetric method of alkalimetry is merely a particular case of the general method of "Analysis by Saturation," described in the article ANALYSIS, VOLUMETRIC (which see). The valuation of an alkali by the amount of a standard acid solution which it will saturate, was first introduced by Descroizille, afterwards perfected by Gay-Lussac, and still further by Mohr. (Lehrbuch der chemisch-analytischen Titrirmethode, Braunschweig, 1855.)

Instead of the sulphuric or hydrochloric acid generally used for the purpose, Mohr recommends oxalic acid, because it can be weighed with greater accuracy than any liquid acid, and because its standard solution may be kept for any length of time without change. To obtain it pure, the commercial acid, which is generally contaminated with the oxalates of potassium and calcium, is finely pounded, and treated with a quantity of lukewarm water sufficient to dissolve only a portion of it; the solution is filtered and left to crystallise; and the crystals are collected on a filter and dried in the air, till they no longer adhere to each other or to the paper. The acid is thus obtained pure, and containing exactly $C^2H^2O^4 + 2H^2O$, the atomic weight of which is 126.

The standard solution is best made of such a strength that 1000 cubic centimetres (1 litre), shall contain exactly one $\frac{1}{2}$-gramme-atom (*i.e.* 1 atom expressed in $\frac{1}{2}$-grammes) of the acid. This is effected by dissolving in water $\frac{126}{2} = 63$ grammes of the crystals, and diluting the solution to the bulk of 1 litre. 1000 c. c. of this solution contain one $\frac{1}{2}$-gramme-atom of acid: hence 2 c. c. contain 1 milligramme-atom of acid, and saturate 2 milligramme-atoms of a caustic alkali (KHO or NaHO), 1 milligramme of an anhydrous alkali (K^2O or Na^2O), or of an alkaline carbonate (CO^3K^2 or CO^3Na^2.)

To estimate the value of a sample of commercial potash or soda, 3 or 4 grammes of it are first ignited in a platinum crucible in order to determine the amount of water contained in it. The residue is then dissolved in water; a few drops of litmus are added; and the standard acid is gradually added from a burette till the first appearance of a purple-red or wine-red colour. This takes place when a little more than half the alkaline carbonate is decomposed by the oxalic acid: for the first portions of carbonic acid disengaged by the oxalic acid, unite with the remaining portion of alkaline carbonate to form acid carbonate, and it is only when half the alkali has been neutralised in this way that the carbonic acid is actually set free and reddens the litmus. After this stage has been attained, the oxalic acid must be very cautiously added till the purple-red produced by the carbonic acid, just passes into a bright yellowish-red, indicating the presence of free oxalic acid, and showing that the whole of the alkali is neutralised by that acid. Each c. c. of acid thus employed corresponds to 1 milligramme of caustic alkali, or to one $\frac{1}{2}$-milligramme of alkaline carbonate, *i.e.* to 0·040 grm. caustic soda (NaHO), 0·056 grm. caustic potash (KHO), 0·069 grm. carbonate of potassium (CO^3K^2), and 0·053 grm. of carbonate of sodium. The amount of caustic alkali or alkaline carbonate is then found by a simple proportion; thus:

100 : 5·3 : : number of c. c. employed : amount of carbonate of sodium.

By operating on 100 times the $\frac{1}{2}$-milligramme-atom (*e.g.* 6·9 grms. of carbonate of potassium, or 5·3 grms. of carbonate of sodium), all calculation is saved: for as this amount, if perfectly pure, would require 100 c. c. of acid for its saturation, the number of c. c. actually required indicates at once the percentage of alkaline carbonate. The burettes commonly used contain 50 c. c., and are graduated into half c. c.; so that by operating on 50 times the $\frac{1}{2}$-milligramme-atom, the number of divisions employed indicates the percentage.

In operating upon alkaline carbonates in the manner just described, it is difficult to notice the exact moment when the wine-red colour of the litmus due to the presence of free carbonic acid, changes to the light red produced by oxalic or other strong acid. For this reason Mohr recommends the following, called the *residual method*. The standard acid is added till the colour of the litmus is distinctly bright red; the solution is then heated to boiling, and a slight excess (5 to 10 c. c.) of acid is added. The hot solution is freed from carbonic acid by agitation and by drawing air through it by means of a glass tube, and then neutralised with a standard solution of caustic soda (ANALYSIS, VOLUMETRIC), till the colour just changes from red to blue. Since the acid and alkaline solutions neutralise each other, volume for volume, it is only necessary to deduct the number of cubic centimetres employed of the latter from that of the former, and calculate the amount of alkali from the residue. In estimating the strength of caustic alkaline solutions, this residual method is of course unnecessary.

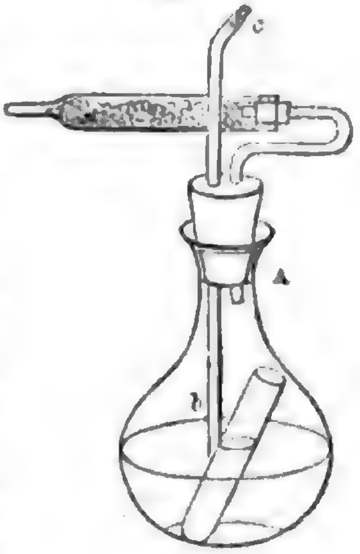
To determine the proportion of caustic alkali and alkaline carbonate in a mixture of the two, two equal portions of the solution must be taken: one of them treated with chloride of barium, whereby the alkaline carbonate is converted into chloride, and carbonate of barium is precipitated. The liquid is filtered and the quantity of caustic alkali determined in the filtrate as above. The second portion of the solution is neutralised with the standard acid, without previous treatment with chloride of barium, and the total amount of alkali, existing both in the caustic state and as carbonate, is thereby determined. The first result deducted from the second, gives the quantity of alkali existing as carbonate.

If it be preferred to make these estimations with the ordinary English weights and measures, the standard solution of oxalic acid may be made by dissolving 63 grains ($\frac{1}{2}$-grain-atom) of the crystallised acid in water and diluting the solution to 1000 grain-measures at 60° F. This quantity of the solution will then neutralise 1 grain-atom of a caustic alkali (40 grains of soda NaHO, or 56 grains of potash KHO), and $\frac{1}{2}$-grain-atom of alkaline carbonate (69 grains of CO^3K^2, or 53 grains of CO^3Na^2), and by operating on $\frac{1}{10}$ of these quantities of the substance to be tested, the percentages will be given at once by the number of grain-measures of the standard acid employed.

A convenient method of estimating by volumetric analysis the proportion of potash and soda in a caustic mixture of the two, has been kindly communicated to the Editor by Mr. John Dale of Cornbrook, near Manchester. It depends upon the fact that acid tartrate of potassium, though moderately soluble in water, is but very sparingly, if at all, soluble in a liquid containing acid tartrate of sodium. The method is as follows: Add to the mixture a standard solution of tartaric acid till an acid reaction just becomes perceptible; the alkalis are thereby converted into neutral tartrates; then add a second quantity of tartaric acid equal to the first, so as to convert them into acid tartrates: the whole (or nearly the whole) of the acid tartrate of potassium then separates. Next filter off the solution of acid tartrate of sodium, and add a standard solution of caustic soda till the liquid just exhibits an alkaline reaction. The quantity of the soda solution thus added is equal to the amount of soda present in the mixture.—The quantity of tartaric acid required to form acid tartrate with the soda, subtracted from the total quantity added to the mixture of the two alkalis, gives the quantity required to form acid tartrate with the potash; and thus the amount of potash is determined. This method would scarcely be applicable where scientific accuracy is required; but, for rapid estimation in commercial practice, it is found to give good results.

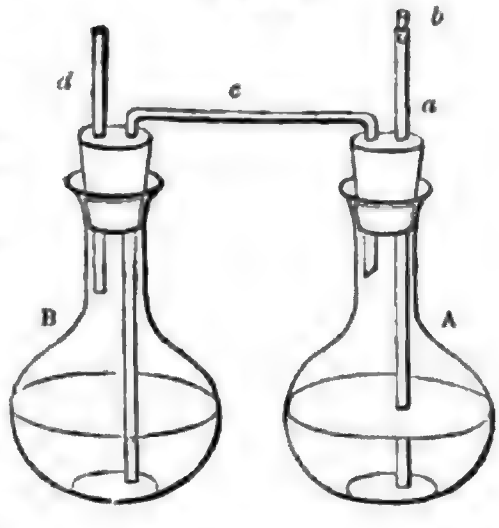
Alkalimetry by Weight-analysis.—The proportion of alkali in the commercial carbonates of potassium and sodium may be estimated by determining the quantity of carbonic anhydride evolved when the carbonates are decomposed by an acid: for 22 parts of carbonic anhydride (CO^2) correspond to 69 parts of carbonate of potassium (CO^3K^2), and to 53 parts of carbonate of sodium (CO^3Na^2). The apparatus employed is the same as that described in the article ACIDIMETRY; but the method of using it is slightly different. A weighed quantity of the carbonate to be examined is dissolved in warm water in the flask A, and a quantity of hydrochloric or dilute sulphuric acid more than sufficient to decompose the carbonate, is placed in a short test-tube *b*, which is carefully introduced into the flask, so that it may rest against the side. The apparatus having been then weighed, the extremity of the tube *c* is closed by a plug of wax, and the flask is tilted so that the acid may run over into the alkaline liquid. When the evolution of gas ceases, the flask is heated to complete the decomposition; the wax plug is removed and air drawn through the apparatus to remove the carbonic acid remaining in it; and the flask after cooling is again weighed to ascertain the loss of carbonic acid. At the conclusion of the experiment, a piece of blue litmus-paper must be thrown into the flask, to try whether the liquid is acid; if not, more acid must be added, and the process repeated.

Fig. 5.



The apparatus of Will and Fresenius (*fig.* 6) may also be used. The alkali dissolved in water is then placed in the flask A, and strong sulphuric acid in B; and the whole apparatus is weighed; the tube *a b* is closed with a wax plug; and suction is applied by the mouth at the end of the tube *d*, so as to draw a few bubbles of air from A into B. On discontinuing the suction the pressure of the air forces a small quantity of the acid in B into the flask A, whereby a portion of the alkaline carbonate is decomposed. This process is repeated as long as any gas continues to be evolved, after which the flask A is heated, and the experiment completed in the manner just decribed.

Fig. 6.



If the alkaline carbonate contains any caustic alkali, which may be known (in the absence of sulphide), by its solution having an alkaline reaction after the addition of excess of chloride of barium, another equal portion must be mixed with about one-third of its weight of carbonate of ammonium, and 3 parts of quartz-sand (to prevent caking), and heated till the water and ammonia are expelled; the dry residue is then decomposed as above. The excess of alkaline carbonate obtained in the second determination is due to the caustic alkali in the sample, which is converted into carbonate by ignition with the carbonate of ammonium; and from it the amount of caustic alkali is easily calculated; thus for soda:

$$CO^3Na^2 : 2NaHO \ [\text{or } CO^2.NaO : NaO.HO] = 106 : 80.$$

The sulphites, hyposulphites, and sulphides of the alkali-metals, which often occur in commercial samples of alkali, especially in "ball-soda," introduce errors both into the volumetric and the weight-analyses: into the former, by neutralising a portion of the test-acid, and into the latter by evolving sulphurous acid or sulphuretted hydrogen, which would be estimated as carbonic acid. When the amount of alkali is to be determined by the volumetric method, these compounds may be decomposed by igniting the substance with chlorate of potassium, whereby they are all converted into sulphates. For the carbonic acid estimation, they may be oxidised by adding a small quantity of neutral chromate of potassium to the solution in the flask, before commencing the decomposition.

The carbonates of the earths, which would introduce similar errors, may be removed by dissolving the alkaline carbonate in water and filtering.

ALKALOIDS. *Organic Alkalis, Organic Bases.*—At the beginning of this century, the only substances in which alkaline properties had been recognised were potash, soda, ammonia, and the alkaline earths (see ALKALI). In 1817, Sertürner drew attention to the existence in opium of a substance whose alcoholic solution acted upon vegetable colours like the solutions of the alkalis, which combined directly with acids, forming neutral salts, soluble in water, and giving the usual reactions of the acids from which they were formed; and which was precipitated from solutions of its salts by the mineral alkalis. To this substance, Sertürner gave the name *morphine*, and in consequence of its possessing the properties just mentioned, regarded it as a kind of alkali. After the discovery of morphine, it was soon found that many vegetable products which had been long known as exerting marked physiological effects (*e. g.* cinchona bark, nux vomica, tobacco, &c.), contained similar alkaline principles. The number of such natural *alkaloids* now known is very great, and includes many substances which cannot in any strict sense be termed alkalis, but which are connected by such insensible gradations (between intermediate terms) with substances decidedly alkaline, that they must be regarded as possessing essentially the same chemical nature as the latter. Since 1848, a great number of organic alkalis have been obtained artificially. Some of these rival potash and soda in the degree of their alkalinity, while in others the existence of alkaline properties is barely perceptible.

The only property which is possessed by all alkaloids, whether natural or artificial, is that of combining directly with acids to form salts possessing a certain degree of stability, and capable, when dissolved in water, of producing the ordinary phenomena of saline double decomposition. Those alkaloids, whose salts possess any considerable degree of stability, generally exhibit, when dissolved in water or alcohol, an alkaline reaction with vegetable colours.

Most of the natural alkaloids contain carbon, hydrogen, nitrogen, and oxygen, and are, at ordinary temperatures, solid, and not volatile without decomposition. Some natural alkaloids contain carbon, hydrogen, and nitrogen only; these are, for the most part, liquid at ordinary temperatures, and can be distilled without decomposition. The greater number of the artificial alkalis are composed of carbon, hydrogen, and nitrogen; some, however, contain oxygen in addition. In both natural and artificial alkaloids, hydrogen may be replaced by chlorine, bromine, iodine, peroxide of nitrogen, &c. Alkaloids have also been obtained artificially, in which nitrogen is replaced by phosphorus, arsenic, antimony, or bismuth. (See PHOSPHINES, ARSINES, &c.)

Most of the alkaloids, as they are obtained in the free state, correspond in composition to ammonia, NH^3, rather than to the fixed alkalis; that is to say, they form salts by direct union with acids, without elimination of water or any other substance. In order to make them strictly comparable to the fixed alkalis, they require, like ammonia, the addition of H^2O to their formulæ: they may then be considered as hydrates of compound radicles analogous to ammonium. A few alkaloids, however, are known which, when dehydrated as far as possible, correspond precisely to the fixed alkalis; *e.g.* hydrate of tetrethylium, $C^8H^{21}NO = C^8H^{20}N.H.O$. These bodies, for the most part, resemble potash and soda very closely in properties.

The constitution of most of the artificial alkaloids is tolerably well known. The processes by which they are obtained show that they must be considered as ammonia, or as hydrate of ammonium, in which the hydrogen is replaced wholly, or in part, by a compound radicle generally composed of carbon and hydrogen (see AMIDES, AMMONIUM-BASES). The phosphorus, arsenic, &c. alkaloids are similarly related to phosphide, arsenide, &c. of hydrogen, PH^3,AsH^3, &c. The constitution of the natural alkaloids is, as yet, very imperfectly understood. They are probably, like the artificial alkalis, derivatives of ammonia; but it is unknown by what radicles the hydrogen is replaced.

The following is a list of the most important nitrogen-alkaloids, natural and artificial, which are now known.

1. Alkaloids comparable to ammonia, forming salts by direct union with acids.

Name.	Formula.	Source or Mode of Formation.
Acediamine	$C^2H^6N^2$	Acetamide heated in hydrochloric acid gas.
? Acetonine	$C^9H^{18}N^2$	Action of ammonia on acetone.
Acetylamine. (See VINYLAMINE.)		
Aconitine	$C^{30}H^{47}NO^7$	*Aconitum Napellus.*
Alanine	$C^3H^7NO^2$	Hydrochloric and hydrocyanic acids on aldehydammonia.
Alkaloid	$C^3H^5N.$	Nitrous ether on creatine (Dessaignes).
Alkaloid	$C^4H^8N^4$	Distillation of ethylcyanamide (Cahours and Cloez).
Alkaloid	$C^8H^{13}NO$	From aldehydammonia (Babo).
Alkaloid	$C^{10}H^{15}NO$	
Allylamine	$C^3H^7N.$	
Dibromdiallylamine	$C^6H^9Br^2N$	Tribromide of allyl on ammonia
Ethyldibromdiallylamine	$C^8H^{13}Br^2N.$	
Amarine	$C^{21}H^{18}N^2$	Potash on hydrobenzamide.
Diethylamarine	$C^{25}H^{26}N^2.$	
Ammeline	$C^3H^5N^5O$	Strong acids or alkalis on cyanamide.
Amylamine	$C^5H^{13}N.$	
Diamylamine	$C^{10}H^{23}N.$	
Diethylamylamine	$C^9H^{21}N.$	
Methylethylamylamine	$C^8H^{19}N.$	
Triamylamine	$C^{15}H^{33}N.$	
Aniline. (See PHENYLAMINE.)		
Anisine	$C^{24}H^{24}N^2O^3$	Action of heat on anishydramide.
Aricine	$C^{23}H^{26}N^2O^4$	Cinchona bark.
Asparagine	$C^4H^8N^2O^3$	*Asparagus officinalis*, and other plants.
Atropine	$C^{17}H^{23}NO^3$	*Atropa belladonna, Datura Stramonium.*
Azonaphtylamine	$C^{10}H^{10}N^2$	Reduction of dinitronaphtalene.
Azophenylamine	$C^6H^8N^2$	Reduction of dinitrobenzine.
Bebirine	$C^{19}H^{21}NO^3$	"*Bebeeru*," a species of *Nectandra*, British Guiana.
Benzidine	$C^{12}H^{12}N^2$	Reducing agents on azobenzide and on azoxibenzide.
Berberine	$C^{21}H^{19}NO^5$	*Berberis vulgaris.*
Brucine	$C^{23}H^{26}N^2O^4$	*Strychnos nux vomica, S. Ignatii, S. Colubrina.*
Ethylbrucine	$C^{25}H^{30}N^2O^4.$	
Caffeine	$C^8H^{10}N^4O^2$	Tea, coffee, &c.
Caproylamine. (See HEXYLAMINE.)		
Caprylamine. (See OCTYLAMINE.)		
Carbamide. (See UREA.)		
Carbotriphenyltriamine, or Cyantriphenyldiamine	$C^{19}H^{17}ON^3$	Dichloride of carbon on phenylamine.
Carbothialdine	$C^5H^{10}N^2S^2$	Sulphocarbonic anhydride on aldehyd-ammonia.
Cetylamine.		
Tricetylamine	$C^{48}H^{99}N.$	
? Chelidonine	$C^{20}H^{19}N^3O^3$	*Chelidonium majus.*
Cinchonicine	$C^{20}H^{24}N^2O$	Isomeric transformation of cinchonine or of cinchonidine.
Cinchonidine	$C^{20}H^{24}N^2O$	Cinchona bark.
Methylcinchonidine	$C^{21}H^{26}N^2O.$	
Cinchonine	$C^{20}H^{24}N^2O$	Cinchona bark.
Methylcinchonine	$C^{21}H^{26}N^2O.$	
Codeine	$C^{18}H^{21}NO^3$	Opium.
Ethylcodeine	$C^{20}H^{25}NO^3.$	

Name.	Formula.	Source or Mode of Formation.
Colchiceine	$C^{34}H^{44}N^2O^{11}$	*Colchicum autumnale.*
Collidine	$C^8H^{11}N$	Bone-oil.
Conhydrine	$C^8H^{17}NO$	Hemlock (*Conium maculatum*).
Conine	$C^8H^{15}N$	Hemlock (*Conium maculatum*).
Ethylconine	$C^{10}H^{19}N$.	
Methylconine	$C^9H^{17}N$.	
Cotarnine	$C^{12}H^{13}NO^3$ *	Oxidation of narcotine.
Coumaramine	$C^9H^7NO^2$	Reduction of nitro-coumarine.
Creatine	$C^4H^9N^3O^2$	Juice of flesh.
Creatinine	$C^4H^7N^3O$	Action of acids on creatine.
Cryptidine	$C^{11}H^{11}N$	Coal-tar.
Cumidine	$C^9H^{13}N$	Reduction of nitro-cumine.
Cyanamide	CH^2N^2	Gaseous chlor. of cyanogen on ammonia.
Amylcyanamide	$C^6H^{12}N^2$.	
Diamylcyanamide	$C^{11}H^{22}N^2$.	
Diethylcyanamide	$C^5H^{10}N^2$.	
Ethylcyanamide	$C^3H^6N^2$.	
Methylcyanamide	$C^2H^4N^2$.	
Methylethylcyanamide	$C^4H^8N^2$.	
Cyanethine	$C^9H^{15}N^3$	Potassium on cyanide of ethyl.
Cyanetholine	C^3H^5NO	Chloride of cyanogen on ethylate of sodium.
Cyaniline	$C^{14}H^{14}N^4$	Do. on phenylamine (aniline.)
Cyanocumidine	$C^{20}H^{26}N^4$	Do. on cumidine.
Cyanomelamine	$C^{15}H^{13}N^5$	Do. on melaniline.
Cyanotoludine	$C^{16}H^{18}N^4$	Do. on toluidine.
Diphenine	$C^{12}H^{12}N^4$	Reduction of dinitrazobenzide.
Diphenylformyldiamine	$C^{13}H^{12}N^2$	Chloroform on phenylamine.
Ethylamine	C^2H^7N.	
Diethylamine	$C^4H^{11}N$.	
Triethylamine	$C^6H^{15}N$.	
Ethylenamine	$C^2H^8N^2$	Bromide of ethylene on ammonia.
Diethylenamine	$C^4H^{10}N^2$	
Phenylethylenamine	C^8H^9N.	Bromide of ethylene on phenylamine.
(or Diphenylbiethylenamine	$C^{16}H^{18}N^2$?	
Triethylenamine	$C^6H^{12}N^2$	Bromide of ethylene on ammonia.
Flavine	$C^{13}H^{12}N^2O$	Reduction of binitrobenzophenone.
Furfurine	$C^{15}H^{12}N^2O^3$	Furfuramide boiled with potash.
Glycocoll	$C^2H^5NO^2$	Ammonia on chlor- or bromacetic-acid.
Glycosine	$C^6H^6N^4$	Ammonia on glyoxal.
Glyoxaline	$C^3H^4N^2$	
Guanine	$C^5H^5N^5O$	Guano, &c.
Harmaline	$C^{13}H^{14}N^2O$	Seeds of *Peganum Harmala.*
Hydrocyanharmaline	$C^{14}H^{13}N^3O$	Hydrocyanic acid and harmaline.
Harmine	$C^{13}H^{12}N^2O$	Seeds of *Peganum Harmala*; also oxidation of harmaline.
Hexylamine.		
Trihexylamine	$C^{18}H^{39}N$	Sulphite of œnanthylsodium distilled with lime.
? Jervine	$C^{30}H^{46}N^2O^3$	*Veratrum album*, white hellebore.
Lepidine	$C^{10}H^9N$	Coal-tar; also quinine and cinchonine distilled with potash.
Leucine	$C^6H^{13}NO^2$	Hydrochloric and hydrocyanic acids in valeral ammonia.
Lophine	$C^{21}H^{16}N^2$	Distillation of hydrobenzamide.
Lutidine	C^7H^9N.	Bone-oil.
Melamine	$C^3H^6N^6$	Action of heat on cyanamide.

---

* According to unpublished analyses by Matthiessen and Foster.

Name.	Formula.	Source or Mode of Formation.
Melaniline	$C^{13}H^{13}N^{3}$	Cyananilide (cyanophenylamine) and phenylamine.
Menaphthylamine	$C^{21}H^{17}N^{3}$	Chloride of cyanogen on naphtylamine.
Methylamine	$CH^{5}N$.	
Dimethylamine	$C^{2}H^{7}N$.	
Trimethylamine	$C^{3}H^{9}N$.	
Methyluramine	$C^{2}H^{7}N^{3}$.	Creatine or creatinine heated with oxide of mercury.
Metoluidine	$C^{15}H^{17}N^{3}$	Chloride of cyanogen on toluidine.
Morphine	$C^{17}H^{19}NO^{3}$	Opium.
Ethylmorphine	$C^{19}H^{23}NO^{3}$.	
Methylmorphine	$C^{18}H^{21}NO^{3}$.	
Naphtylamine	$C^{10}H^{9}N$	Reduction of nitronaphtylene.
Ethylnapthylamine	$C^{12}H^{13}N$.	
Nareeine	$C^{23}H^{29}NO^{9}$	Opium.
Narcotine	$C^{22}H^{23}NO^{7}$*	
Nicotine	$C^{10}H^{14}N^{2}$ or $C^{5}H^{7}N$	Tobacco.
Ninaphtylamine	$C^{10}H^{8}N^{2}O$	Reduction of dinitronaphtylene.
Octylamine	$C^{8}H^{19}N$	
Papaverine	$C^{20}H^{21}NO^{4}$	Opium.
Parvoline	$C^{9}H^{13}N$	Distillat. of bituminous shale of Dorsetshire.
Pelosine, or Cissampeline	$C^{18}H^{21}NO^{3}$	*Cissampelos pareira*, L. (Antilles).
Phenylamine	$C^{6}H^{7}N$.	Reduction of nitrobenzene, &c.
Amylphenylamine	$C^{11}H^{17}N$.	
Diamylphenylamine	$C^{16}H^{27}N$.	
Diethylphenylamine	$C^{10}H^{15}N$.	
Dicetylphenylamine	$C^{38}H^{71}N$.	
Cetylphenylamine	$C^{22}H^{39}N$.	
Ethylamylphenylamine	$C^{13}H^{21}N$.	
Ethylphenylamine	$C^{8}H^{11}N$.	
Methylamylphenylamine	$C^{12}H^{19}N$.	
Methylethylphenylamine	$C^{9}H^{13}N$.	
Methylphenylamine	$C^{7}H^{9}N$.	
Triphenylamine	$C^{18}H^{15}N$	Sulphite of cinnamyl-ammonium distilled with lime.
Vinylphenylamine (Phenylacetylamine	$C^{8}H^{9}N$. or $C^{16}H^{18}N^{2}$	
Phtalidine	$C^{8}H^{9}N$	Reduction of nitrophtalene.
Picoline	$C^{6}H^{7}N$	Coal-tar.
Piperidine	$C^{5}H^{11}N$	Piperine distilled with potash.
Amylpiperidine	$C^{10}H^{21}N$.	
Ethylpiperidine	$C^{7}H^{15}N$.	
Methylpiperidine	$C^{6}H^{13}N$.	
? Piperine	$C^{34}H^{38}N^{2}O^{6}$	Pepper (*Piper nigrum*, *P. longum*).
Propylamine. (See TRITYLAMINE.)		
Pyridine	$C^{5}H^{5}N$	Bone-oil.
Quinicine	$C^{20}H^{24}N^{2}O^{2}$	Isomeric transformation of quinine, or of quinidine.
Quinidine	$C^{20}H^{24}N^{2}O^{2}$	Cinchona bark.
Quinine	$C^{20}H^{24}N^{2}O^{2}$	
Ethylquinine	$C^{22}H^{28}N^{2}O^{2}$.	
Methylquinine	$C^{21}H^{26}N^{2}O^{2}$.	
Quinoleine	$C^{9}H^{7}N$	Quinine or Cinchonine distil. with potash.
Amylquinoleine	$C^{14}H^{17}N$.	
Ethylquinoleine	$C^{11}H^{11}N$.	
Methylquinoleine	$C^{10}H^{9}N$.	

* According to unpublished analyses by Matthiessen and Foster.

Name.	Formula.	Source or Mode of Formation.
Sarcine	$C^{5}H^{4}N^{4}O$	Juice of flesh.
Sarcosine	$C^{3}H^{7}NO^{2}$	Baryta-water on creatine.
Sinamine	$C^{4}H^{6}N^{2}$	Oxide of mercury on thiosinamine.
Ethylsinamine	$C^{6}H^{10}N^{2}$	Ethylthiosinamine heated with hydrate of lead.
Sinapine	$C^{16}H^{23}NO^{5}$	White mustard.
Sinapoline	$C^{7}H^{12}N^{2}O$	Hydrate of lead in oil of mustard (sulphocyanate of allyl).
Sincaline	$C^{5}H^{13}NO$	Alkalis on sinapine.
Sparteine	$C^{8}H^{13}N$	*Spartium scoparium*, L. (*Cytisus scoparius*, Linck.)
Strychnine	$C^{21}H^{22}N^{2}O^{2}$	*Strychnos nux vomica*, *S. Ignatii*, *S. colubrina.*
Tetrylamine (Petinine)	$C^{4}H^{11}N$	Bone-oil.
Thebaine	$C^{19}H^{21}NO^{3}$	Opium.
Theine. (See CAFEINE.)		
Theobromine	$C^{7}H^{8}N^{4}O^{2}$	Cacao-beans.
? Thiacetonine	$C^{9}H^{19}NS^{2}$	Ammonia and hydrosulphuric acid on acetone.
Thialdine	$C^{6}H^{13}NS^{2}$	Hydrosulphuric acid on aldehydammonia.
Thiosanime	$C^{4}H^{8}N^{2}S$	Ammonia on sulphocyanate of allyl (oil of mustard.)
Ethylthiosanimine	$C^{6}H^{12}N^{2}S$	Ethylamine on sulphocyanate of allyl.
Toluidine (Toluylamine)	$C^{7}H^{9}N$	Reduction of nitrotoluene.
Diethyltoluidine	$C^{11}H^{17}N.$	
Ethyltoluidine	$C^{9}H^{13}N.$	
Tritylamine	$C^{3}H^{9}N.$	
Urea (Carbamide	$CH^{4}N^{2}O.$	
Allylurea	$C^{4}H^{8}N^{2}O.$	
Amylurea	$C^{6}H^{14}N^{2}O.$	
Diallylurea. (See SINAPOLINE.)		
Diethylurea	$C^{5}H^{12}N^{2}O.$	
Diphenylurea. (See FLAVINE.)		
Ethylallylurea	$C^{6}H^{12}N^{2}O.$	
Ethylamylurea	$C^{8}H^{18}N^{2}O.$	
Ethylpiperylurea	$C^{8}H^{16}N^{2}O.$	
Ethylurea	$C^{3}H^{8}N^{2}O.$	
Methylethylurea	$C^{4}H^{10}N^{2}O.$	
Methylpiperylurea	$C^{7}H^{14}N^{2}O.$	
Methylurea	$C^{2}H^{6}N^{2}O.$	
Naphtylurea	$C^{11}H^{10}N^{2}O.$	
Phenylallylurea	$C^{10}H^{12}N^{2}O.$	
Phenylurea	$C^{7}H^{8}N^{2}O.$	
Piperylurea	$C^{6}H^{12}N^{2}O.$	
Sulphallylurea. (See THIOSINAMINE).		
Tolylurea	$C^{8}H^{10}N^{2}O.$	
Valeraldine	$C^{15}H^{31}NS^{2}$	Hydrosulphuric acid on valeral ammonia.
Veratrine	$C^{32}H^{52}N^{2}O$	*Veratrum album.*
?Vinylamine	$C^{2}H^{5}N$	Chloride of ethylene on ammonia.

2. Alkaloids comparable to hydrate of ammonium, forming salts by combining with acids and eliminating water.

Name.	Formula.
Amylium.	
Hydrate of Methyldiethylamylium	$C^{10}H^{25}NO.$
" Tetramylium	$C^{20}H^{45}NO.$
" Triethylamylium	$C^{11}H^{27}NO.$
Brucium.	
Hydrate of Ethylbrucium	$C^{25}H^{32}N^{2}O^{5}.$

Name.	Formula.
Conium.	
Hydrate of Diethylconium	$C^{12}H^{25}NO$.
„ Methylethylconium	$C^{11}H^{23}NO$.
Ethylenium.	
Hydrate of Trimethylethylenium	$C^{5}H^{15}NO$.
Ethylium.	
Hydrate of Methyltriethylium	$C^{7}H^{19}NO$.
„ Tetrethylium	$C^{8}H^{21}NO$.
Methylium.	
Hydrate of Tetramethylium	$C^{4}H^{13}NO$.
Nicotium.	
Hydrate of Ethylnicotium	$C^{7}H^{13}NO$.
„ Methylnicotium	$C^{6}H^{11}NO$.
Phenylium.	
Hydrate of Ethyltriphenylium	$C^{20}H^{21}NO$.
„ Methylethylamylophenylium	$C^{14}H^{25}NO$.
„ Triethylphenylium	$C^{12}H^{21}NO$.
Piperylium.	
Hydrate of Diethylpiperylium	$C^{9}H^{21}NO$.
Pyridine.	
Hydrate of Ethylpyridine	$C^{7}H^{11}NO$.
Strychnium.	
Hydrate of Amylstrychnium	$C^{26}H^{34}N^{2}O^{3}$.
„ Ethylstrychnium	$C^{23}H^{28}N^{2}O^{3}$.
Tolylium.	
Hydrate of Triethyltolylium	$C^{13}H^{23}NO$.

There are some substances not included in the above list, such as acetamide, $C^{2}H^{5}NO$, acetonitrile, $C^{2}H^{3}N$, &c., which possess the most important properties of alkaloids to quite as great an extent as some of the bodies there enumerated, but which, in most of their relations, are associated with other well defined groups of compounds, and are in consequence seldom classed among alkaloids. On the other hand, this list contains some bodies, such as urea and its derivatives, which also find their places in other classes, but which had long been regarded solely as alkaloids before their relations to other compounds were discovered. This inconsistency is unavoidable. There is not in nature any sharp distinction between alkaloids and other substances; hence, in determining whether particular bodies ought, or ought not, to be classed as alkaloids, we must sometimes decide by reference to customary usage, or other circumstances equally arbitrary.—G. C. F.

Alkaloids, detection of, in chemico-legal investigations. — The certain detection of the poisonous alkaloids in chemico-legal investigations involves their separation, in a state of purity, from the substances with which they are mixed. When, as is often the case, a very small quantity of an alkaloid is contained in a large quantity of a complicated mixture of animal or vegetable matter, its accurate separation is a problem of considerable difficulty. The first chemist who gave a systematic method of proceeding in such cases was Stas (Bulletin de l'Académie Royale de Médecine de Belgique, xi. 304 (1851); Ann. Ch. Pharm. lxxxiv. 379; J. Pharm. Chim. xxii. 281), and the method which he proposed continues to be the one most generally employed. His process consists in the successive and systematic use of various solvents, such as dilute acids, alcohol, and ether.

The method of carrying it out is as follows: When an alkaloid has to be sought for among the contents of the stomach or intestines, the substances to be examined are treated with twice their weight of pure absolute alcohol, to which from 0·5 gramme to 2 grammes of tartaric or oxalic acid (the former is preferable) have been added, and the mixture is heated in a flask to between 70° and 75° C. (When an entire organ, such as the liver, heart, or lungs, has to be examined for an alkaloid, it must first be divided as finely as possible, then moistened with pure absolute alcohol, squeezed, and afterwards washed with alcohol till all the soluble constituents are removed. The liquid thus obtained is treated in the same way as a mixture of suspected matter and alcohol.) When quite cold, the mixture is filtered, the insoluble part washed with strong alcohol, and the alcoholic solution evaporated either in vacuo, or in a rapid current of air at a temperature not exceeding 35° C.

If the residue left on evaporating the alcohol contains fat or other insoluble matter, it must be filtered again through a filter wetted with distilled water, the filtrate must be evaporated nearly to dryness in vacuo over sulphuric acid, and the residue exhausted with cold absolute alcohol. The alcoholic solution is once more evaporated at the atmospheric temperature, either in the air, or better in vacuo, and the acid residue of this evaporation is dissolved in the *smallest possible* quantity of water. To the solution so obtained, pure, powdered acid carbonate of potassium or of sodium is added *very gradually* until there is no more effervescence. The neutralised solution is shaken with from four to five times its bulk of *pure* ether, and then allowed to settle. When the layer of ether has become perfectly clear, a little of it is decanted into a glass capsule, and left to spontaneous evaporation in a very dry place. If, after the evaporation of the ether, slight streaks of liquid appear on the side of the capsule, and run together slowly to the bottom of it, a liquid and volatile alkaloid is probably present. If this be the case, the warmth of the hand will be sufficient to cause the contents of the capsule to exhale a disagreeable smell which, according to the nature of the alkaloid, is more or less sharp, choking, and irritating. If these indications are wanting, the alkaloid, if any is present, is probably solid and non-volatile. According to the nature of the alkaloid, as indicated by this preliminary trial, Stas recommends different processes for its further purification.

A. *The alkaloid is liquid and volatile.*—In this case 1 or 2 cub. cent. of strong solution of caustic potash or soda are added to the contents of the flask, from which the small quantity of the ethereal solution was taken, and the whole is again well shaken. After standing for a sufficient time, the ether is poured off, and the residue is again shaken three or four times with fresh quantities of ether. The ethereal liquids so obtained, containing the alkaloid in solution, are united and shaken with 1 or 2 cub. cent. of a mixture of 4 parts by weight of water and 1 part of sulphuric acid; after being allowed to stand, the ether is poured off, and the acid liquid is washed with a second quantity of ether.

As the sulphates of the volatile alkaloids are soluble in water, but almost all insoluble in ether, the alkaloid sought is contained in the dilute sulphuric acid, in the form of pure sulphate [*], while the animal matter which the ether may have taken up from the alkaline liquid together with the alkaloid, remains still dissolved by it.

In order to obtain the alkaloid from the solution of its sulphate, the latter is mixed with a strong solution of caustic potash or soda; the mixture is well shaken, and then exhausted with pure ether, which dissolves the alkaloid together with ammonia. The ethereal solution is allowed to evaporate [†] at as low a temperature as possible, and in order to remove from the residue the last traces of ammonia, the vessel containing it is placed for an instant in vacuo over sulphuric acid. The alkaloid then remains in a state of purity, with its characteristic chemical and physical properties.

B. *The alkaloid is solid and fixed.*—If on evaporating a small quantity of the ether with which the liquid neutralised by acid carbonate of sodium has been mixed (see above), there is no sign of the presence of a volatile alkaloid, the liquid must be further examined for fixed alkaloids as follows. Caustic potash or soda is put into the flask containing ether and the neutralised solution, the mixture is again vigorously shaken, the ethereal layer is poured off as soon as it is clear, and the watery alkaline liquid is several times washed with a considerable quantity of fresh ether. The ether now contains the free alkaloid in solution [‡], and on evaporation leaves either a solid residue or a colourless milky liquid containing solid particles in suspension. The smell of this residue is disagreeably animal, but not sharp; it colours red litmus-paper permanently blue.

In order to obtain the alkaloid in the crystalline state, a few drops of alcohol are poured into the capsule containing it and allowed to evaporate. Usually, however, it is still too impure to crystallise in this way. When this is the case, a few drops of water made very slightly acid by sulphuric acid, are poured upon the residue left by the evaporation of the alcohol, and made to come in contact with the whole of it by properly inclining the capsule in various directions: the alkaloid is thus dissolved, while the fatty impurities remain adhering to the capsule. The acid solution, which, if the last operation has been well performed, is clear and colourless, is poured off, the capsule is washed with a few drops more of the acid water, the washings are mixed with the first solution, and the whole is evaporated over sulphuric acid to about three quarters of its bulk. A saturated solution of pure carbonate of potassium

---

[*] Sulphate of *conine* being not quite insoluble in ether, a little of this alkaloid may remain in the ethereal solution; the greater part, however, is always in the aqueous acid solution.

[†] If *conine* be present, a great part of it will evaporate with the ether.

[‡] If *morphine* has to be sought for the liquid should be shaken with ether *immediately* after being neutralised with carbonate of sodium, and the ether should be poured off as quickly as possible, for, if the alkaloid have time to separate in the crystalline form, scarcely any of it is dissolved by the ether. (Otto.)

is added to the remaining liquid, and the mixture is treated with absolute alcohol, which dissolves the liberated alkaloid, but leaves undissolved the sulphate and excess of carbonate of potassium. On evaporating the alcoholic solution, the alkaloid is obtained crystallised, and in a state to show its characteristic reactions.

According to Otto (Ann. Ch. Pharm. c. 39) the above process of purifying the fixed alkaloids may be advantageously modified as follows. Instead of decomposing the impure tartrate or oxalate by acid carbonate of potassium or sodium, and obtaining a solution of the free alkaloid in ether, as described in the first part of this article, the salt dissolved in a small quantity of water is washed with ether, as long as the ether is coloured by it and leaves a residue on evaporation, and *afterwards* the solution is neutralised by carbonate of sodium and ether added to dissolve the alkaloid as already described. On evaporating the ethereal solution thus prepared, the alkaloid is left in a state of great purity. Or, the acid sulphate of the alkaloid may be formed and washed with ether, as in the process for purifying a volatile alkaloid.

Another method of detecting and separating the organic alkaloids from mixtures of other substances has been given by Sonnenschein (Ann. Ch. Pharm. civ. 45). This method is founded upon the property which the alkaloids possess, in common with ammonia, of giving precipitates in an acid solution of *phosphomolybdate* of *sodium*: it is very easy of execution, and seems to give very accurate results.

Phosphomolybdate of sodium is thus prepared. The yellow precipitate obtained by mixing acid solutions of molybdate of ammonium and phosphate of sodium is well washed, suspended in water, and heated with carbonate of sodium till it is completely dissolved. The solution is evaporated to dryness, and the residue ignited till all ammonia is expelled: if any reduction of molybdic acid take place during the ignition, the product is moistened with nitric acid and again ignited. It is then heated with water, nitric acid added till the solution has a strongly acid reaction, and the gold-yellow solution thus obtained is diluted till 10 parts of the solution contain 1 part of solid residue. It must be carefully preserved from contact with ammonia.

This reagent is applied to the separation of the alkaloids in the following manner. The whole of the organic matter to be examined is repeatedly exhausted with very dilute hydrochloric acid: the extract is evaporated at a heat of 30° C. to the consistence of a thin syrup, then diluted, and left for some hours in a cool place before filtration. The filtrate is precipitated by excess of phosphomolybdic acid, the precipitate collected on a filter, thoroughly washed with water containing phosphomolybdic and nitric acids, and introduced while moist into a flask. Caustic baryta is added, to a distinct alkaline reaction: and the flask having been fitted with a delivery-tube which is connected with a bulb-apparatus containing hydrochloric acid, heat is gradually applied, when the ammonia and volatile organic bases distil over, and are collected in the hydrochloric acid. The residue in the flask (containing the non-volatile alkaloids) is freed from excess of baryta by a current of carbonic anhydride, carefully evaporated to dryness, and extracted with strong alcohol. On evaporating the alcoholic solution, the bases are commonly obtained in a state of such purity that they will at once exhibit their characteristic reactions: occasionally, however, they require to be further purified by recrystallisation from alcohol or ether.

A process has been employed by Graham and Hofmann (Chem. Soc. Qu. J. v. 173; Ann. Ch. Pharm. lxxxiii. 39; Pharm. J. Trans. xi. 504) for the detection of strychnine in beer, which might doubtless be employed with equal advantage for the detection of other alkaloids in large quantities of liquid. It consists in leaving the liquid to be examined in contact with about a fortieth of its weight of good animal charcoal for a day, the whole being frequently shaken, collecting the charcoal on a filter, washing it once or twice with water, and then boiling it for half an hour with alcohol, which dissolves out the alkaloid. The alcoholic solution is evaporated, the residue is made alkaline by the addition of a few drops of potash or soda, and then shaken up with ether, which, when poured off and evaporated, leaves the organic base with its characteristic properties.

Schulze (Ann. Ch. Pharm. cix. 177) has indicated the acid liquid obtained by dropping pentachloride of antimony into aqueous phosphoric acid as a very delicate reagent for certain alkaloids, and as a substance which may probably serve for the separation of the alkaloids in general.

When an alkaloid has been separated in a state of purity by one of the above processes, or by any other, its chemical and physical properties must be carefully observed in order to determine its individual character, and the reactions obtained should in every case be controlled by comparison with those given by a pure specimen of the substance suspected.

From what has been stated above relative to the absorption of the alkaloids by animal charcoal, it is evident that that substance should never be employed to decolorise a solution previous to its being examined for poisonous organic bases. The employment of basic acetate of lead for the same purpose should also be avoided, since it not only introduces a poisonous metal into the substance to be examined, but the sulphuretted hydrogen, which is required to remove the lead, is apt to combine with some of the organic matters present, forming compounds which, in contact with the air, give rise to highly coloured and disagreeably smelling products, very difficult afterwards to get rid of. (Stas.)

For further details concerning modifications of Stas's process, and for some methods which are not mentioned in this article, the reader is referred to the article on the same subject in Liebig, Poggendorff, and Wöhler's "Handworterbuch der reinen und angewandten Chemie," 2nd edition, i. 464; and for the reactions of the individual alkaloids, to the various articles in this Dictionary in which they are specially described.—G. C. F.

ALKANET. The commercial name of two different plants. *True alkanet* consists of the leaves and roots of the *Lawsonia inermis*, which grows wild in the Levant. The leaves pulverised and made into a paste with water yield a yellow dye. The root, which contains a red pigment, is used as a cosmetic.

False alkanet (*Orcanette, Radix alcannæ spuriæ*) is the root of *Anchusa tinctoria*, which grows in France, Spain, Italy, Hungary and Greece. It is inodorous, has a faint, somewhat astringent taste, and colours the saliva. It is used in dyeing to produce a very brilliant violet and a grey; and for this purpose, linen or cotton goods previously prepared with alum-mordants for violet, and with iron-mordants for grey, are dipped in an alcoholic extract of the root. It is also used for dyeing silk, but not for wool. The colouring matter is called *Anchusin* (which see).

ALKARGEN and **ALKARSIN.** (See ARSENIDES OF METHYL.)

ALLAGITE. A mineral which appears to be an intimate mixture of hornstone and silicate of manganese, perhaps also with carbonate of manganese.

ALLAITE. Syn. of DIOPSIDE and AUGITE.

ALLANITE. (See ORTHITE.)

ALLANTOIC and **AMNIOTIC LIQUIDS.** The fœtus of most mammiferous animals is enveloped in two membranes, the outer of which is called the *allantois*, and the inner the *amnium*. The space between the two is connected by a duct with the urinary bladder of the fœtus, and contains a liquid called the allantoic liquid, which is in fact the urine of the fœtus. The amnium at first lies close upon the fœtus, but gradually separates and becomes filled with a liquid in which the fœtus floats suspended by the umbilical cord. This liquor is the *liquor amnii.*

The allantoic liquid is especially distinguished by containing allantoin, together with albumin, alkaline lactates, chloride of sodium and phosphates, and sometimes glucose. The amniotic liquid contains albumin, pyin, a substance resembling mucus, extractive matter, and in some instances glucose, together with alkaline chlorides, sulphates and phosphates.

These liquids have been investigated by many distinguished chemists, but the most exact analyses of them are those which have been recently made by Schlossberger (Ann. Ch. Pharm. xcvi. 67, and ciii. 193), and by Majewski (Dissert. de Substantiarum, &c., Dorpat, 1858; J. pr. Chem. lxxvi. 99). Majewski's results are as follows:

Both liquids, in the earlier stages of development of the embryo of cows and sheep, are clear and colourless: at a later stage, the amniotic liquid of the cow becomes gummy and yellowish, also turbid; in sheep and swine on the contrary, it always remains clear and colourless, and never becomes gummy. The allantoic liquid becomes yellower with age, and at last reddish yellow, but remains clear, excepting in swine, in which it is always turbid. Both liquids generally exhibit an alkaline reaction.

In both liquids, the solid constituents, organic and inorganic, increase for the most part in quantity as the development of the fœtus progresses. In the human fœtus, however, the quantity of solid matter in the amniotic liquid decreases considerably towards the time of birth (see table). The same result was obtained by Vogt and by Scherer, the latter of whom found 2·416 per cent. of solid constituents in the amniotic liquid in the fifth month of gestation, and only 0·852 at birth.

The amniotic liquid retains its albumin up to the period of maturity of the fœtus, but (as appears from investigations on the human embryo) this amount decreases in the later period of the development of the embryo, and this diminution appears to be connected with the formation of the placenta. In the amniotic liquid of the cow, the albumin may be recognised by its ordinary properties in the earlier stages of development, but afterwards the liquid becomes gummy and no longer exhibits the usual reaction with nitric acid. The same result was obtained by Schlossberger, (p. 130).

The allantoic liquid increases in quantity and consistence as the development of the embryo advances; it is always clear (excepting in swine) and resembles saturated urine. The allantoic liquid of swine contains iron and a peculiar compound of lime and albumin.

In both liquids, the quantity of sugar gradually increases from the earliest period of fœtal life, and is greatest a short time before birth. Sugar appears however to be present only in the vegetable feeders: in human embryonic liquids it cannot be detected.

The quantity of inorganic salts increases as development advances. Both liquids contain chlorides, phosphates and sulphates, the quantity being greater in the allantoic than in the amniotic liquid.

The following table exhibits a summary of the quantitative results obtained by Majewski:

	Period of Development.		Quantity in cub. cent.	Spec. grav.	In 100 parts.								
					Water.	Solid substance.	Organic.	Inorganic.	Albumin.	Sugar.	Urea.	P^2O^5	SO^3

Schlossberger found in the embryonic liquid of cows the following quantities of water and inorganic salts: — The ages of the fœtus were: of (*a*) 30 weeks; (*b*) 18 weeks; (*c*) 15 weeks; (*d*) 7—8 weeks; (*e*) 5 weeks, and (*f*) 3 weeks:

		Water.	Ash.	Soluble Salts.	Insoluble Salts.
Amniotic liquid.	*a.*	97·18			
	b.	97·28	0·72	0·694	0·026
	c.	98·96	1·02	1·00	0·02
	d.	98·67			
	e.		0·89	0·86	0·03
	f.	98·12			
Allantoic liquid.	*c.*	97·33	0·93	0·91	0·02
	e	98·76	0·73	0·70	0·03
	f.	97·35	0·71		

The liquids, even in the fresh state, exhibited an alkaline reaction, and effervesced briskly with acids: and they all exhibited the reactions of sugar, the amniotic liquid of *d* containing 0·092 per cent. of that substance, and the allantoic liquid of the same, 0·454 per cent. Schlossberger did not find urea in the amniotic liquid.

The albuminoïdal substances of both liquids exhibited differences of character amongst themselves, and many unusual reactions, indicating the presence of compounds intermediate between albumin casein, mucus and pyin. The reactions observed by Schlossberger are given in the following table:

	Amniotic liquid of *a* and *c*.	Allantoic liquid of *b* and *c*.
Appearance. Reaction on boiling and on addition of acetic acid.	*a.* Viscid like white of egg: mixed easily with water, and filtered readily. On boiling, became more mobile, with scarcely perceptible turbidity. On neutralising with acetic acid: scarcely perceptible turbidity, the liquid remaining viscid. On boiling, small flocks separated. The greater part of the protein-substance remained dissolved. On evaporation: films. *b.* Not viscid. Remained perfectly clear when boiled, either alone or with acetic acid.	*b.* Not viscid; clear on boiling. Acetic acid produces slight turbidity, and redissolves the flocks but slowly, even in excess and at the boiling heat. *c.* Coagulates even when boiled alone, the coagulum being but partially soluble in acetic acid. On evaporation: films. Both *b* and *c* become very turbid when boiled with chloride of calcium or sulphate of magnesium, especially *c*. The turbidity (arising in *b* most probably from carbonates) disappears on adding acetic acid.
Alcohol.	*a.* Throws down flocks soluble in warm water. *c.* No change.	*b.* No change. *c.* Turbidity.
Nitric acid.	*a.* Slight turbidity, disappearing with excess of acid. *c.* No turbidity. Liquid does not become yellow on boiling.	*b.* Scarcely perceptible turbidity. *c.* Precipitate and yellow colour on boiling.
HgCl.	*a.* Slight turbidity: small flakes on boiling. *c.* Turbidity. (With NO^6Hg: copious precipitate).	*b.* No change. *c.* Precipitate.
Ferrocyanide of potassium.	*a.* No change. *c.* Turbidity only after addition of acetic acid.	*b.* No change. *c.* After acidulation: flocks.
Acetate of lead. Basic acetate of lead. Tannin.	Copious precipitates.	Copious precipitates.
Alum.	No change in any instance.	

ALLANTOIN. $C^4H^6N^4O^3$, or $C^8H^6N^4O^6$.—Discovered by Vauquelin and Buniva (Ann. Chim. xxxiii. 269) in the amniotic liquid of the cow.* Lassaigne (Ann. Ch. Phys. [2] xvii. 301) obtained it from the allantoic liquid of the cow, and Wöhler (Ann. Ch. Pharm. lxx. 220) from the urine of calves. It is formed artificially by treating uric acid with water and peroxide of lead. (Liebig and Wöhler, Ann. Ch. Pharm. xxvi. 244.)

$$\underbrace{C^5H^4N^4O^3}_{\text{Uric acid.}} + H^2O + 2PbO = \underbrace{C^4H^6N^4O^3}_{\text{Allantoin.}} + \underbrace{CPb^2O^3}_{\text{Carbonate of lead.}};$$

or with a mixture of ferricyanide of potassium and caustic potash. (Schlieper, Ann. Ch. Pharm. lxvii. 216.)

$$\underbrace{C^5H^4N^4O^3}_{\text{Uric acid.}} + \underbrace{2C^6N^6Fe^2K^3}_{\text{Ferricyanide of potassium.}} + 4KHO = \underbrace{C^4H^6N^4O^3}_{\text{Allantoin.}} + \underbrace{CK^2O^3}_{\text{Carbonate of potassium.}} + \underbrace{4C^3N^3FeK^2}_{\text{Ferrocyanide of potassium.}} + H^2O.$$

Preparation.—Pulverised uric acid is suspended in water, nearly at the boiling heat, and finely pounded oxide of lead is added by small portions, and with frequent stirring, till the last portions no longer turn white. The liquid filtered while hot deposits on

---

* As, however, subsequent experimenters have not been able to obtain it from that source, it is probable that the amniotic liquid was mixed with allantoic liquid.

cooling, crystals of allantoin, while urea remains in solution, and oxalate of lead is left on the filter. The two latter compounds are produced by the action of the excess of peroxide of lead on the allantoin. (Liebig and Wöhler.)

$$C^4H^6N^4O^3 + 2PbO + H^2O = \underbrace{2CH^4N^2O}_{\text{Urea.}} + \underbrace{C^2Pb^2O^4}_{\text{Oxalate of lead.}}$$

To obtain allantoin from the allantoic liquid, the liquid is evaporated to a fourth of its bulk, and the crystals which are deposited on cooling are decolorised with animal charcoal. From calves' urine, it is prepared by evaporating the liquid to a syrup, and leaving it at least for several days, then diluting with water; washing the deposit with water to separate a quantity of gelatinous matter, chiefly consisting of urate of magnesium; boiling the crystalline residue of allantoin and phosphate of magnesium with water and animal charcoal; filtering at the boiling heat; and adding a few drops of hydrochloric acid to the filtrate to retain in solution the small quantity of phosphate of magnesium dissolved in the boiling liquid. The allantoin is then deposited in crystals on cooling.

Properties.—Allantoin forms shining colourless prisms, having a vitreous aspect, and belonging, according to Dauber (Ann. Ch. Pharm. lxxi. 68), to the monoclinic system. It is tasteless and without action on vegetable colours. It dissolves in 160 pts. of water at 20° C., and in 30 pts. of boiling water. Alcohol dissolves it in larger quantity.

Decompositions.—By dry distillation, allantoin is resolved into carbonate and cyanide of ammonium, a small quantity of empyreumatic oil and a very porous charcoal. When gently heated with nitric or hydrochloric acid, it is converted into urea and allanturic acid. (Pelouze, Gerhardt.)

$$C^4H^6N^4O^3 + H^2O = CH^4N^2O + \underbrace{C^3H^4N^2O^3}_{\text{Allanturic acid.}}$$

Heated with *sulphuric acid*, it is resolved into carbonic acid, carbonic oxide, and ammonia. (Liebig and Wöhler.)

$$C^4H^6N^4O^3 + 3H^2O = 2CO^2 + 2CO + 4NH^3.$$

Boiled with *baryta water*, it gives off ammonia and precipitates oxalate of barium:

$$C^4H^6N^4O^3 + 4BaHO + H^2O = 4NH^3 + 2C^2Ba^2O^4.$$

Similarly with aqueous *potash* (Liebig and Wöhler). A solution of allantoin in cold potash deposits all the allantoin unaltered, if immediately mixed with acids; but in the course of a day or two, it changes spontaneously into *hydantoate of potassium* ($C^4H^7KN^4O^4$), and is then no longer precipitated by acids, gives off but little ammonia when boiled, and does not form any oxalic acid:

$$C^4H^6N^4O^3 + KHO = C^4H^7KN^4O^4;$$

by the further action of the alkali, the hydantoate of potassium is resolved into urea and lantanurate of potassium:

$$C^4H^7KN^4O^4 = CH^4N^2O + C^3H^3KN^2O^3.$$

When the aqueous solution of allantoin is boiled with *metallic oxides*, compounds are formed which may be called *salts of allantoin*. Some of them consist simply of allantoin in which 1 at. H is replaced by a metal; thus, the *cadmium*-compound is $C^4H^5CdN^4O^3$: and the *silver*-compound, obtained by mixing a solution of allantoin with nitrate of silver and then with ammonia, is $C^4H^5AgN^4O^3$. But most of them contain an excess of the metallic oxide; thus, the zinc-compound is $Zn^2O.2C^4H^5ZnN^4O^3$, and the lead-compound $Pb^2O.4C^4H^5PbN^4O^3$. These compounds are insoluble or sparingly soluble in water, and decompose at 100° or a little above (Limpricht, Ann. Ch. Pharm. lxxxviii. 94). The silver-compound was obtained by Liebig and Wöhler.

When a solution of allantoin is boiled with excess of mercuric oxide, the filtrate becomes milky on cooling, and after a while deposits an amorphous powder containing $Hg^2O.3C^4H^5HgN^4O^3$, or $5HgO.3C^8H^5N^4O^5$. Three other compounds are said to be obtained from the mother-liquor. Allantoin does not precipitate corrosive sublimate; but with mercuric nitrate, in a cold and very dilute solution, it forms a precipitate containing $3Hg^2O.4C^4H^5HgN^4O^3$, or $5HgO.2C^8H^5N^4O^6$.

On this last property is founded a method for the quantitative estimation of allantoin, by precipitation with a graduated solution of mercuric nitrate. The method is similar to Liebig's process for the estimation of urea (*q. v.*), but is applicable to the estimation of allantoin only in liquids not containing urea. To precipitate 100 grms. of dry allantoin, $C^4H^6N^4O^3$, requires 172 grms. of mercuric oxide: consequently 10 cub. cent. of a graduated solution of mercuric nitrate containing 0·770 grm.

mercuric oxide, will precipitate 0·448 grm. allantoin. The liquid should contain a considerable excess of the mercuric salt.

ALLANTURIC ACID. $C^3H^4N^2O^3$.—A product of the decomposition of allantoin under the influence of nitric acid, hydrochloric acid, or peroxide of lead (p. 131): also obtained by treating uric acid with nitric acid or chlorine. It is a white solid body, slightly acid, deliquescent, nearly insoluble in alcohol, and yields by distillation a product containing hydrocyanic acid, with a bulky residue of charcoal. With nitrate of silver and acetate of lead, it forms white bulky precipitates, soluble in excess of these salts, and of allanturic acid. (Pelouze, Ann. Ch. Phys. [3] vi. 71.)

ALLEMONTITE. Arsenide of Antimony. (p. 371.)

ALLITURIC ACID. $C^3H^3N^2O^2$? Obtained by mixing an aqueous solution of alloxantin with excess of hydrochloric acid, boiling the liquid rapidly down to a small quantity, treating the pulverulent mixture of alliturie acid and undecomposed alloxantin with nitric acid to dissolve out the latter, and dissolving the residue in 15 or 20 pts. of hot water. The solution on cooling deposits alliturie acid in the form of a bulky yellowish white powder. It dissolves in strong sulphuric acid, and is precipitated from the solution by water. Its solution in ammonia yields *allliturate of ammonium*, by spontaneous evaporation, in colourless shining needles. The acid is decomposed by boiling with potash, with evolution of ammonia. (Schlieper, Ann. Ch. Pharm. lvi. 20.)

ALLIUM SATIVUM. (*Garlic.*) 100 pts. of the ash of the fresh plant yield 0·54 p.c. ash, containing in 100 parts: 12·17 carbonic anhydride, 4·82 sulphuric anhydride, 2·18 phosphoric anhydride, 35·13 potash, a trace of soda, 2·75 chloride of sodium, 5·74 carbonate of calcium, 6·89 carbonate of magnesium, 30·09 basic phosphate of calcium, 0·22 silica, and traces of the phosphates of magnesium and iron.

ALLOCHROÏTE. A variety of garnet, fine-grained, massive, and of dark dingy colour. (See GARNET.)

ALLOGONITE. Syn. with HERDERITE.

ALLOMORPHITE. Breithaupt's name for a mineral from Rudolstadt, which, according to the analysis of Gerngross, appears to be merely sulphate of barium.

ALLOPHANE. A hydrated silicate of aluminium, of a blue and sometimes green or brown colour, occurring massive, or in imitative shapes, in a bed of iron-shot limestone, or greywacke slate in the forest of Thuringia. It is transparent or translucent on the edges, moderately hard, but very brittle. Fracture imperfectly conchoidal. Lustre vitreous. Specific gravity 1·89. According to Stromeyer's analysis, it contains 21·92 silver, 32·2 alumina, 3·06 ferric hydrate, 0·73 lime, 0·52 sulphate of calcium, 3·06 carbonate of copper, and 41·30 water. Bunsen found in a specimen from a bed of lignite near Bonn, nearly the same composition, with a slight admixture of the carbonates of calcium and magnesium, but no copper. The mineral appears from the analyses of Walchner, Berthier, Guillemin, and others, to vary considerably in composition, but irrespective of foreign admixtures it agrees nearly with the formula $Al^4O^3.3SiO^2 + 5H^2O$. Schnabel (Jahresber. d. Chem. 1850, s. 731), has, however, analysed several allophanes containing from 14 to 19 per cent. of oxide of copper.

ALLOPHANIC ACID. $C^2H^4N^2O^3 = \left.\begin{matrix}C^2H^3N^2O^2\\ H\end{matrix}\right\}O$. *Ureo-carbonic acid.* (Gm. ix. 266; Gerh. i. 418.) By passing the vapour of cyanic acid into absolute alcohol, Liebig and Wöhler obtained in 1830 a peculiar ether, which they regarded as cyanate of ethyl; but in 1847 (Ann. Ch. Pharm. lix. 291), they discovered that the substance thus formed was the ether of a peculiar acid which they called allophanic acid.

This acid contains the elements of 2 at. cyanic acid and 1 at. water:

$$C^2H^4N^2O^3 = 2CHNO + H^2O.$$

Its ethers are produced when the vapour of cyanic acid comes in contact with the corresponding alcohols, and these ethers, treated with caustic alkalis, yield the corresponding salts of allophanic acid. The acid itself is not known in the separate state; when its salts are decomposed by a stronger acid, it is resolved into carbonic anhydride and urea:

$$C^2H^4N^2O^3 = CO^2 + CH^4N^2O.$$

In like manner the salts when heated in the state of aqueous solution, are resolved into carbonic anhydride, a carbonate, and urea.

Allophanate of Barium.—Obtained by dissolving allophanate of methyl or ethyl in baryta-water, whereby wood-spirit or alcohol is set free. The best method is to triturate allophanate of ethyl with crystals of hydrate of barium and baryta-water, without applying heat, till the ether disappears; filter from the remaining baryta-crystals; and set aside the filtrate for some days in a closed vessel; the barium-salt then separates gradually in hard crystalline nodules and crusts. The crystals are separated from the vessel under the liquid; the liquid quickly decanted; any carbonate of barium that may have been formed, is separated by elutriation; and the crystals are washed a few times with a small quantity of cold water, and dried on paper at the temperature of the air.

The barium-salt has an alkaline reaction. When heated alone, it does not give off a trace of water, but evolves monocarbonate of ammonium, and leaves cyanate of barium. Its aqueous solution becomes turbid below 100° C., gives off carbonic anhydride with effervescence, deposits all the baryta in the form of carbonate, and afterwards contains nothing but urea in solution:

$$2C^2H^3BaN^2O^3 + H^2O = CO^3Ba^2 + CO^2 + 2CH^4N^2O.$$

This salt, when an acid is poured upon it, is decomposed with brisk effervescence, yielding carbonic anhydride and urea; even carbonic acid produces this decomposition, though slowly; neither cyanic acid nor ammonia is formed.

Allophanate of Calcium.—Prepared like the barium-salt. Crystallisable. Sparingly soluble in water.

Allophanate of Potassium.—A solution of allophanic ether in alcoholic potash quickly deposits this salt in laminæ resembling those of chlorate of potassium.

Allophanate of Sodium.—Obtained like the potassium-salt, or by triturating the barium-salt, without application of heat, with an equivalent quantity of aqueous sulphate of sodium, and pouring alcohol upon the filtrate, which causes the sodium-salt to crystallise out in small prisms having an alkaline reaction. The aqueous solution of the salt evaporated without heat in vacuo, leaves the salt in the form of an iridescent gelatinous mass; evaporated between 40° and 50° C. it leaves the salt partly undecomposed, partly resolved into urea and carbonate of sodium. The aqueous solution mixed with nitric acid gives off carbonic anhydride and deposits shining scales of nitrate of urea. It does not precipitate chloride of barium, in the cold, but, when heated with it, forms an immediate precipitate of carbonate of barium.

Allophanic Ethers.—These compounds contain the elements of 2 at. cyanic acid, and 1 at. of an alcohol, monatomic, diatomic, or triatomic, *e. g.*

Allophanate of Ethyl . . . $C^4H^8N^2O^3 = 2CNHO + C^2H^6O$
Allophanate of Ethylene . . $C^4H^8N^2O^4 = 2CNHO + C^2H^6O^2$
Allophanate of Glyceryl . . $C^5H^{10}N^2O^5 = 2CNHO + C^3H^8O^3$

They are obtained by passing the vapour of cyanic acid into the alcohols.

Allophanate of Amyl, $C^7H^{14}N^2O^3 = C^2H^3(C^5H^{11})NO^3$.—Amylic alcohol rapidly absorbs the vapours produced by the action of heat on cyanuric acid, the liquid, after a while, solidifying into a magma of crystals, which may be purified by solution in boiling water. (Schlieper, Ann. Ch. Pharm. lix. 23.)

Allophanate of amyl forms nacreous scales, unctuous to the touch, and without taste or odour. It is insoluble in cold water, and its solution in hot water is neutral to vegetable colours, and does not precipitate metallic salts. It is very soluble in alcohol and in ether, and is precipitated from the solutions by water. It is not attacked by chlorine, bromine, nitric acid, or hydrosulphuric acid. It melts at a gentle heat, and sublimes without alteration; but its melting-point is very near that at which decomposition takes place. When heated above 100° C. it boils, gives off vapours of amylic alcohol, and leaves a residue of cyanuric acid, $3C^7H^{14}N^2O^3 = 3C^5H^{12}O + 2C^3N^3H^3O^3$. Distilled with fixed alkalis, it gives off amyl-alcohol (Schlieper). According to Wurtz (Compt. rend. xxix. 186), hot potash-ley converts it into carbonate of potassium, amylamine, and ammonia:

$$C^7H^{14}N^2O^3 + 4KHO = 2CO^3K^2 + C^5H^{13}N + NH^3 + H^2O.$$

Allophanate of Ethyl, or *Allophanic Ether*, $C^4H^8N^2O^3 = C^2H^3(C^2H^5)N^2O^3$.—When the vapours evolved from heated cyanuric acid are passed into absolute alcohol, the liquid becomes very hot and gradually deposits crystals of allophanic ether. The product is washed with a small quantity of alcohol, then dissolved in a mixture of alcohol and ether, and left to crystallise by evaporation (Liebig and Wöhler, Ann. Ch. Pharm. lviii. 260; lix. 291). According to Debus, allophanic ether is likewise produced by the action of ammonia on dicarbonate of ethylic disulphide.

Allophanic ether crystallises in colourless transparent needles, having a strong lustre. It is insoluble in cold water, but dissolves in boiling water and in alcohol, sparingly in ether. The solutions are neutral to test-papers, have no taste, and do not precipitate metallic salts.

The ether dissolves in ammonia somewhat more freely than in water, and crystallises therefrom, apparently free from ammonia. It dissolves in dilute sulphuric and nitric acid at the boiling heat, apparently without decomposition.

The crystals when heated in an open vessel melt and volatilise, the vapours condensing in the air in woolly flocks.

Treated with cold alcoholic potash or baryta-water, it yields a metallic allophanate and alcohol; with a boiling solution of potash, it forms cyanurate of potassium.

Allophanate of Ethylene, $C^4H^8N^2O^4 = \left.\begin{matrix}C^2H^3N^2O^2\\ H.C^2H^4\end{matrix}\right\}O^2$. *Allophanate of Glycol.*—Glycol (hydrate of ethylene) absorbs cyanic acid vapour with considerable force, so that it is best to cool the liquid during the absorption. The product is a white mass which dissolves in boiling alcohol, and separates on cooling in colourless shining laminæ. It is soluble in water, and melts at 100° C. without decomposition, to a clear colourless liquid, which solidifies in the crystalline form on cooling. At a stronger heat, it gives off carbonate of ammonium, and a thick viscid liquid, while cyanuric acid remains behind. Strong acids decompose it. With hydrate of barium, it behaves like the glycerin-compound next to be described; also with alcoholic potash. Strong aqueous potash likewise decomposes it, without formation of cyanuric acid. (Baeyer, Ann. Ch. Pharm. cxiv. 160.)

Allophanate of Glyceryl, $C^5H^{10}N^2O^5 = \left.\begin{matrix}C^2H^3N^2O^2\\ H^2.(C^3H^5)'''\end{matrix}\right\}O^3$. *Allophanate of Glycerin.*—Glycerin absorbs cyanic acid vapour, and is thereby converted into a white sticky mass, which dissolves in alcohol, leaving only a small quantity of cyamelide. The hot saturated solution, on cooling, deposits allophanate of glyceryl in hard crusts, composed of small translucent nodules. The crystallisation is often slow, especially when much glycerin is present; hence it is best to wash the crude product with cold alcohol before dissolving it in hot alcohol. The nodules, after recrystallisation from alcohol and drying at 100°, gave by analysis 33·6 per cent. carbon, 5·7 hydrogen, and 15·5 N, the formula requiring 33·7 C, 5·6 H, and 15·7 N.

Allophanate of glyceryl has neither taste nor smell, dissolves slowly but abundantly in water, and with tolerable facility in boiling alcohol. Heated in the dry state, it melts at about 160° C. to a colourless liquid, which solidifies in a gelatinous mass on cooling. On raising the temperature, a large quantity of carbonate of ammonium is evolved, and the mass ultimately turns brown and emits an odour of burnt horn.

It is not decomposed by *dilute acids* at ordinary temperatures, but strong nitric and sulphuric acids decompose it, with evolution of carbonic anhydride.

When triturated with water and *hydrate of barium*, it dissolves with facility; but the clear filtered solution deposits, after a short time, a bulky crystalline precipitate of carbonate of barium. The precipitation takes place even when the quantity of baryta is less than sufficient to saturate the allophanic acid present, so that it does not appear possible to prepare allophanate of barium in this manner. A certain quantity of that salt appears, however, to be formed, inasmuch as the liquid, after long standing, still deposits carbonate of barium when heated. If alcohol be added to the liquid containing an insufficient quantity of baryta, allophanate of ethyl is produced, probably by a catalytic action. Allophanate of glyceryl heated with baryta-water, yields nothing but carbonate of barium, urea, and glycerin.

In an alcoholic solution of *potash*, allophanate of glyceryl cakes together to a sticky mass, then gradually dissolves, the solution after a while depositing long needles which gradually change to small bulky masses of needles, apparently consisting of ethyl-carbonate of potassium. (Baeyer.)

Allophanate of Methyl, $C^3H^6N^2O^3 = C^2H^3(CH^3)N^2O^3$.—Discovered by Richardson in 1837 (Ann. Ch. Pharm. xxiii. 128), and originally called *ureo-carbonate of methyl*. When cyanic acid vapour is passed into methyl-alcohol, colourless crystals are obtained, which must be repeatedly washed with water, and then dried at 100° C. When heated, they partly volatilise undecomposed, and are partly resolved into ammonia, methylene gas (?), carbonic anhydride, and cyanuric acid:

$$3C^3H^6N^2O^3 = 3NH^3 + 3CH^2 + 3CO^2 + C^3H^3N^3O^3.$$

Heated with potash, they are decomposed in the same manner as the ethyl-compound. They dissolve readily in water, wood-spirit, and alcohol, especially when heated, forming neutral solutions.

Allophanate of Eugenic acid, $C^{12}H^{14}N^2O^4 = C^2H^3(C^{10}H^{11}O)N^2O^3$.—Eugenic acid rapidly absorbs cyanic acid vapour, forming a thick mass, which dissolves in hot alcohol and separates in long shining needles on cooling. At 100° C. it gave 57·0—57·9 per cent. C, 5·7—5·9 H, and 11·3 N (calc. 57·6 C, 5·6 H and 11·2 N). It contains the elements of 2 at. cyanic acid, and 1 at. eugenic acid ($2CNHO + C^{10}H^{12}O^2$), and is therefore analogous in composition to the allophanic ethers.

It is insoluble in water, sparingly soluble in cold alcohol, abundantly in hot alcohol.

It exhibits strong tendency to crystallise, so that even small quantities of the solution yield needles of proportionably considerable length. It is very soluble in ether, is destitute of taste and smell, has a silky lustre, and is permanent in the air.

Strong acids decompose it. Triturated with water and hydrate of barium, it forms a stiff paste, consisting of eugenate and allophanate of barium. Alcoholic potash does not appear to convert it into allophanate of potassium. When heated, it is resolved into eugenic and cyanuric acids. (Baeyer, Ann. Ch. Pharm. cxiv. 164.)

ALLOTROPY. See ISOMERISM.

ALLOXAN. (*Alloxanhydride*, Laurent.) $C^4H^2N^2O^4$, or $C^8H^2N^2O^8$.

History.—Discovered in 1817 by Brugnatelli, who designated it *Erythric acid:* first completely investigated by Liebig and Wöhler, in 1838 (Ann. Ch. Pharm. xxvi. 256); more recently by Schlieper (Ann. Ch. Pharm. lv. 253).

Formation and Preparation.—Alloxan is one of the numerous products of the oxidation of uric acid. Its preparation is a matter of some nicety. Liebig and Wöhler (*loc. cit.*) and Gregory (Phil. Mag. 1846), prepare it by the action of nitric acid on uric acid: concentrated nitric acid specific gravity 1·4 to 1·42), must be employed, and the temperature must not be allowed to rise above from 30° to 35° C. The process is thus conducted. From $1\frac{1}{2}$ to 2 parts strong nitric acid are placed in a beaker or porcelain basin, surrounded with cold water, and 1 pt. uric acid is added in successive small portions, with constant stirring, care being taken not to add a fresh portion of uric acid until the action caused by the addition of the former portion has quite subsided. Carbonic anhydride and nitrogen are evolved with effervescence, the action becoming gradually less violent as the operation proceeds; and crystals of alloxan gradually separate out. When the decomposition is complete, the mixture is left over night in a cool place, and the crystalline magma is then thrown on a funnel plugged with asbestos or coarsely pounded glass, and the last portions of the mother-liquor are carefully removed by washing with ice-cold water, till the washings have only a faintly acid reaction. Schlieper recommends removing the alloxan as it forms, in order to withdraw it from the further action of the nitric acid. The crystals of alloxan are dried by standing on filtering-paper or a porous tile, and then purified by solution in the smallest possible quantity of water at from 60° to 80° C.; the solution is filtered, and cooled till it crystallises: by evaporating the mother-liquor at a heat not exceeding 50° C. further crystals are obtained. The mother-liquor from these crystals, as well as that originally drained off, still contains alloxan, which is best separated by being previously converted into alloxantin. For this purpose, Schlieper proceeds as follows:—The mixed mother-liquors are *nearly* neutralised by carbonate of calcium or sodium—if the neutralisation were complete, the alloxan would be converted into alloxanic acid—and $\frac{5}{6}$ of the mixture are saturated with sulphuretted hydrogen, whereby sulphur and alloxantin are precipitated, some dialuric acid being also formed by the further action of the gas. The remaining $\frac{1}{6}$ is then added, the alloxan in which reconverts the dialuric acid formed into alloxantin. The alloxantin, which separates out completely in 24 hours, is freed from sulphur by solution in boiling water and crystallisation. In order to convert it into alloxan, one half of it is boiled with twice its volume of water, nitric acid being added drop by drop until the evolution of nitric oxide is perceptible, and the whole is heated in a water-bath until effervescence has ceased: small portions of the remaining half are then added successively, until a fresh addition produces no effervescence, then a little nitric acid, and so on till the nitric acid is completely decomposed, a little alloxantin remaining in excess. The solution is then filtered hot, and 3 or 4 drops of nitric acid added to the filtrate, which deposits crystals of alloxan on cooling. The total weight of alloxan thus obtained, should be about equal to that of uric acid employed. It is not advisable to operate on more than 70 to 80 grm. nitric acid at once.

Schlieper prefers chlorate of potassium to nitric acid as an oxidising agent. Into a basin containing 124 grm. or 4 oz. of uric acid, and 240 grm. or 8 oz. of moderately strong hydrochloric acid, he adds in successive portions, with constant stirring, 31 grm. or 6 dr. pulverised chlorate. Heat is evolved, which must not be allowed to rise above a certain limit; and a solution is obtained, containing only alloxan and urea ($C^5H^4N^4O^3 + H^2O + O = C^4H^2N^2O^4 + CH^4N^2O$). If proper care be taken, no gas is evolved. The solution is diluted with twice its volume of cold water, and decanted after three hours from any undissolved uric acid, which is heated to 50° with a little strong hydrochloric acid, and oxidised by a fresh portion of chlorate. In order to separate the alloxan from the urea, it is converted into alloxantin and reconverted into alloxan in the manner above described.

The alloxan prepared by the above methods contains 1 or 4 atoms of water of crystallisation. Anhydrous alloxan is obtained by heating the monohydrated compound to 150°—160° C. in a stream of dry hydrogen: the tetrahydrated compound must be first converted into the monohydrate by very careful heating to 100°. (Gmelin.)

Properties. — Anhydrous alloxan is of a pale reddish colour, which is probably due to the action of heat. When crystallised, it contains 1 or 4 atoms of water of crystallisation. The crystals obtained by evaporating a warm aqueous solution, contain 1 atom of water: they are oblique rhombic prisms, belonging to the monoclinic system, having the appearance of rhomboidal octahedra truncated at the extremities; they are large, transparent, and colourless, of a glassy lustre, and do not effloresce in the air. Liebig and Wöhler regarded this compound as anhydrous. Those obtained by cooling a warm saturated aqueous solution are transparent, pearly crystals, often an inch long, belonging to the trimetric system: they effloresce rapidly in warm air, and when heated to 100° are converted in the monohydrated compound. According to Gregory, there exists a third hydrate containing $2\frac{1}{2}$ atoms of water.

Alloxan is readily soluble in water or alcohol, forming colourless solutions, whence it may be precipitated by nitric acid. Its aqueous solution has an astringent taste, and colours the skin purple after a time, imparting a peculiar and disagreeable smell. It reddens litmus, but does not decompose alkaline-earthy carbonates: neither does it attack oxide of lead, even on boiling.

The following is the percentage composition of the three varieties:

C^4.	48	33·8
H^2.	2	1·41
N^2.	28	19·72
O^4.	63	45·07
$C^4H^2N^2O^4$.	142	100·00

		Calc.	Gm.
$C^4H^2N^2O^4$	142	88·75	88·65
H^2O	18	11·25	11·35
$C^4H^2N^2O^4$ + aq.	160	100·00	100·00

		Calc.	L. a. W.	Gm.
$C^4H^2N^2O^4 + H^2O$	160	74·77	73·5	74·72
$3H^2O$	54	25·23	26·5	25·28
$C^4H^2N^2O^4$ + 4 aq.	214	100·00	100·0	100·00

Decompositions. — 1. *By Heat.* When heated, alloxan melts, and is decomposed, forming, besides other products, cyanide of ammonium and urea. (Handwb. d. Chim.)

2. *By Electrolysis.* — An aqueous solution of alloxan is decomposed by the voltaic current, oxygen being evolved at the positive pole, and crystals of alloxantin formed at the negative pole.

3. *By Nitric acid.* — Hot dilute nitric acid converts alloxan into parabanic acid and carbonic anhydride:

$$C^4H^2N^2O^4 + O = \underset{\text{Parabanic ac.}}{C^3H^2N^2O^3} + CO^2$$

Further action of nitric acid converts the parabanic acid into nitrate of urea and carbonic anhydride. Monohydrated alloxan is scarcely attacked by heating with strong nitric acid. (Schlieper.)

4. *By Hydrochloric and Sulphuric acids.* — When heated with these acids, alloxan is converted into alloxantin, which gradually separates, and the mother-liquor yields on evaporation acid oxalate of ammonium. The decomposition goes through several stages: first, alloxantin, oxalic and oxaluric acids are formed; then the oxaluric acid is decomposed into oxalic acid and urea; and the urea is finally resolved into carbonic anhydride and ammonia, which last combines with the oxalic acid. (Liebig and Wöhler.)

5. An aqueous solution of alloxan is decomposed by *boiling* into carbonic anhydride, parabanic acid, and alloxantin, which separating on cooling:

$$3C^4H^2N^2O^4 = CO^2 + \underbrace{C^3H^2N^2O^3}_{\text{Parabanic acid.}} + \underset{\text{Alloxantin.}}{C^8H^4N^4O^7}$$

6. *By reducing agents*, alloxan is converted into alloxantin. This decomposition is effected by protochloride of tin, sulphuretted hydrogen, or zinc and hydrochloric acid (nascent hydrogen):

$$2C^4H^2N^2O^4 + H^2 = C^8H^4N^4O^7 + H^2O$$

the further action of the two latter reagents converts the alloxantin into dialuric acid:

$$C^8H^4N^4O^7 + H^2 + H^2O = \underbrace{2C^4H^4N^2O^4}_{\text{Dialuric acid.}}$$

The same decomposition is effected when an aqueous solution of alloxan is boiled with excess of sulphurous acid. When, however, aqueous alloxan is saturated with sulphurous anhydride, and the solution evaporated at a gentle heat, it yields on cooling large efflorescent tables of a conjugated acid, which, by analysis of its potassium-salt, appears to contain the elements of 1 atom alloxan and 1 atom sulphurous anhydride (Gregory). When a cold saturated solution of aqueous alloxan is treated with sulphurous acid in excess, ammonia added, and the whole boiled, thionurate of ammonium is formed:

$$C^4H^2N^2O^4 + NH^3 + SO^3H^2 = \underset{\text{Thionuric acid.}}{C^4H^5N^3SO^6} + H^2O$$

7. *By fixed alkalis and alkaline earths*, alloxan is converted into alloxanic acid:

$$C^4H^2N^2O^4 + H^2O = \underset{\text{Alloxanic acid.}}{C^4H^4N^2O^5}$$

Aqueous alloxan gives with baryta- or lime-water a gradual white precipitate of alloxanate of barium or calcium: a similar action is produced by a mixture of chloride of barium, or nitrate of silver, with ammonia. If the alkali be in excess, the precipitated alloxanate contains mesoxalate, and the filtrate contains urea (Schlieper). By boiling with aqueous alkalis, alloxan is decomposed into mesoxalic acid and urea:

$$C^4H^2N^2O^4 + 2H^2O = \underset{\text{Mesoxalic acid.}}{C^3H^2O^5} + \underset{\text{Urea.}}{CH^4N^2O}$$

8. *By Ammonia.*—A solution of alloxan in aqueous ammonia turns yellow when gently heated, and on cooling forms a yellow transparent jelly of mycomelate of ammonium: the liquid retains in solution alloxanate and mesoxalate of ammonium and urea (Liebig):

$$C^4H^2N^2O^4 + 2NH^3 = \underset{\text{Mycomelic acid.}}{C^4H^4N^4O^2} + 2H^2O$$

9. With *ferrous salts*, aqueous alloxan gives a deep blue colour, but no precipitate unless an alkali be added.

10. When aqueous alloxan is heated with *peroxide of lead*, carbonic anhydride is evolved, carbonate of lead precipitated, and urea is contained in the solution:

$$C^4H^2N^2O^4 + 4PbO + H^2O = CH^4N^2O + 2CO^3Pb^2 + CO^2.$$

11. When aqueous alloxan is gradually added to a boiling solution of *neutral acetate of lead*, mesoxalate of lead is precipitated, and urea remains in solution. When the lead-solution is added to the alloxan-solution, alloxantin and oxalic acid are formed.

F. T. C.

ALLOXANIC ACID. $C^4H^4N^2O^5$. = alloxan + H^2O.

History.—Discovered by Liebig and Wöhler, in 1838 (Ann. Ch. Pharm. xxvi. 292), further examined by Schlieper. (Ann. Ch. Pharm. lv. 263, lvi. 1.)

Formation and Preparation.—Alloxanic acid is formed when alloxan is brought into contact with aqueous fixed alkalis (see ALLOXAN), alkaline carbonates, or acid carbonate of calcium (Städeler). It is prepared by decomposing alloxanate of barium by sulphuric acid. The salt is suspended in a little water, and a slight excess of dilute sulphuric acid added, with constant agitation: 5 pts. salt require $1\frac{1}{3}$ pt. strong sulphuric acid, duly diluted. After digestion for some time at a gentle heat, the excess of sulphuric acid is removed by pure carbonate of lead, the excess of lead by sulphuretted hydrogen, and the excess of gas by heat: the solution is then filtered, and evaporated to a syrup, either over sulphuric acid in vacuo, or at a temperature not exceeding 40° C.

Properties.—Thus prepared, alloxanic acid forms hard white needles, arranged in radiated groups, or in warty masses: if it has been heated above 40° C. it crystallises with difficulty, or not at all. The crystals are permanent in the air: have a sour taste, but a sweetish aftertaste; are readily soluble in water, less readily, viz. in 5 to 6 pts. alcohol, still less in ether. The solution is acid to litmus, readily decomposes carbonates and acetates, and dissolves zinc, cadmium, &c., with evolution of hydrogen. Its composition is:

C^4	48	30·0
H^4	4	2·5
N^2	28	17·5
O^5	80	50·0
$C^4H^4N^2O^5$	160	100·0

It is a dibasic acid, forming acid as well as normal salts: the formula of normal alloxanates is $C^4H^2M^2N^2O^5$, of acid alloxanates, $C^4H^3MN^2O^5$. It also appears to form basic salts with some heavy metals. Alloxanates are mostly obtained by the action of aqueous alloxanic acid on metallic carbonates. The alkaline alloxanates are soluble in water: the normal salts of other metals are generally more or less insoluble, the acid salts readily soluble. They part with their water of crystallisation at temperatures varying from 100° C. to 150°; and require a stronger heat for their decomposition.

The alloxanates have been investigated principally by Schlieper (*loc. cit.*). The only one which requires special mention is the normal *barium-salt*, which is employed for the preparation of alloxanic acid. It is obtained by mixing 2 vols. of a cold saturated solution of alloxan with 3 vols. of a cold saturated solution of chloride of barium, heating the mixture to 60° or 70°, and adding gradually potash-solution, with constant agitation. Each addition of potash produces a white curdy precipitate, which soon redissolves: at last the precipitate remains permanent, and the liquid suddenly becomes filled with alloxanate of barium, which falls down as a heavy crystalline powder, and may be freed from chloride of potassium by washing with cold water. If too much potash has been added, a persistent curdy precipitate forms, consisting of basic alloxanate and mesoxalate of barium; it must be redissolved by the addition of a little alloxan-solution. A less abundant, but more certainly pure product is obtained by adding baryta-water to aqueous alloxanic acid.

Decompositions. 1. *By Heat.*—When heated, the acid melts with intumescence, becomes carbonised, and evolves vapours of cyanic acid. Alkaline alloxanates are decomposed by heat into a mixture of carbonate and cyanide. An aqueous solution of alloxanic acid is decomposed by boiling, carbonic anhydride being abundantly evolved, and two new bodies formed, one of which, *leucoturic acid*, being insoluble in water, separates as a white powder when the solution, after evaporation to a syrup, is diluted with water; while the other, *difluan*, remains in solution, but may be precipitated by alcohol. The latter is formed in far the larger quantity. The composition of these bodies is not accurately established: Schlieper assigns to the former the formula $C^3H^3N^2O^3$, to the latter, $C^3H^4N^2O^{2\frac{1}{2}}$ or $C^6H^4N^2O^5$. Schlieper states that a third substance is also formed, soluble in water and alcohol, with the formula $C^3H^5N^2O^3$. The alcoholic solution of alloxanic acid is not decomposed by boiling. Alloxanates are decomposed by boiling with water into mesoxalate and urea:

$$C^4H^4N^2O^5 + H^2O = C^3H^2O^5 + CH^4N^2O$$

2. When heated with nitric acid, alloxanic acid is decomposed into parabanic acid and carbonic anhydride:

$$C^4H^4N^2O^5 + O = C^3H^2N^2O^3 + CO^2 + H^2O.$$

3. Alloxanate of potassium gives a dark blue precipitate with ferrous-salts. (See ALLOXAN.)

Alloxanic acid is not decomposed by sulphuretted hydrogen, or by boiling with bichromate of potassium or bichloride of platinum.

According to Gmelin, the compound described by Vauquelin (Mém. du. Mus. vii. 253) by the names *acide purpurique blanc* or *urique suroxigenée* (oxuric acid) is to be regarded as impure alloxanic acid.—F. T. C.

ALLOXANTIN. (*Uroxin.*) $C^8H^4N^4O^7 + 3H^2O$ [or $C^{16}H^4N^4O^{14} + 6HO$].

History.—Probably first noticed by Prout; first described by Liebig and Wöhler in 1838; further examined by Fritzsche, who called it *uroxin* (J. pr. Chem. xiv. 237).

Formation and preparation.—Alloxantin is formed in various reactions. 1. By the action of warm dilute nitric acid on uric acid.—2. By the action of electrolysis, or of reducing agents on alloxan, or by heating it with water or dilute sulphuric acid (see ALLOXAN): also by dissolving alloxan in dialuric acid.—3. By heating dialuramide (uramil) with dilute sulphuric or hydrochloric acid, or thionurate of ammonium with a large quantity of dilute sulphuric acid.—4. By the action of the air on dialuric acid.—5. In the decomposition of caffeine by chlorine. (Rochleder.)

The following are the most usual processes for the preparation of alloxantin. 1. Dry uric acid is added gradually to warm, very dilute, nitric acid, as long as it is dissolved, and the solution evaporated till it has an onion-red colour; or dilute nitric acid is added to 1 pt. uric acid in 32 pts. water, till all is dissolved, and the solution evaporated to two-thirds; the crystals obtained in either case are purified by re-crystallisation from hot water.—2. Sulphuretted hydrogen is passed through an aqueous solution of alloxan, till a crystalline magma forms; this is dissolved by heat, the precipitated sulphur filtered off hot, and the filtrate crystallised.—3. A solution of alloxan in dilute sulphuric acid is heated for a few minutes, when it becomes turbid, and deposits crystals of alloxantin on cooling.—4. Dialurate of ammonium is evaporated at a gentle heat with a large excess of dilute sulphuric acid; when dialuric acid crystallises out, which is converted into alloxantin by the action of the air, without changing its crystalline form. (Gregory.)

Properties. — The alloxantin obtained by the above methods, contains 3 atoms of water of crystallisation, which it does not lose till heated to above 150°C. Of the properties of anhydrous alloxantin nothing is known. The crystals are small, transparent, colourless, or yellowish, oblique rhombic prisms, hard, but very friable. In those prepared by methods 1, 2, and 3, the angle of the obtuse lateral edge is 105°: in the dimorphous crystals obtained from dialurate of ammonium, it is 121°. They redden litmus, but do not exhibit acid properties in other respects. They are very slightly soluble in cold water, more abundantly, but still slowly, in boiling water, from which solution the alloxantin separates almost completely on cooling. The following is the percentage composition of anhydrous and hydrated alloxantin.

Anhydrous.		*Calc.*	*Crystals.*		*Calc.*	L. and W.	Fritzsche.
C^8	96	35·8	C^8	96	29·81	30·52	30·06
H^4	4	1·5	H^{10}	40	3·11	3·15	3·04
N^4	56	20·9	N^4	56	17·39	17·66	17·52
O^7	112	41·8	O^{10}	160	48·67	48·67	49·38
$C^8H^4N^4O^7$	268	100·0	$C^8H^4N^4O^7 + 3aq.$	322	100·00	100·00	100·00

Decompositions. — 1. *By heat*, alloxantin yields a peculiar crystalline product.

2. *By oxidising agents*, alloxantin is converted into alloxan. This change takes place slowly, when its aqueous solution is exposed to the air, much more rapidly when it is heated with chlorine-water; or when it is diffused in boiling water and a small quantity of nitric acid added. Selenious acid also converts the hot solution of alloxantin into alloxan, with separation of selenium.

3. *By reducing agents, e. g.* sulphuretted hydrogen, a hot solution of alloxantin is converted into dialuric acid:

$$C^8H^4N^4O^7 + H^2S + H^2O = \underset{\text{Dialuric acid.}}{2C^4H^4N^2O^4} + S.$$

4. When boiled with excess of hydrochloric acid, it is partly decomposed, and deposits on cooling, a white powder of alliturie acid, $C^3H^3N^2O^2$ (Schlieper). At the same time, alloxan and parabanic acid are formed, together with an acid which Schlieper calls dilituric acid, which he has not succeeded in isolating.

5. *With baryta-water*, alloxantin gives a violet precipitate, which, on boiling, turns white, and then disappears; the solution contains alloxanate and dialurate of barium,

$$C^8H^4N^4O^7 + 3BaHO = \underset{\substack{\text{Alloxanate}\\\text{Ba.}}}{C^4H^2Ba^2N^2O^5} + \underset{\text{Dialurate Ba.}}{C^4H^3BaN^2O^4} + H^2O.$$

6. *By ammonia*, alloxantin is converted into purpurate of ammonium (murexide).

$$C^8H^4N^4O^7 + 2NH^3 = \underset{\text{Murexide.}}{C^8H^8N^6O^6} + H^2O$$

This change takes place either in the wet or the dry way. In the dry way it occurs when alloxantin is heated to 100° C. in an atmosphere of dry ammonia (Gmelin): or when it is exposed at the ordinary temperature to air containing ammonia. In the wet way, an aqueous solution of alloxantin is coloured purple-red by ammonia: the colour disappears on further heating, or when left for some time in the cold. When nitric acid is gradually added to the hot alloxantin-solution, so as to form alloxan, the addition of ammonia produces a deeper purple colour as the quantity of nitric acid, and consequently of alloxan, increases; but the coloration ceases when the alloxantin is entirely converted into alloxan. When a solution of alloxantin in thoroughly boiled water is mixed with ammonia, and boiled till the purple colour has disappeared, crystals of dialuramide (uramil) are deposited: the yellow mother-liquor becomes purple by exposure to the air, deposits crystals of purpurate of ammonium, and finally coagulates into a jelly of mycomelate of ammonium:

$$C^8H^4N^4O^7 + 4NH^3 = \underset{\text{Uramil.}}{C^4H^5N^3O^3} + \underset{\substack{\text{Mycomel.}\\\text{amm.}}}{C^4H^7N^5O^2} + 2H^2O.$$

The formation of murexide depends upon the oxidation by the air of some of the uramil which is dissolved in the ammonia. When a solution of alloxantin in aqueous ammonia is repeatedly evaporated at a gentle heat in an open vessel, the residue being each time dissolved in ammonia, pure oxalurate of ammonium is finally obtained: if the air be excluded, this substance does not form.

7. Aqueous solutions of alloxantin and sal-ammoniac, both freed from air by boiling,

form a purple-red mixture, which soon becomes paler, and deposits colourless or reddish scales of uramil: the mother-liquor contains alloxan and hydrochloric acid:

$$C^8H^4N^4O^7 + NH^4Cl = \underset{\text{Uramil.}}{C^4H^5N^3O^3} + C^4H^2N^2O^4 + HCl.$$

Acetate or oxalate of ammonium acts like the chloride.

8. When aqueous alloxantin is heated with oxide of silver, carbonic anhydride is evolved, silver reduced, and oxalurate of silver formed:

$$C^8H^4N^4O^7 + 4Ag^2O + H^2O = \underset{\text{Oxalurate silver.}}{2C^3H^3AgN^2O^4} + 2CO^2 + 6Ag.$$

From nitrate of silver, alloxantin precipitates metallic silver: the filtrate gives a white precipitate with baryta-water. Aqueous alloxantin dissolves mercuric oxide with evolution of gas, probably forming mercurous alloxanate. By peroxide of lead alloxantin is converted like alloxan. — 9. Aqueous alloxantin is decomposed by long keeping, even out of contact with air, and is converted into alloxanic acid. (Gregory.)

Tetramethyl-Alloxantin, $C^8H^{14}N^4O^8 = C^4(CH^3)^4N^4O^7 + H^2O$.—This composition is assigned by Gerhardt to a product of the action of chlorine on caffeine, discovered by Rochleder (Ann. Ch. Pharm. lxxi. 1), also called *Amalic acid* (*q. v.*)—F. T. C.

ALLOYS. (See METALS.)

ALLUAUDITE. (See TRIPHYLINE.)

ALLYL. *Acryl, Propylenyl.* C^3H^5.—Berthelot and De Luca in 1854 (Ann. Ch. Phys. [3] xliii. 257), by acting on glycerin with iodine and phosphorus, obtained the compound C^3H^5I, which they regarded as *iodotritylene*, that is to say, tritylene, C^3H^6, having 1 at. H replaced by iodine, but which is now rather regarded as the iodide of the radicle allyl. Zinin, in 1855 (Ann. Ch. Pharm. xcv. 128) by acting on this iodide with sulphocyanate of potassium, obtained a volatile oil, the sulphocyanate of allyl, $C^3H^5.CyS$, identical with volatile oil of mustard, and afterwards (Ann. Ch. Pharm. xcvi. 361) prepared the benzoate, acetate, &c. of the same series. Hofmann and Cahours, in 1856 (Compt. rend. xlii. 217; more fully, Phil. Trans. 1857, 1; Ann. Ch. Pharm. cii. 285; Chem. Soc. Qu. J. x. 316), discovered allylic alcohol and prepared a great number of its derivatives. Lastly, Berthelot and De Luca in the same year isolated the radical allyl, and prepared the dibromide and diniodide. The existence of this radicle in the oils of mustard and garlic was first demonstrated by Wertheim. (Ann. Ch. Pharm. li. 289; lv. 297.)

Allyl is the third term in the series of homologous radicles C^nH^{n-1}, vinyl C^2H^3 being the second; it is the only radicle of the series that has yet been isolated.

Allyl, in the free state, $C^6H^{10} = C^3H^5.C^3H^5$, is obtained by decomposing the iodide, C^3H^5I, with sodium at a gentle heat, and afterwards distilling the liquid product. It is a very volatile liquid having a peculiar pungent, ethereal odour, somewhat like that of horse-radish. Specific gravity 0·684 at 14. Boils at 59° C. Vapour-density by experiment 2·92, by calculation from the formula C^6H^{10} (2 vol.) 2·89. Allyl is but little attacked by strong sulphuric acid. Fuming nitric acid changes it into a neutral liquid nitro-compound, soluble in ether and decomposed by heat. Chlorine acts strongly upon it, hydrochloric acid being evolved and a liquid compound formed heavier than water. Bromine and iodine unite directly with it, forming the compounds $C^3H^5Br^2$ and $C^3H^5I^2$. (Berthelot and De Luca.)

ALLYL-ALCOHOL. *Hydrate of Allyl*, $C^3H^6O = \left.\begin{matrix}C^3H^5\\H\end{matrix}\right\}O$.—Prepared by the action of ammonia on oxalate of allyl, oxamide being formed at the same time:

$$\underbrace{(C^2O^2)''(C^3H^5)^2O^2}_{\text{Oxalate of allyl.}} + 2NH^3 = 2\underbrace{(C^3H^5.H.O)}_{\text{Allyl-alcohol.}} + \underbrace{N^2.(C^2O^2)''.H^4}_{\text{Oxamide.}}.$$

Dry gaseous ammonia is passed into oxalate of allyl till the whole is converted into a solid mass of oxamide saturated with allyl-alcohol. The latter is then distilled off in a bath of chloride of calcium, and rectified over anhydrous sulphate of copper. The alcohol appears also to be produced by distilling benzoate or acetate of allyl with potash (Zinin, Ann. Ch. Pharm. xcvi. 362). It is a colourless liquid, having a pungent but not unpleasant odour, and a spirituous burning taste. It mixes in all proportions with water, common alcohol, and ether. It burns with a brighter flame than common alcohol. Boiling-point 103° C.* It gave by analysis, 62·08 per cent. C and 10·43 H, the formula C^3H^6O requiring 62·07 C, 10·34 H, and 27·59 O.

---

* One sample of the alcohol very carefully prepared, was found to boil between 90° and 100° C. This, however, may have arisen from decomposition; at all events, the number 103° agrees with the differences generally observed in analogous ethyl and allyl-compounds. (Hofmann.)

Allyl-alcohol is strongly attacked by phosphoric anhydride, a colourless gas, probably C^3H^4, being given off, which burns with a very bright flame. It is violently oxidised by a mixture of acid chromate of potassium and sulphuric acid, with formation of allylic aldehyde (acrolein), C^3H^4O, and acrylic acid, $C^3H^4O^2$. The same transformation is effected, though more slowly, by platinum black. Potassium (or sodium) decomposes allyl-alcohol, with evolution of hydrogen and formation of a gelatinous mass of allylate of potassium, C^3H^4KO. Strong sulphuric acid acts on it in the same manner as on common alcohol, converting it into allyl-sulphuric acid, $C^3H^5.H.SO^4$. With potash and disulphide of carbon, it yields the potassium-salt of allyl-xanthic acid, $C^4H^6S^2O$.

ALLYL, BROMIDES OF. The *monobromide*, C^3H^5Br, which is isomeric, or perhaps identical with bromotritylene, is obtained by the action of bromide of phosphorus on allyl-alcohol (Hofmann and Cahours); or by distilling dibromide of tritylene, $C^3H^6Br^2$ (or hydrobromate of bromotritylene, $C^3H^5Br.HBr$) with alcoholic potash (Cahours). Its specific gravity is 1·47, and boiling-point 62° C. (Cahours.)

The hydrobromate of this compound, or dibromide of tritylene, is produced when bromine is gradually passed into an excess of tritylene gas; but when tritylene is passed into excess of bromine, a number of compounds are formed which may be regarded as compounds of hydrobromic acid with bromide of allyl having its hydrogen more or less replaced by bromine. (See TRITYLENE.)

Dibromide of Allyl, $C^3H^5Br^2$.—Allyl unites directly with bromine, the combination being attended with evolution of heat. If the action be stopped just as the liquid begins to show colour from excess of bromine, and to give off hydrobromic acid, and if the liquid be then treated with potash, dibromide of allyl is obtained as a crystalline body, very soluble in ether. It melts at 37° C. and when once fused, sometimes remains liquid at ordinary temperatures. It may be volatilised without decomposition (Berthelot and De Luca). The allyl in this compound takes the place of 2 at. H.

Tribromide of Allyl, $C^3H^5Br^3$.—Obtained by gradually adding bromine to iodide of allyl in a vessel surrounded by a freezing mixture. The mixture is left to itself till the next day; freed from crystallised iodine by washing first with alkaline and afterwards with pure water; then dried and distilled; the liquid which passes over is again washed and distilled, collecting apart that which goes over from 210° to 220 °C.; the purple liquid then obtained is cooled to 0° C. whereupon it solidifies in a crystalline mass; the mother-liquor is drained off; and the product is fused and again rectified. By this method, tribromide of allyl is obtained as a colourless neutral liquid, of not unpleasant odour, specific gravity 2·436 at 23° C., boiling at 217° or 218°, and solidifying below 10°. By slow solidification, it yields shining prisms, which melt at 16°. (Wurtz, Ann. Ch. Phys. [3] lx. 84.)

Alcoholic potash converts it into an ethereal substance boiling at 135° C. Heated to 100° in a sealed tube with alcoholic ammonia, it is converted into *Dibromallylamine*, $N.H.(C^3H^4Br)^2$ (M. Simpson, Phil. Mag. [4] xvi. 257). The decomposition appears to consist of two stages; in the first, the compound $C^3H^5Br^3$, is converted into $C^3H^4Br^2$, and in the second, this latter is converted into dibromallylamine:

$$C^3H^5Br^3 + NH^3 = C^3H^4Br^2 + NH^4Br.$$

$$\text{and}\qquad 2C^3H^4Br^2 + 3NH^3 = N\begin{cases} C^3H^4Br \\ C^3H^4Br \\ H \end{cases} + 2NH^4Br.$$

Dissolved in glacial acetic acid, and heated with acetate of silver to 120°—125° C. for a week, it yields bromide of silver and triacetin (p. 25.)

$$C^3H^5.Br^3 + O^3\begin{cases}(C^2H^3O)^3 \\ Ag^3\end{cases} = O^3\begin{cases}(C^3H^5)''' \\ (C^2H^3O)^3\end{cases} + 3AgBr.$$

The radicle C^3H^5 in this compound is triatomic, replacing 3 at. hydrogen, as seen in the reaction just mentioned; in other words the compound is formed on the type $H^3.H^3$. Wurtz has obtained two compounds (or perhaps only one) isomeric with it, by the action of bromine on bromotritylene, C^3H^5Br, and on the isomeric body bromide of allyl. These compounds are perhaps formed on the type $H^2.H^2$, their rational formula being $C^3H^4Br.Br^2$. They both have a specific gravity of 2·392 at 23° C., and boil at about 195°; but they differ somewhat in odour and in their action on silver-salts, the former being more energetic in both respects than the latter (Wurtz). The action of bromide of bromallyl on ammonia is totally different from that of tribromide of allyl, giving rise, not to dibromallylamine, but to the compound $C^3H^4Br^2.C^3H^5Br^4$. (Simpson.)

ALLYL, CHLORIDE OF. *Chlorotritylene*, C^3H^5Cl, is obtained like the bromide, by the action of chloride of phosphorus on allyl-alcohol, or by treating chloride of tritylene, $C^3H^6.Cl^2$ (hydrochlorate of allyl-chloride, $C^3H^5Cl.HCl$) with alcoholic potash. The last mentioned compound treated with excess of chlorine yields substitution-products similar to those obtained with the bromide. (See TRITYLENE.)

ALLYL HYDRIDE OF, $C^3H^6 = C^3H^5.H$.—Tritylene or propylene, the third term in the series of hydrocarbons C^nH^{2n}, is perhaps the hydride of allyl.

ALLYL, IODIDES OF. The *monoiodide* (iodotritylene) C^3H^5I, is obtained by distilling glycerin at a gentle heat with diniodide of phosphorus;

$$2C^3H^8O^3 + 2PI^2 = 2C^3H^5I + P^2O^3 + 3H^2O + 2I.$$

A quantity of tritylene-gas is given off, due to a secondary action, and a mixture of oxygen-acids of phosphorus with iodine and undecomposed glycerin remains in the retort. Tri-iodide of phosphorus may also be used, but the action is less regular. The distillate is purified by rectification, the portion which passes over at 100° C. being collected apart (Berthelot and De Luca). Iodide of allyl is also produced by the action of iodine and phosphorus on allyl-alcohol. (Hofmann and Cahours.)

When first prepared, it is colourless, and has an ethereal alliaceous odour; but by the action of air and light, it becomes coloured and then gives off irritating vapours Specific gravity 1·789 at 160° C. Boiling-point 101°. It is insoluble in water, but dissolves in alcohol and ether. By the action of zinc or mercury, and hydrochloric or dilute sulphuric acid, it is converted into tritylene (hydride of allyl):

$$C^3H^5I + 4Hg + HCl = C^3H^6 + Hg^2Cl + Hg^2I.$$
$$\text{and} \quad C^3H^5I + 2Zn + HCl = C^3H^6 + ZnCl + ZnI.$$

Iodide of allyl is decomposed by silver-salts, iodide of silver being formed, and the acid radicle being transferred to the allyl.

Diniodide of Allyl, $C^3H^5I^3$.—Obtained by dissolving 6 or 7 pts. of iodine in 1 pt. of allyl at a gentle heat. The mixture, which is liquid at first, solidifies after a few minutes; and by triturating the mass with aqueous potash, then digesting in boiling ether, and evaporating the ethereal solution, the diniodide of allyl is obtained in the crystalline form. It is decomposed by distillation, yielding iodine and a neutral liquid. It is scarcely attacked by aqueous potash; but alcoholic potash decomposes it, producing a liquid which smells like allyl. It is not acted upon by mercury and hydrochloric acid. (Berthelot and De Luca.)

Iodide of Mercurallyl, $C\,H^5Hg^2I$, is obtained by agitating iodide of allyl with metallic mercury. On crystallising the resulting yellow mass from a boiling mixture of alcohol and ether, nacreous scales are formed, which turn yellow when exposed to light, especially if moist. They dissolve but sparingly in cold alcohol, and are nearly insoluble in boiling alcohol. Heated to 100° C. they sublime in rhombic plates; at 135° they melt, and solidify in a crystalline mass on cooling. When quickly heated, they decompose, yielding a yellow sublimate and a carbonaceous residue. The alcoholic solution treated with oxide of silver, yields a strongly alkaline liquid, which when evaporated leaves a syrupy mass, probably consisting of hydrate of mercurallyl. (Zinin.)

ALLYL, OXIDE OF. *Allylic ether*, $(C^3H^5)^2O$, is produced by the action of iodide of allyl on allylate of potassium:

$$C^3H^5KO + C^3H^5I = KI + (C^3H^5)^2O;$$

also by the action of oxide of silver or oxide of mercury on iodide of allyl:

$$2C^3H^5I + Ag^2O = 2AgI + (C^3H^5)^2O.$$

A body having the same composition was obtained by Wertheim (Ann. Ch. Pharm. li. 309; lv. 297), by acting on oil of garlic, $(C^3H^5)^2S$, with nitrate of silver, and distilling the crystalline product thereby produced; also by heating oil of mustard (sulphocyanate of allyl), with fixed alkalis, *e. g.* with soda-lime.

Oxide of allyl is a colourless liquid, lighter than water, and insoluble in water. It boils at 82° C. (Hofmann and Cahours); between 85° and 87° C. (Berthelot and De Luca). It forms with sulphuric acid a conjugated acid yielding a soluble barium-salt. Nitric acid converts it into a nitro-compound heavier than water. With iodide of phosphorus, it yields iodide of allyl. Heated with butyric acid it is decomposed, with formation of butyrate of allyl. (B. and L.)

Ethyl-allyl-ether, $C^5H^{10}O = C^2H^5.C^3H^5.O$, is obtained by the action of iodide of ethyl on allylate of potassium, or of iodide of allyl on ethylate of potassium. It is a colourless aromatic, very volatile liquid, boiling at about 84° C. Similar compounds are produced by treating iodide of allyl with methylate, amylate, and phenylate of potassium (Hofmann and Cahours). *Amyl-allyl-ether* boils at about 120° C. (Berthollet and De Luca.)

Oxide of Allyl and Glyceryl, or Triallylin, $C^{12}H^{20}O^{6} = \left.\begin{matrix}(C^3H^5)'''\\(C^3H^5)^3\end{matrix}\right\} O^6$.—Iodide of allyl distilled with potash and glycerin yields this compound in the form of a liquid, boiling at 232° C., soluble in ether, and having a disagreeable odour. (Berthelot and De Luca):

$$(C^3H^5)'''.H^3.O^3 + 3C^3H^5I = 3HI + (C^3H^5)'''.(C^3H^5)^3O^3.$$

The formula is that of a triple molecule of water H^6O^3, in which 3 at. H are replaced by the triatomic radicle glyceryl, and the other three by 3 at. of the monatomic radicle allyl.

ALLYL, OXYGEN-SALTS OF. Acetate, oxalate, sulphate, &c. (See the several acids.)

ALLYL, SULPHIDE OF. *Oil of garlic*, $C^6H^{10}S = (C^3H^5)^2S$ [or C^6H^5S].—This compound is produced by distilling iodide of allyl with protosulphide of potassium:

$$2C^3H^5I + K^2S = 2KI + (C^3H^5)^2S,$$

and is contained in the essential oils produced by distilling with water the leaves and seeds of various plants of the liliaceous and cruciferous orders. It forms the principal constituent of the oil obtained from the bulbs of garlic (*Allium sativum*), from which it was first obtained in the pure state by Wertheim in 1844; and it exists in smaller quantity in oil of onions (*Allium cepa*). It occurs also, together with 10 per cent. of oil of mustard (sulphocyanate of allyl), in the herb and seeds of *Thlaspi arvense*, passing over when these matters are bruised with water and distilled. The leaves of *Alliaria officinalis* distilled with water yield oil of garlic; the seeds yield oil of mustard (Wertheim). The bruised seed distilled after maceration in water, yields a mixture of 10 per cent. oil of garlic, and 90 oil of mustard; but the seed produced in sunny places yields only the latter. The herb and seeds of *Thlaspi arvense* yield a mixture of 90 per cent. oil of garlic, and 10 oil of mustard. The herb and seeds of *Iberis amara* likewise yield a mixture of the two oils; and very small quantities of the same mixture are obtained from the seeds of *Capsella Bursa Pastoris*, *Raphanus Raphanistrum*, and *Sisymbrium Nasturtium*. (Pless, Ann. Ch. Pharm. lviii 36.)

To obtain the whole of the mixed oils, the several parts of the plants, especially the seeds, must be macerated in water some time before distillation. For, in the seeds of *Thlaspi arvense*, for example, the oils do not exist ready formed; the seeds, in fact, emit no odour when bruised, and if before distillation with water, they are heated to 100° C. or treated with alcohol, no oil passes over; and if the seed be exhausted with alcohol, and the filtrate evaporated, there remains a crystalline residue mixed with mucus, which, when triturated with water and with the seed of *Sinapis arvensis*, yields, not oil of garlic, but oil of mustard. (Pless, Ann. Ch. Pharm, lviii. 36.)

Preparation. a. From Iodide of Allyl.—The iodide is cautiously dropped into a concentrated alcoholic solution of sulphide of potassium, the liquid then becoming very hot, and an abundant crystalline deposit of iodide of potassium being formed. As soon as the action ceases, the liquid is mixed with a slight excess of sulphide of potassium; water is then added, and the oil which rises to the surface is rectified.

b. From Garlic.—The crude oil is obtained by distilling bruised garlic-bulbs with water in a large still. The oil passes over with the first portions of water, the product amounting to 3 or 4 oz. from 100 pounds of the bulbs. The milky water which passes over at the same time, contains a large quantity of oil in solution, and serves therefore for cohobation. The crude oil is heavier than water, of dark brownish-yellow colour, and has a most intense odour of garlic. It decomposes at 140° C.; that is to say, somewhat below its boiling-point, which is 150°, becoming suddenly heated, assuming a darker colour, and giving off intolerably stinking vapours, without yielding a trace of garlic oil; the residue is a black-brown glutinous mass. (Wertheim.)

Preparation of the rectified oil.—The crude oil is distilled in a salt-bath (in the water-bath the distillation is slower) as long as anything passes over. One-third of the crude oil remains behind as a thick dark-brown residue. The rectified oil is lighter than water, and of a pale yellow colour, or after two distillations, colourless, and smells like the crude oil, though less offensive. Does not evolve a trace of of ammonia when treated with hydrate of potash. It covers potassium with a liver-coloured film of sulphide of potassium, depositing an organic substance, and giving off a small quantity of a gas which burns with a pale blue flame. With fuming nitric acid, oil of vitriol, hydrochloric acid gas, dilute acids and alkalis, corrosive sublimate, nitrate of silver, bichloride of platinum and nitrate of palladium, it behaves like pure sulphide of allyl. Even after being several times rectified and dried with chloride of calcium, it exhibits a variable composition and a certain amount of oxygen, and must therefore contain, besides sulphide of allyl, an oxygen compound, probably oxide of allyl, the presence of which is indeed indicated by the reaction with potassium. (Wertheim.)

Preparation of pure Oil of Garlic or *Sulphide of Allyl.*—The rectified oil is again rectified several times; dehydrated over chloride of calcium; decanted; a few pieces of potassium introduced into it; and as soon as the evolution of gas thereby produced has ceased, the oil is quickly distilled off from the residue. The rectified oil appears to contain oxide as well as sulphide of allyl, together with excess of sulphur, these impurities either pre-existing in the crude oil, or being formed from sulphide of allyl by the action of atmospheric oxygen, that portion of the sulphide which takes up the oxygen, giving up its sulphur to the rest. If the potassium be not suffered to complete its action before the liquid is distilled, it merely removes the excess of sulphur, but does not decompose the oxide of allyl, and a distillate is obtained, containing from 65·17 to 64·75 per cent. C, and 9·22 to 9·15 H. (Wertheim.)

Properties.—Colourless oil, of great refracting power, and lighter than water. Boils at 140° C. May be distilled without decomposition. Smells like the crude oil but less disagreeably. It dissolves sparingly in water, readily in alcohol and ether.

	Calculation.		Wertheim.
6C	72	63·16	63·22
10H	10	8·77	8·86
S	32	28·07	27·23
$(C^3H^5)^2S$	114	100·00	99·31

Decompositions.—1. Sulphide of allyl dissolves with violent action in *fuming nitric acid;* the solution when diluted with water, deposits yellowish-white flakes, and is found to contain oxalic and sulphuric acids; according to Hlasiwetz (J pr. Chem. li. 355) oil of garlic treated with nitric acid, yields formic and oxalic acids.—2. With cold *oil of vitriol*, it forms a purple solution, from which it is separated by water, apparently without alteration.—3. It absorbs *hydrochloric acid gas* in large quantities; the deep indigo-coloured mixture becomes gradually decolorised on exposure to the air, and immediately if gently heated or diluted with water.—4. From *nitrate of silver*, it throws down a large quantity of sulphide of silver, whilst nitrate of silver and allyl remains in solution (Wertheim). It is not altered by dilute acids or alkalis, or by potassium.

Combinations.—Sulphide of allyl does not precipitate the aqueous or alcoholic solutions of acetate of nitrate of lead, or acetate of copper; neither does it precipitate the solution of arsenious or arsenic acid in aqueous sulphide of ammonium.

With solutions of *gold, mercury, palladium, platinum,* and *silver,* it forms precipitates, consisting of a double sulphide of allyl and the metal, either alone or associated with a double chloride.

Gold-precipitate.—Sulphide of allyl forms with aqueous trichloride of gold, a beautiful yellow precipitate, which resembles the platinum-precipitate, but soon cakes together in resinous masses, and becomes covered with films of gold.

Mercury-precipitate.—Alcoholic solutions of oil of garlic and corrosive sublimate form a copious white precipitate, which when left to stand for some time, and especially if diluted with water, increases to a still greater quantity. It is a mixture of the compounds *a* and *b*, which may be separated by continued boiling with strong alcohol, only the compound *a* being soluble therein. (Wertheim.)

a. The alcoholic filtrate, when left to itself or evaporated with water, and after washing and drying, yields a white powder, agreeing in composition with the formula $(C^3H^5)^2S.2Hg^2S + 2(C^3H^5Cl.2HgCl)$, or $2(C^3H^5)^2S.Hg^2S.6HgCl$ (anal. 10·91 C, 1·61 H, 63·67 Hg, and 16·41 Cl:—calc. 11·32 C, 1·57 H, 62·87 Hg, and 16·70 Cl). It blackens superficially on exposure to the sun; when heated, it gives off vapours smelling like onions, and yields a sublimate of calomel and mercury. When immersed in moderately strong potash-ley, it acquires a light yellow colour from separation of oxide of mercury; if this oxide be then removed by dilute nitric acid, there remains a white substance, probably = $(C^3H^5)^2S.2Hg^2S$. When distilled with sulphocyanate of potassium, it yields oil of mustard, together with other products. It is insoluble in water, and dissolves but sparingly in alcohol and ether. (Wertheim.)

b. The portion of the mercury-precipitate insoluble in hot alcohol contains the same constituents, and has the carbon and hydrogen likewise in the ratio of 6 : 5 at., but is much richer in mercury. (Wertheim.)

Palladium-precipitate.—When rectified oil of garlic is gradually added to a solution of nitrate of palladium, kept in excess, a brown precipitate is formed, which appears to contain $2C^6H^{10}S.3Pd^2S$.—Chloride of palladium forms with oil of garlic a yellow precipitate, probably consisting of the preceding compound mixed with chloride of palladium.

Platinum-precipitate.—Oil of garlic forms a yellow precipitate with dichloride of platinum. This precipitate is obtained of a finer yellow colour by the use of alcoholic solutions; but when strong alcohol is used, its formation is gradual, becoming instantaneous however on addition of water. If the water be added too quickly and in too great quantity, the precipitate is yellowish-brown, resinous, and difficult to purify; the addition of water must therefore be stopped as soon as a strong turbidity appears; in that case, if the oil of garlic is not in excess, a copious flocculent precipitate is sure to be obtained, resembling chloro-platinate of ammonium. The precipitate is washed on the filter, first with alcohol, then with water, and dried at 100° C.—When heated considerably above 100°, it changes colour, and leaves sulphide of platinum in so porous a condition that it takes fire at a higher temperature, and continues to glow till it is reduced to pure platinum. Fuming nitric acid decomposes and dissolves the precipitate completely, forming dichloride of platinum and platinic sulphate. When immersed in hydrosulphate of ammonium, it is gradually converted into the kermes-brown compound next to be described. Aqueous potash and sulphuretted hydrogen have no action upon it. The precipitate is nearly insoluble in water, and dissolves but sparingly in alcohol and ether. It gives by analysis 17·85 per cent. C, 2·87 H, 48·53 Pt, 18·29 S, and 13·22 Cl, whence Wertheim deduces the somewhat improbable formula, $3(C^6H^{10}S.2PtS) + 2(C^3H^5Cl.PtCl^2)$, which requires 17·77 C, 2·47 H, 48·88 Pt, 17·77 S, and 13·11 Cl.

Kermes-brown compound, $(C^3H^5)^2S.2PtS$.—Formed, together with dissolved sal-ammoniac, when the platinum-precipitate just described is left in contact and shaken up with hydrosulphate of ammonium. The brown compound heated to 100° C. emits an alliaceous odour, and gives off 4·88 per cent. of sulphide of allyl. The darker substance containing excess of platinum which remains, continues unaltered till it is heated to 140° C. but between 150° and 160°, gives off 5·17 per cent. more, therefore in all 9·55 per cent. of sulphide of allyl, leaving a still darker compound of $(C^3H^5)^2S$ with 3PtS. The kermes-brown compound is insoluble in water, alcohol, and ether. (Wertheim.)

Silver-precipitate.—When a solution of nitrate of silver in aqueous ammonia is mixed with excess of sulphide of allyl, one portion of the compound resolves itself into oxide of allyl, which rises to the surface as an oil, and nitrate of ammonium; but there is also formed at the beginning a white or pale yellow precipitate, which perhaps consists of $(C^3H^5)^2S + xAg^2S$. For if it be immediately washed with alcohol, and dried between paper, it is resolved by distillation into sulphide of allyl and a residue of sulphide of silver. But if it remains half an hour immersed in the liquid, it assumes a continually darker brown colour, and is finally converted into black sulphide of silver. (Wertheim.)

ALLYL and HYDROGEN, SULPHIDE OF. *Allyl-mercaptan*, $C^3H^6S = C^3H^5.H.S$.—Produced by distilling iodide of allyl with sulphide of hydrogen and potassium:

$$C^3H^5I + KHS = KI + C^3H^5.H.S.$$

It is a volatile oily liquid, having an odour like that of oil of garlic, but more ethereal. It boils at 90 °C. It is powerfully attacked by nitric acid, assuming a red colour, and yielding an acid analogous to ethyl-sulphurous acid. It acts with great energy on mercuric oxide, forming a compound C^3H^5HgS, which dissolves in boiling alcohol, and separates from the solution in pearly scales resembling mercaptide of mercury. (Hofmann and Cahours.)

ALLYL, SULPHOCYANATE OF. $C^4H^5NS = CNS.C^3H^5$.—*Volatile oil of Mustard.* (See SULPHOCYANIC ETHERS.)

ALLYL-SULPHOCARBAMIC, or SULPHOSINAPIC ACID. $C^4H^7NS^2 = S \left\{ \begin{matrix} N.(CS)''.C^3H^5.H \\ H \end{matrix} \right.$.—This acid is not known in the separate state, but its soluble salts, viz. those containing the metals of the alkalis and alkaline earths, are obtained by treating oil of mustard with the hydrosulphates of those metals: *e. g.*

$$C^4H^5NS + KHS = C^4H^6KNS^2.$$

It may be regarded either as composed according to the preceding formula, that is to say, as hydrosulphate of ammonium, $NH^4.H.S$, having 1 at. H in the ammonium-molecule replaced by allyl and two more by the diatomic radicle CS, or as a compound of sulphocyanide of allyl with sulphide of hydrogen. The mode of formation leads directly to the latter view. (See SULPHOSINAPIC ACID.)

ALLY-SULPHOCARBONIC, or **ALLYL-XANTHIC ACID.** *Sulphide of Allyl, Carbonyl, and Hydrogen,* $C^4H^6S^2O = S^2\left\{\begin{matrix}(CO)''\\ H.C^3H^5\end{matrix}\right.$—When allyl-alcohol is treated with potash and disulphide of carbon, a salt is formed, which crystallises in yellow needles like xanthate of potassium. (Hofmann and Cahours.)

ALLYL-SULPHURIC ACID. $C^3H^5.H.SO^4$.—*Sulphate of Allyl and Hydrogen.* (See SULPHURIC ETHERS.)

ALLYL-UREA. (See CARBAMIDE.)

ALLYLAMINE. $C^3H^7N = N.H^2.(C^3H^5)$, is obtained by the action of ammonia on iodide of allyl, or by boiling cyanate of allyl with strong aqueous potash

$$CNO.C^3H^5 + 2KHO = CO^3K^2 + N.H^2(C^3H^5).$$

If the alkaline distillate be condensed in hydrochloric acid, a saline mass is obtained, which when distilled with potash, yields, among other products, a basic oil having the composition of allylamine. The platinum-salt, $C^3H^7N.HCl.PtCl^2$, separated from solution by slow evaporation forms magnificent crystals.

DIALLYLAMINE, $C^6H^{11}N = N.H.(C^3H^5)^2$, is formed, together with other products, by the action of iodide of allyl on allylamine.

DIBROMALLYLAMINE, $C^6H^9Br^2N = N.H.(C^3H^4Br)^2$.—Produced by the action of ammonia on tribromide of allyl (p. 141).

$$2C^3H^5Br^3 + 5NH^3 = C^6H^9Br^2N + 4NH^4Br.$$

1 vol. tribromide of allyl is mixed with about 6 vol. of a solution of ammonia in weak alcohol, and heated to 100° C. in sealed tubes for 10 or 12 hours; the liquid is then filtered from the separated bromide of ammonium, and the filtrate mixed with a large quantity of water, whereupon it becomes turbid, and deposits dibromallylamine in the form of a heavy oil, which may be purified by dissolving it in hydrochloric acid, evaporating to dryness at 100° C., redissolving in water, filtering to separate a small quantity of oil, again evaporating, and treating the residue with ether, in which the hydrochlorate is nearly insoluble. From the salt thus purified, the base is separated by distillation with potash. It is alkaline to test-paper, and forms a cloud with hydrochloric acid: it is however but a weak base, incapable of decomposing the salts of copper or silver. It cannot be distilled without alteration. It is but sparingly soluble in water, but dissolves readily in alcohol and in acids. It has a peculiar sweet and aromatic taste. It does not show much tendency to form crystallisable salts. The *sulphate* forms a gummy mass.—The hydrochlorate is a yellowish salt easily soluble in water and alcohol, sparingly in ether. It tastes like the base itself. It assumes a darker colour at 100° C. and sublimes partially at 160°. On adding nitrate of silver to the aqueous solution, the whole of the chlorine is precipitated as chloride of silver, but the bromine remains in solution. The *chloroplatinate*, $C^6H^9Br^2N.HCl.PtCl^2$, is an orange-coloured precipitate nearly insoluble in absolute alcohol. Alcoholic solutions of dibromallylamine and chloride of mercury form, when mixed, a copious white precipitate. (Maxwell Simpson, Phil. Mag. [4] xvi. 257.)

Ethyldibromallylamine, $C^8H^{13}Br^2N = N.C^2H^5.(C^3H^4Br)^2$. — Obtained by enclosing dibromallylamine with a large excess of iodide of ethyl in a sealed tube, and heating the mixture to 100° C. for a considerable time. The excess of iodide of ethyl is then distilled off, and the remaining hydriodate of ethylbibromallylamine is dissolved in water and distilled with potash. It has a very bitter and pungent taste, smells like nutmeg, is insoluble in water, soluble in acids, and alkaline to test-paper. It is a stronger base than dibromallylamine, and precipitates oxide of copper from cupric salts. (Simpson.)

TRIALLYLAMINE, $C^9H^{15}N = N.(C^3H^5)^3$, is formed by the destructive distillation of hydrate of tetrallylium.

TETRALLYLIUM, $C^{12}H^{20}N = N(C^3H^5)^4$.—The iodide of this base is the chief product of the action of ammonia on iodide of allyl. The action takes place without the aid of heat, a large quantity of the iodide dissolving after a few days' contact; the solution afterwards deposits splendid crystals of the iodide, and sometimes becomes a solid mass. The separation of the crystals may be accelerated by adding a strong solution of potash, in which the iodide is completely insoluble. The iodide is purified by exposing it to the air till the potash is converted into carbonate, and then recrystallising from absolute alcohol. Treated with oxide of silver, it yields the hydrated oxide of tetrallylium, and the solution of this oxide mixed with hydrochloric acid and bichloride of platinum, forms a yellow salt containing $N(C^3H^5)^4Cl,PtCl^2$.

Tetrallylarsonium, $As(C^3H^5)^4$.—When iodide of allyl is digested with arsenide of potassium, several liquid compounds are formed, having a very fetid odour, and at the same time a solid crystalline body separates, which is the iodide of tetrallyl-arsonium. (Hofmann and Cahours.)

ALLYLENE. C^3H^4.—A diatomic radicle which bears to allyl the same relation that ethylene C^2H^4, bears to ethyl C^2H^5. Respecting its properties in the free state and the mode of separating it, see ADDENDA (p. 1112).

Chloride of Allylene, $C^3H^4.Cl^2$. *Acroleinchlorid.*—Obtained by the action of perchloride of phosphorus on acrolein (p. 56). To prevent the action from becoming too violent, the retort should be externally cooled, the perchloride of phosphorus covered with a layer of oxychloride, and the acrolein added by small portions at a time. The proportions are 1 pt. acrolein to 3 pts. of the perchloride. The crude distillate is shaken up with water to remove oxychloride of phosphorus, and further purified by digestion with chloride of calcium and rectification, the chloride of acrolein passing over at about 90° C. It is a colourless oil, having a sweetish ethereal taste, and an odour like that of chloroform. Specific gravity 1·170 at 27·5 C. Boiling-point (corrected) 84·4° C.—Another oily liquid, apparently isomeric with chloride of allylene, is likewise formed by the action of perchloride of phosphorus on acrolein.

Chloride of allylene is slowly oxidised by nitric acid. Heated with aqueous nitrate of silver, it precipitates chloride of silver. Chlorine converts it into a crystalline compound, probably sesquichloride of carbon. Sodium has no action upon it. Heated with ethylate of sodium, it appears to yield a compound corresponding to acetal (p. 3). Heated in a sealed tube with alcoholic potash, it appears to yield the same compound, together with *chloride of acryl*, C^3H^3Cl. Heated in a sealed tube with ammonia, it yields sal-ammoniac and acrolein-ammonia (p. 56). (Hübner and Geuther, Ann. Ch. Pharm. cxiv. 36.)

Acetate of Allylene, $C^7H^{10}O^4 = \left.\begin{matrix}(C^3H^4)''\\(C^2H^3O)^2\end{matrix}\right\}O^2$. *Acetate of Acrolein.*—Produced, 1. By heating in sealed tubes a mixture of 1 at. acrolein (C^3H^4O), and 1 at. acetic anhydride ($C^4H^6O^3$.)—2. By heating 1 at. chloride of allylene with 2 at. acetate of silver in a sealed tube, first in the water-bath for several hours, then to 160° C. in an oil-bath, rectifying the product, and collecting apart that which passes over between 135° and 160°: $C^3H^4Cl^2 + (C^2H^3O)^2.Ag^2.O^2 = (C^2H^3O)^2.C^3H^4.O^2 + 2AgCl$. It is a colourless liquid, having a strong fishy odour, and very sharp taste. Specific gravity 1·076 at 22° C.; boils at about 180°. It slowly reduces an ammoniacal solution of nitrate of silver. Heated with caustic-potash, it yields acrolein and acetate of potassium. It may he regarded as a compound of 1 at. acrolein with 1 at. acetic anhydride, $C^3H^4O.C^4H^6O^3$. (Hübner and Geuther.)

ALMAGRERITE. Native anhydrous sulphate of zinc. (See SULPHATES.)

ALMANDINE. (See GARNET.)

ALMONDS, OIL OF.—Both sweet and bitter almonds yield by pressure a fixed oil, having a light yellow colour, an agreeable taste, but no odour. Specific gravity 0·918 at 15°. It consists chiefly of olein, with but little solid fats, and consequently requires a very low temperature (−25° C.) to solidify it. It easily turns rancid. It dissolves in 25 pts. of cold alcohol, in 6 pts. of boiling alcohol, and mixes in all proportions with ether.

Bitter almonds macerated with cold water and distilled, yield also a volatile oil, of fragrant odour, which is the *hydride of benzoyl* ($C^7H^5O.H$). This oil does not exist ready formed in the almonds, but is produced by the action of an azotised body, *emulsin*, on the amygdalin contained in the fruit. Sweet almonds do not contain emulsin, and therefore do not yield the volatile oil. (See BENZOYL, HYDRIDE OF.)

ALOERETIC ACID. (See ALOETIC ACID.)

ALOES. The thickened juice of various species of aloe, a genus of plants belonging to the liliaceous order. It is chiefly extracted from the *Aloe soccotrina* in Arabia; from *Aloe spicata* and *A. linguiformis* at the Cape of Good Hope; and from *A. vulgaris* or *sinuata* in Barbadoes and Jamaica. The best sorts of aloes are prepared by exposing to the sun the juice which exudes spontaneously from incisions in the leaves; inferior kinds are obtained by pressing the leaves. Aloes occurs in commerce in large red-brown masses, having a shining conchoidal fracture; in thin plates it is red and translucent; it is easily reduced to a yellow powder. It has an odour like that of saffron, and a very persistent bitter taste. It dissolves completely in alcohol and in boiling water. It possesses active purgative properties, due to a crystallisable principle *aloin*, which is contained in it, and may be extracted in a state of purity from Barbadoes aloes.

ALOETIC ACID. $C^{14}H^{4}N^{2}O^{12}$? *Polychromic Acid. Artificial Bitter of Aloes.*—Produced by the action of nitric acid upon aloes, chrysammic acid being formed at the same time (Schunck, Ann. Ch. Pharm. xxxix. 24; lxv. 235; G. J. Mulder, J. pr. Chem. xlviii. 39). 1 part of aloes is gently heated with 8 pts. of moderately strong nitric acid till gas begins to escape; the vessel is then removed from the fire, and as soon as the disengagement of gas ceases, the solution is concentrated by evaporation, till a yellow powder separates, the quantity of which may be increased by addition of water. The aloetic acid is separated from the chrysammic acid in this powder by treatment with boiling alcohol, which dissolves the aloetic acid; and on evaporating the solution, the acid is obtained in the form of an orange-yellow powder having a bitter taste. It is but slightly soluble in water, but dissolves more freely in boiling water, forming a solution of a splendid purple colour, which is changed to yellow by nitric acid, but restored by alkalies. It is dissolved by ammonia, potash, and soda, forming purple solutions. Strong nitric acid converts it into chrysammic acid. It is monobasic. The *barium*-salt, $C^{7}H^{3}BaN^{2}O^{6}$, is a brown-red nearly insoluble powder, obtained by precipitating the aqueous acid with acetate of barium. The *potassium*-salt separates by slow evaporation in crystals of a fine ruby colour. According to Schunck, the formula of aloetic acid is $C^{16}H^{4}NO^{13}$; according to Mulder $C^{14}H^{3}N^{2}O^{11}$. According to the formula above given, it is isomeric with dinitrobenzoic acid.

The alcoholic mother-liquor obtained in the preparation above described contains another acid called *Aloeretic acid*, $C^{7}H^{3}ON^{6}$? which, according to Mulder, is the first product of the action of nitric acid on aloes. It is separated by neutralising with chalk, mixing the filtrate with acetate of lead, decomposing the lead-precipitate with hydrosulphuric acid, and evaporating. It is a brown amorphous mass, which when boiled with nitric acid is converted first into aloetic, then into chrysammic acid. (Mulder.)

The name aloeretic acid is also applied by Schunck to an acid produced by the action of alkalis on chrysammic acid, and called by Mulder *chrysatric acid* (which see).

ALOÏN. $C^{17}H^{18}O^{7}$, or $C^{34}H^{18}O^{14}$.—A crystalline bitter principle obtained from aloes: also called *Bitter of aloes.* It is prepared by mixing Barbadoes aloes with sand, to prevent agglomeration, treating it several times with cold water, and evaporating the aqueous extract in vacuo to the consistence of a syrup. It then separates in small crystals. The solution must not be heated to the boiling-point, since aloïn undergoes alteration at 100° C.

According to Dr. Stenhouse (Phil. Mag. [3] xxxvii. 481), the Cape and Socotrin aloes contain large quantities of foreign matters which prevent the crystallisation of the aloïn; he has succeeded in isolating the aloïn, only by operating on the Barbadoes aloes.

Pure aloïn separates from an alcoholic solution, in the form of small prismatic needles, grouped in stars, of a pale yellow colour. Its taste is at first sweet, then extremely bitter. It is much more purgative than aloes itself. In the cold, it is but slightly soluble in water and alcohol, but dissolves better when hot; the solutions are yellow and neutral to test-paper. Dried at 100°C. it contains $C^{17}H^{18}O^{7}$.

The caustic and carbonated *alkalis* dissolve aloïn with a bright yellow colour.

By digestion with concentrated *nitric acid*, aloïn is transformed into chrysammic acid. *Chlorine* passed into an aqueous solution of aloïn, produces a bright yellow precipitate, *chloraloïl*, containing, according to Robiquet, $C^{13}ClO^{5}$. Solution of *chloride of lime* colours aloïn bright yellow, this tint passing rapidly to brown.

Bromine added in excess to a cold aqueous solution of aloïn produces a yellow precipitate of *bromaloïn*, $C^{17}H^{15}Br^{3}O^{7}$? which dissolves in boiling alcohol, and separates in shining yellow needles, grouped in stars, and much larger than the crystals of aloïn. It is less soluble in cold water and alcohol than aloïn: the solutions are neutral.

ALOISOL.—$C^{6}H^{8}O^{2}$? An oily liquid obtained in very small quantity by distilling aloes with half its weight of quick lime. It is colourless, has a sharp penetrating odour, is insoluble in water, but mixes in all proportions with alcohol and ether. Specific gravity 0·877. Boiling-point 130°C. By contact with the air, or by the action of strong nitric acid on chlorine water, it is converted into a brown-red liquid, heavier than water, and having a very decided odour of castoreum. Treated with oxide of copper or chromic acid, it yields carbonic acid, water, and hydride of benzoyl. (Robiquet, J. Pharm. [3] x. 167 and 241.)

ALOUCHI, or **ALUCHI RESIN** is imported from Madagascar, where it is obtained, according to Valmont de Bomare, from a tree called Timpi. According to others, from *Wintera aromatica.* It is friable, whitish on the outside, black within, has a marbled appearance, and a strongly aromatic, peppery, bitter taste. According to Bonastre (J. Pharm. x. 1), it contains 68·12 p. c. of resin easily soluble in cold alcohol, 20·45 of resin sparingly soluble in cold alcohol, 1·58 essential oil, together with small quantities of free acid and ammonia-salt, besides earthy impurities. The sparingly soluble resin appears to be of peculiar nature.

ALPHENE, SULPHIDE OF. (See SULPHOCYANIDE OF AMMONIUM.)

ALSTONITE. A mineral having the same composition as *barytocalcite*, $CO^3.BaCa$. [or $BaO.CO^2 + CaO.CO^2$], but crystallising in oblique prisms, whereas baryto-calcite forms right rhombic prisms: hence carbonate of barium and calcium is dimorphous. Alstonite is found on Alston Moor in Cumberland.

ALTAITE. (See TELLURIDE OF LEAD.)

ALTHEIN. Syn. of ASPARAGIN.

ALTHIONIC ACID. $C^2H^6SO^4$.—This acid, isomeric with ethylsulphuric or sulphovinic acid, is produced, according to Regnault (Ann. Ch. Phys. [2] lxv. 98), when alcohol is heated with excess of strong sulphuric acid till olefiant gas begins to be evolved (between 160° and 180° C.) When equal parts of sulphuric acid and alcohol are used, nothing but sulphovinic acid is formed, and even in the residues of the ether-preparation on the large scale, the latter is the only acid found.

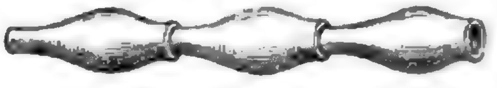
To prepare the barium-salt of althionic acid, the residue obtained in the preparation of olefiant gas from 6 pts. sulphuric acid and 1 pt. alcohol, is saturated with milk of lime; the filtrate, after evaporation, is treated with oxalic acid to precipitate the lime; the liquid again filtered and saturated with baryta-water; the excess of baryta precipitated by carbonic acid; and the filtrate evaporated, first by heat, and finally in vacuo, crystallisation then taking place as soon as the liquid acquires a syrupy consistence. The salt when purified by recrystallisation, forms spherules composed of small needles permanent in the air, and giving off 8·59 p. c. (1 at.) of water in vacuo. The formula of the crystallised salt is $C^2H^5BaSO^4 + H^2O$. It is more soluble in water than the sulphovinate of barium, and dissolves also in alcohol especially when hot.

From the aqueous solution of the barium-salt, the free acid (the hydrogen-salt) may be obtained by precipitating the baryta with sulphuric acid, and from this the other salts may be prepared by direct combination. The *calcium*-salt evaporated at the gentlest possible heat, solidifies completely in a mass, without crystallising. The *copper*-salt forms pale green, very thin rhombohedrons, having an acute angle of 60°. (Regnault.)

Magnus (Pogg. Ann. xlvii. 523) was not able to find althionic acid in the residues of the preparation of olefiant gas, but only ethionic, isethionic, and sometimes also sulphovinic acid.

ALUDELS. Pear-shaped earthern vessels used by the older chemists for subliming. They are open at each end and fit into one another in the manner shown in *fig.* 7. At the quicksilver works at Almaden in Spain, vessels of this shape are used to condense the mercurial vapours issuing from the retorts. For this purpose they are laid in the form of a chain on a slightly inclined surface called the *aludel-bath.* (See MERCURY.)

Fig. 7.



ALUM. (See SULPHATES.)

ALUMINATES. Compounds of alumina with the stronger bases.

ALUMINITE. A basic sulphate of aluminium, $Al^2O^3.SO^3 + 9HO$, found native at New Haven in America. It is a white, opaque, earthy mass, of specific gravity 1·705, soluble in hydrochloric acid. Gives off its acid at a red heat. (Stromeyer.)

ALUMINIUM. *Symbol*, Al; *Atomic weight*, 13·75.—This metal occurs in a great variety of forms, viz. as oxide (alumina) anhydrous, and hydrated, sometimes alone, but more generally associated with the oxides of other metals, iron zinc, glucinum, magnesium, &c.;—as sulphate and phosphate; as silicate, which is the chief constituent of all clays, and in combination with other silicates, forms a vast number of minerals, especially the felspars; also as mellitite, or honeystone, as fluoride of aluminium and sodium in cryolite; and in very small quantities in plants.

Alumina was first shown to be a distinct earth by Marggraff in 1754, having been previously confounded with lime. Oerstedt, in 1826, showed how to prepare the chloride of aluminium by passing chlorine over a red-hot mixture of alumina and charcoal; and Wöhler, in 1828 (Pogg. Ann. xi. 136) succeeded in eliminating the metal by igniting the chloride with potassium. It was thus obtained in the form of a grey powder intermixed with tin-white globules arising from partial fusion. It has lately been obtained in the compact form, and in much larger quantity, by H. Sainte-Claire Deville and others.

Preparation.—The mode of preparation now adopted is the same in principle as that of Wöhler, depending on the action of sodium at a red heat on the chloride or fluoride of aluminium, or better, on the double chloride or double fluoride of aluminium and sodium. Sodium is used to effect the reduction in preference to potassium, partly because it acts more regularly and with less violence, and partly because it is more easily prepared, and, having a lower atomic weight than potassium, a smaller quantity of it suffices for a given amount of chemical work.

The process first adopted by Deville consisted in passing the vapour of chloride of aluminium over sodium contained in a tube of iron or copper which was kept at a dull red heat. Metallic aluminium was thus obtained, mixed with chloride of aluminium and sodium. The latter was removed by washing with water, and the metallic globules which remained were made to unite by heating them till they began to melt, and pressing them together with a pipe-stem. The mass thus obtained was then remelted and cast into bars. Another method which promised to yield good results, but has not yet been perfected, was to reduce the chloride of aluminium by vapour of sodium. The mixture of carbonic oxide and sodium-vapour produced by heating a mixture of charcoal and carbonate of sodium (see SODIUM) was conveyed into a large earthen crucible by means of an iron tube passing through a hole near the bottom and reaching nearly to the other side; and as the sodium and carbonic oxide burned and thereby heated the crucible, portions of chloride of aluminium were thrown in from time to time. The crucible when cold was broken, and the aluminium separated from the saline mass in the manner above described.

The quantity of compact aluminium obtained by these methods was however considerably below the theoretical amount, a large portion of the metal being reduced in the form of a fine powder which re-fused to unite into globules. This inconvenience may be obviated and much better results obtained by the use of fluor spar or cryolite as a flux. These fluorides assist the union of the particles, apparently by dissolving small quantities of alumina—produced by moisture adhering to the chloride,—which surround the particles of metal at the moment of reduction, and, not being decomposed by the sodium, prevent them from uniting into globules. The reduction may be performed in crucibles, or better, in a reverberatory furnace.

a. 400 parts of chloride of aluminium and sodium, 200 pts. of chloride of sodium, 200 pts. of fluor spar or cryolite—the latter being preferable—all perfectly dry and finely pulverised, are placed together, with 75 or 80 pts. of sodium, in alternate layers, in an earthen or iron crucible, which is moderately heated till the action begins, and afterwards to redness, the melted mass being stirred with an iron rod and afterwards poured out. If the process goes on well, 20 pts. of aluminium are thus obtained in a compact mass, and about 5 pts. more in globules encrusted in a hard mass.

The aluminium thus obtained is, however, somewhat contaminated with silicon, derived from the earthy matter of the crucible, which is attacked by the sodium, by the aluminium itself, and by the fluorides in the slag. This evil may be corrected to a certain extent, but not completely, by lining the crucible with a paste composed of calcined alumina, or aluminate of calcium. If iron crucibles are used, the aluminum is found to contain iron.

b. The reduction is performed with greater facility, and on a much larger scale, by heating the mixture on the hearth of a reverberatory furnace.

The proportions used are:

Chloride of aluminium and sodium	10 parts.
Fluor spar or cryolite	5 „
Sodium	2 „

The double chloride and the cryolite or fluor spar are mixed in the state of powder with sodium in small ingots, and the whole is thrown on the hearth of the furnace previously raised to the required temperature. The dampers are then closed to prevent access of air. A vivid action soon takes place, accompanied by evolution of heat, sufficient to raise the walls of the furnace and the mixture itself to bright redness; and the mixture is almost completely liquefied. When the reduction is complete, the fused mass is run out through an aperture at the back, the slag escaping first, and then the aluminium flowing out in a single jet, and collecting in one mass below the liquid slag. With a furnace having a hearth about 16 square feet in surface, about

16 lbs. of aluminium may be obtained at one operation. The slag consists of two layers, the upper containing a large quantity of common salt, while the lower, which is pasty and less fusible, consists chiefly of fluoride of aluminium. On pulverising this latter and passing it through a sieve, an additional quantity of aluminium is obtained in globules. The fluoride of aluminium may be used for the preparation of alumina.

This process (which has been patented by MM. Rousseau, Frères and M. Paul Morin, both in France and in this country, 1856, No. 1810) is peculiarly advantageous in this respect, that the reduced metal is very little exposed to contamination with silicon. The introduction of this impurity generally arises from the action of the sodium or of the slag on the earthy matters of the vessels in which the reduction takes place. Now, when crucibles are used and the heat is applied from below, the part of the mixture in contact with the crucibles is necessarily the hottest, and consequently the action exerted on the crucible is considerable; but when the mixture is fused on the hearth of a reverberatory furnace, with the flame playing on its surface, the coolest part is in contact with the hearth, which is therefore less acted upon. Moreover with the proportions above given, the whole of the fluorine is separated as fluoride of aluminium, a compound which exerts but little action on silicious substances.

Preparation from Cryolite.—The pulverised mineral is mixed with half its weight of common salt, and the mixture is arranged in alternate layers with sodium (2 pts. of sodium to 5 pts. of cryolite), in an earthen or iron crucible, a layer of pure cryolite being placed at top, and the whole covered with common salt. The mass is rapidly heated till it melts completely, and then left to cool after being stirred with an iron rod. The aluminium is generally found in large globules. Such was the method originally practised by Professor H. Rose in Berlin, and by Dr. Percy and Mr. Allen Dick in this country. It is now carried on, on the manufacturing scale, at Amfreville, near Rouen, by C. and A. Tissier.

A peculiar apparatus for effecting the reduction of aluminium, either from the double chloride or from cryolite, the object of which is to prevent loss of sodium by ignition, has been invented and patented by F. W. Gerhard (1858, No. 2247). It consists of a reverberatory furnace having two hearths, or two crucibles or reverberatory furnaces placed one above the other, and communicating by an iron pipe. In the lower is placed the mixture of sodium with the aluminium-compound, and in the upper a stratum of chloride of sodium, or of a mixture of sodium and cryolite, or of the slag obtained in a former operation. This layer when melted, is made to run into the lower furnace in quantity sufficient to cover completely the mixture contained therein, so as to protect it from the air.

The chief inducement for using cryolite as a source of aluminium, is that it is a natural product obtained with tolerable facility, and enables the manufacturer to dispense with the troublesome and costly preparation of the chloride of aluminium and sodium. But the aluminium thus obtained is less pure than that prepared from the double chloride by the method previously described. If earthen crucibles are used, the aluminium is contaminated with silicon, because the fluoride of sodium produced by the decomposition acts strongly on the silicious matter of the crucible; and if crucibles of iron are used, the aluminium takes up a portion of that metal. For these reasons, Deville is of opinion, that the best use of cryolite is as a flux in the preparation of aluminium from the double chloride. In that case, as already observed, the slag consists, not of fluoride of sodium, but of fluoride of aluminium, which acts but slightly on the containing vessel.

Reduction of aluminium by means of hydrogen or carbon.— Several attempts have been made, but with doubtful success, to separate aluminium from its compounds by means of the ordinary reducing agents.

F. W. Gerhard decomposes fluoride of aluminium, or the double fluoride of aluminium and potassium or sodium, by subjecting it to the action of hydrogen gas at a red heat. The aluminium-compound is placed in a number of shallow dishes of glazed earthenware, each of which is surrounded by a number of other dishes containing iron filings. These dishes are placed in an oven previously heated to redness; hydrogen gas is then admitted, and the heat increased. Aluminium is then separated, and hydrofluoric acid evolved, which is immediately taken up by the iron filings, and thereby prevented from acting on the aluminium. To prevent the pressure of gas from becoming too great, an exit-tube is provided, which can be opened or closed at pleasure by means of a stopcock. This process, which was patented in 1856 (No. 2980), is ingenious and was said to yield good results; the inventor has however since returned to the use of the more costly reducing agent, sodium (see above), which would seem to imply that the hydrogen method has not quite fulfilled his expectations.

Sir Francis C. Knowles has patented a process (1857, No. 1742) for reducing aluminium from its chloride by means of cyanide of potassium or cyanide of sodium, the chloride, either in the fused state or in the form of vapour being brought in contact either with the melted cyanide or its vapour. Pure alumina may be added to increase the product.

L. F. Corbelli, of Florence, states that aluminium may be obtained by mixing the impure sulphate (prepared by heating clay with strong sulphuric acid), with 2 pts. of ferrocyanide of potassium, and 1½ pt. common salt, and heating the mixture to whiteness. The metal thus obtained must however be very impure, perhaps consisting chiefly of iron. The process was patented in this country in 1858 (No. 142).

M. Cumenge, of Paris, obtains aluminium from the sulphide (Al^4S^3) either by heating that compound in an atmosphere of hydrogen, or by heating it with alumina or sulphate of aluminium, in such proportion that the oxygen contained in that compound shall be just sufficient to convert the whole of the sulphur into sulphurous anhydride:

$$Al^4S^3 + 2Al^4O^3 = 3SO^2 + 12Al$$

$$\text{or} \quad Al^4S^3 + Al^4(SO^4)^3 = 6SO^2 + 8Al;$$

or, lastly, by decomposing the sulphide with an ordinary metal, such as iron, copper or zinc. This process is also patented (1858, No. 461).

Preparation of Aluminium by Electrolysis.—The electrolytic reduction of aluminium may be performed either in the dry or in the wet way. The reduction from fused chloride of aluminium and sodium was first effected in this manner by Bunsen in 1854 (Pogg. Ann. xcii. 648). The salt is introduced in a fused state into a red-hot porcelain crucible, divided into two parts by a porous earthenware diaphragm, and the extremities of the carbon poles of a Bunsen's battery of ten elements are introduced into the two halves of the fused mass. The metal is then reduced at the negative pole. The heat must be raised considerably above the melting-point of the double chloride, otherwise the aluminium separates in the pulverulent form. It is best to add fresh quantities of chloride of sodium during the reaction, and to raise the temperature ultimately to the melting point of silver. The aluminium is then obtained in globules of considerable size, which may be melted into one by throwing them into chloride of sodium melted at a white heat. Deville adopts a similar method, using, however, platinum instead of charcoal for the negative pole.

The same method may be used for coating metals with aluminium. Thus, if a bar of copper be used as the negative pole, and a bar of aluminium as the positive pole, tha latter dissolves as the action goes on, and is deposited upon the copper.

Aluminium may also be reduced by the action of the current from the solution of its salts. Mr. Gore has in this way obtained a deposit of aluminium on copper, and Messrs. Evans and Tilley have patented a process (1855, No. 2756), for coating metals with aluminium and its alloys, by electrolysing a solution of alumina mixed with cyanide of potassium, the negative pole being formed of the metal to be coated, and the positive pole of platinum or aluminium, or of some other metal, such as copper, tin or silver, which is to be deposited together with the aluminium. The bath may also in some instances be composed of a mixed solution of aluminium and the other metal to be deposited.—M. Corbelli, of Florence, obtains a deposit of aluminium by electrolysing a mixture of rock-alum or sulphate of aluminium with chloride of calcium or chloride of sodium, the positive pole being formed of iron wire coated with an insulating material and dipping into mercury placed at the bottom of the solution, and the negative pole of zinc immersed in the solution. Aluminium is then deposited on the zinc, and the chlorine eliminated at the positive pole unites with the mercury, forming calomel. This process is also patented (1858, No. 507).

Of all the processes above described, the only one that has been successfully applied to the production of aluminium on the large scale, is the decomposition of the double chloride or of cryolite by sodium. The electrolytic method is too expensive, excepting for producing a thin coating of aluminium on other metals; and the attempts which have been made to obtain aluminium by means of the ordinary reducing agents, such as hydrogen and charcoal, do not appear to have led to very satisfactory results. At present, therefore, the progress of the aluminium manufacture depends essentially on the economical production of sodium; and indeed the manufacture of aluminium has already given a great stimulus to that of sodium, and has led to considerable improvements in that process, and consequent reduction of cost. (See SODIUM.) *

Purification.—Aluminium may be purified from *copper* and *iron* by fusion with nitre in an iron crucible, the foreign metals being thereby oxidised, while the aluminium remains

---

* When Deville commenced his experiments in 1854, great hopes were entertained that aluminium might be produced at a price sufficiently low to admit of a variety of useful applications. Hitherto these expectations have been but imperfectly fulfilled, the metal being still too costly to be applied to other than ornamental purposes. Still, however, great progress has been made, the price, which in 1856 was 3l. per oz., being now reduced to 5s.; and further reduction will doubtless be made as the details of the manufacture are improved.

intact. Before introducing the aluminium, the inner surface of the crucible should be well oxidised by the action of the nitre. Aluminium containing zinc, may be freed from that metal by melting the alloy in contact with the air. No method has yet been discovered of purifying aluminium from *silicon*.

Aluminium is very apt to retain portions of the slag in the midst of which it has been formed, causing the surface, when worked and polished, to exhibit a number of points of inferior lustre, which gradually became more and more conspicuous. The best mode of purification is to melt the metal in an open black lead crucible for a considerable time, then remove it from the fire and stir it with an iron skimmer oxidised on the surface. By this means, the whitish slaggy matter is removed, together with a small portion of the aluminium, which may be set aside to be remelted. The metal is then cast into bars, and the whole operation repeated three or four times.

[For further information respecting the preparation of aluminium, see *De l'Aluminium*, par H. Sainte-Claire Deville, 8vo. Paris, 1859; *L'Aluminium et les Metaux Alcalins*, par C. et A. Tissier, 12mo. Paris et Rouen, 1858; *Chemical Technology*, by Richardson and Watts, vol. i. pt. iv. p. 1; *Ure's Dictionary of Arts, Manufactures and Mines*, vol. i. p. 120.]

Properties.—Aluminium is a white metal, with a faint tinge of blue. It takes a fine polish, and its surface may be frosted, like that of silver, by plunging it for an instant into a very weak solution of caustic soda, washing with a large quantity of water, and then digesting it in strong nitric acid. When pure, it is quite destitute of taste and odour. It is very malleable and ductile; may be beaten and rolled as easily as gold and silver, and drawn out into extremely thin wire. In this last operation, however, it becomes very brittle, and requires to be tempered by cautiously heating it over a lamp. In elasticity and tenacity, it is about equal to silver. After fusion it is as soft as pure silver; but after hammering in the cold, it acquires the hardness of soft iron It is highly sonorous, a bar of the metal suspended by a thread and struck with a hard body, emitting a beautifully clear, ringing sound. It is very light, being not much more than 2½ times as heavy as water, and about 4 times lighter than silver. Its density after fusion is 2·56, and after being hammered in the cold, 2·67. Its melting-point is intermediate between the melting-points of zinc and silver, but nearer to the former. It may be cast with the greatest ease in metallic moulds, and still better in moulds of sand. It may be fused without any flux; indeed, the addition of a flux is rather detrimental than otherwise, the metal attacking borax and glass with facility. Aluminium, heated in a closed vessel, does not exhibit the slightest tendency to volatilise.

The electric conducting power of aluminium is eight times as great as that of iron, and about equal to that of silver; it conducts heat even better than silver. Its specific heat is very great, and hence, though its melting-point is comparatively low, it takes a long time to liquefy. The melting together of small pieces of the metal may be facilitated by shaking the crucible and pressing them together with an iron rod oxidised on the surface. When slowly cooled from fusion, it exhibits a crystalline structure; the crystallisation is, however, most distinct when the metal is impure. Aluminium precipitated from its solutions by electrolysis at low temperatures, crystallises in octahedrons, which appear to be regular. It is slightly magnetic.

Aluminium does not oxidise in the *air*, even at a strong red heat; neither does it, in the compact state at least, decompose water, excepting at a white heat, and even then but slowly (Deville). It is not attacked by *sulphuretted hydrogen*, or even by *sulphide of ammonium*, and consequently preserves its lustre in the atmosphere of large towns, where silver is very soon tarnished and blackened. It may also be heated to redness in *vapour of sulphur* without showing any disposition to combine; at very high temperatures, however, combination takes place.

Aluminium is not attacked by *nitric acid*, either dilute or concentrated, at ordinary temperatures, and very slowly even at the boiling heat; neither is it acted upon by *sulphuric acid* diluted to the degree at which that acid dissolves zinc; but *hydrochloric acid*, either dilute or concentrated, dissolves it readily, even at low temperatures, with evolution of hydrogen. The *vegetable acids*, such as acetic and tartaric acid, exert no perceptible action on aluminium; a mixture of acetic acid and common salt exerts a somewhat greater action, because it contains free hydrochloric acid; but even in this case the action is very slow, and not nearly so great as would be exerted upon tin under similar circumstances. Aluminium would therefore be well adapted for culinary vessels, especially as the small quantity of alumina which might be formed from it by the action of certain acid mixtures would not exert any deleterious action on the animal economy.

The *hydrates of potassium* and *sodium* in the state of fusion do not act upon aluminium, but their aqueous solutions dissolve it readily, forming aluminate of potassium or sodium, and giving off hydrogen. Ammonia acts but slightly on it.

A solution of *common salt* or *chloride of potassium* is also without action on aluminium, but the solutions of many other chlorides dissolve it, and more readily, as the metals which they contain are higher in the scale; even a solution of chloride of aluminium dissolves the metal, forming a basic chloride. Solutions of *sulphates* and *nitrates*, on the contrary, do not act upon it. Hence in precipitating other metals upon aluminium by electrolytic action, it is necessary to use acid solutions not containing hydrochloric acid or any chloride. In an acid solution of sulphate of copper, the aluminium quickly becomes coated with metallic copper.

Aluminium may be fused with *nitre* at a moderate heat, without undergoing the slightest alteration; hence this process may be adopted for purifying aluminium from admixtures of other metals. If however the heat be raised till the nitric acid is completely decomposed and begins to give off nitrogen, a new reaction takes place attended with incandescence, and aluminate of potassium is formed.

Uses.—The lustre and whiteness of this metal, its unalterability in the air, and the facility with which it takes a frosted surface, render it well adapted for jewellery, for which purpose it is now much used. It also makes very bright reflectors. Its lightness renders it useful for mounting astronomical instruments, especially sextants. It may also be used for making small weights, such as the divisions of the gramme. Very delicate balance-beams have also been constructed with it. For culinary vessels it is adapted by its lightness and the little tendency which it has to become corroded by any of the liquids likely to come in contact with it. It is necessary however to observe, that this power of resisting the action of corroding agencies, and more especially those of the atmosphere of large towns, is exhibited only by the pure metal. Now, much of the aluminium of commerce is very impure, being contaminated with iron or silicon, or not having been properly freed from slag. Aluminium thus contaminated soon becomes tarnished, and much disappointment has been experienced from this cause by many who have used it for ornamental purposes. According to Deville, the impurities just mentioned are found to the greatest amount in the metal obtained from cryolite (p. 152).

General Characters and Reactions of Aluminium-compounds.—Aluminium forms only one class of salts, and into these it is supposed to enter as a sesqui-equivalent radicle, 2 atoms of aluminium taking the place of 3 atoms of hydrogen: $Al^2 = H^3$, or $Al^{\frac{2}{3}} = H$. Thus, the chloride of aluminium is $(Al^2)'''Cl^3$; the oxide (alumina) is $\left.\begin{matrix}(Al^2)''' \\ (Al^2)'''\end{matrix}\right\}O^3$; the sulphate, $(Al^4)^{vi}.3SO^4$, or $\left.\begin{matrix}(3SO^2)^{vi} \\ (Al^4)^{vi}\end{matrix}\right\}O^6$, &c. These formulæ are based upon the isomorphism of the aluminium-compounds with other compounds of corresponding character, which are known or supposed to contain sesqui-equivalent radicles: thus, alumina, the only known oxide of aluminium, is isomorphous with sesquioxide of iron and sesquioxide of chromium; and common potash-alum $(Al^2)'''K'(SO^4)^2 + 12H^2O$, is isomorphous with iron-alum $(Fe^2)'''K'.(SO^4)^2 + 12H^2O$, and chrome-alum $(Cr^2)'''K'.(SO^4)^2 + 12H^2O$. All these formulæ may, however, be reduced to others containing mono-equivalent radicles, the values of which are two-thirds of those of the corresponding sesqui-equivalent radicles. For instance, the aluminium-compounds may be supposed to contain a radicle (*aluminicum*), $al = \frac{2}{3}\,Al = \frac{2}{3}\,.\,13{\cdot}75 = 10{\cdot}31$. The formula of the chloride will then be $alCl$; that of alumina, al^2O; that of the sulphate al^2SO^4; that of alum, $alK.SO^4$. It is sometimes convenient to write the formulæ in this manner.

Most compounds of aluminium are colourless. The oxide, hydrates, borates, phosphates, arseniates, and silicates, are insoluble in water; most other aluminium-compounds are soluble. All of these, excepting the silicates, are soluble in hydrochloric and sulphuric acid, at least if they have not been strongly ignited.

The aqueous solutions have an acid reaction, and an astringent disagreeable taste. They are not precipitated by any free acid. With *sulphide of ammonium* and other soluble sulphides, they give a white gelatinous precipitate of trihydrate of aluminium, the formation of which is attended with evolution of hydrosulphuric acid gas. The precipitate is insoluble in excess of that reagent, but soluble in caustic potash or soda. With solution of *potash* or *soda*, the same gelatinous precipitate of the hydrate is produced, soluble in excess of the alkali, and reprecipitated by boiling with sal-ammoniac, or by cautious neutralisation with hydrochloric acid.—With *ammonia*, the same precipitate, insoluble in excess.—With *alkaline carbonates*, the same, carbonic acid being given off, and not entering into combination with the alumina.—With *ferrocyanide of potassium*, a white gelatinous precipitate, after some time.—With *phosphate of sodium*, gelatinous precipitate, closely resembling the hydrate in appearance, and dissolving with the same facility in hydrochloric acid and in potash. From these solutions it is precipitated in the same manner as the hydrate, viz. from the hydrochloric acid solution by ammonia, and from the potash-solution by sal-ammoniac; it is distinguished from the hydrate however, by its insolubility in acetic acid, and by exhibiting certain reactions of phosphoric acid (*q. v.*)

Most compounds of aluminium, when moistened with a small quantity of *nitrate of cobalt*, and ignited before the blowpipe, exhibit a fine characteristic blue colour. This character is best exhibited by placing a small quantity of alumina, precipitated as above, on charcoal or platinum-foil, heating it to redness, then moistening with nitrate of cobalt, and igniting again.

Quantitative Estimation of Aluminium.—Aluminium is usually precipitated in the form of hydrate by excess of ammonia or carbonate of ammonium, or better by sulphide of ammonium, because an excess of ammonia or its carbonate dissolves a small but perceptible quantity of the hydrate, which can then be reprecipitated only by boiling the liquid till every trace of ammonia is expelled. The precipitate when ignited leaves anhydrous alumina, containing 53·26 per cent. of the metal.

Aluminium may also be very conveniently separated from its solutions by boiling with *hyposulphite of sodium;* alumina is then precipitated together with sulphur, while sulphurous acid is expelled, and a sodium-salt of the acid previously combined with the alumina remains in solution: thus, if the aluminium exists in solution as sulphate:

$$S^3O^{12}Al^4 + 3S^2O^3Na^2 = Al^4O^3 + 3S + 3SO^2 + 3SO^4Na^2.$$

The liquid should be dilute, and must be boiled till it no longer smells of sulphurous acid; the alumina then separates quickly in a compact mass, not at all gelatinous, and very easy to wash. The sulphur mixed with it is very easily expelled by ignition. (G. Chancel, Compt. rend. xlvi. 987.)

This mode of precipitation by hyposulphite of sodium, serves also to separate aluminium from many metals, especially from iron, the latter metal being reduced to the state of protoxide, and remaining in solution as a sodio-ferrous hyposulphite. To ensure complete separation, the solution must be nearly saturated, if necessary, with an alkaline carbonate, diluted to a considerable extent, and mixed with the hyposulphite while cold; otherwise the alumina separates too quickly, before the iron is completely reduced to protoxide, and then carries some of the iron down with it. After the separation of the alumina, the iron is re-oxidised by nitric acid and precipitated by ammonia. (Chancel.)

Aluminium may also be separated from the *alkalis* and *alkaline earths*, by precipitation with ammonia or sulphide of ammonium. In thus separating it from the alkaline earths, however, care must be taken to protect the solution from the air, otherwise carbonic acid will be absorbed by the excess of ammonia, and will precipitate the alkaline earth together with the alumina. From *barium*, aluminium is most easily separated by sulphuric acid.

Alloys of Aluminium. Aluminium forms alloys with most metals. With *zinc* and *tin* it unites readily, forming brittle alloys; with *cadmium* it forms a malleable alloy. With *iron*, aluminium unites in all proportions, forming alloys which are hard, brittle, and crystallise in long needles, when the proportion of iron amounts to 7 or 8 per cent. Aluminium containing iron dissolves in acids more readily than the pure metal. (Deville.)

Aluminium alloyed with even a small proportion of *silver*, loses all its malleability. An alloy containing 5 per cent. of silver may, however, be worked like the pure metal, and has been used for making knife-blades. An alloy containing 3 per cent. of silver is used for casting ornamental articles. It has the colour and lustre of silver, and is not tarnished by sulphuretted hydrogen. (Deville.)

The alloys of aluminium and *copper* are of especial importance. One in particular, containing 10 pts. of aluminium with 90 pts. of copper, called *aluminium-bronze*, possesses very remarkable properties. It is a definite compound, containing Cu^4Al. It has the colour of gold, takes a high polish, is extremely hard, and possesses a tenacity equal to that of the best steel; it is also very malleable. Another alloy containing only 2 or 3 per cent. of copper, is used for casting ornamental articles of large dimension, intended to be chased. Aluminium may be easily plated on copper. The plates of the two metals are prepared in the usual manner, and well rubbed with sand, then placed between two plates of iron, the whole being well bound together, heated to low redness, and then strongly pressed. (Deville.)

Alloys of aluminium may be prepared by heating a mixture of alumina and the oxide of another metal, such as copper, iron, or zinc, or a mixture of alumina with carbon and the other metal in the free state, granulated copper, for instance, the materials being all very finely divided, and mixed in atomic proportions; or rather with the carbon slightly in excess. This method, due to a foreign inventor, has been patented in this country in the name of E. L. Benzon (1858, No. 2753).

Amalgamation and Gilding of Aluminium.—According to Cailletet, aluminium may be amalgamated by the action of ammonium-amalgam or sodium-amalgam and water, also when it is connected with the negative pole of the voltaic battery, and dipped into the mercury moistened with acidulated water, or into nitrate of mercury.—Ch. Tissier (Compt. rend. xlix. 56), confirms this statement respecting the amalgamation of aluminium in connection with the negative pole of the battery, and adds, that if the aluminium foil is not very thick, it becomes amalgamated throughout, and very brittle. The same chemist finds that aluminium may be made to unite with mercury, merely by the use of a solution of caustic potash or soda, without the intervention of the battery. If the surface of the metal be well cleansed and moistened with the alkaline solution, it is immediately melted by the mercury and forms a shining amalgam on the surface.

The amalgam of aluminium instantly loses its lustre when exposed to the air, becoming heated and rapidly converted into aluminium and metallic mercury. It decomposes water, with evolution of hydrogen, formation of alumina, and deposition of mercury. Nitric acid attacks it with violence. (Tissier.)

To *gild* aluminium, 8 grammes of gold are dissolved in aqua regia, the solution is diluted with water and left to digest till the following day, with a slight excess of lime; after being well washed, it is treated at a gentle heat with a solution of 20 grms. of hyposulphate of sodium. The filtered liquid serves for the gilding of aluminium, without the aid of heat or electricity, the aluminium being simply immersed in it, after having been well cleaned by the successive use of potash, nitric acid, and pure water. (Tissier.)

It is somewhat difficult to *solder* aluminium, partly because no flux has yet been found that will clean the surface without attacking either the aluminium or the solder, partly because the surface of the aluminium is not easily melted by metals more fusible than itself. An imperfect soldering may indeed be effected by means of zinc or tin, but a better method, devised by M. Hulot, is to coat the aluminium with copper, by the electrolytic method, and then solder in the ordinary way. (Deville.)

Arsenide of Aluminium. (See ARSENIDES.)

Boride of Aluminium. Boron unites with aluminium under the same circumstances as silicon (p. 160), and alters its properties in a similar manner.

Bromide of Aluminium, Al^2Br^3, is obtained by the action of bromine on pulverulent aluminium, the metal being in excess. By sublimation, it is obtained in white, shining laminæ, which melt at 90°, forming a mobile liquid which boils at about 265° C. It is decomposed when heated in contact with the air. It dissolves in bisulphide of carbon, forming a solution which fumes strongly in the air. It dissolves in water, and the solution evaporated in vacuo over oil of vitriol, leaves needle-shaped crystals containing $Al^2Br^3 + 6H^2O$. With bromide of potassium, it forms the double salt $KBr.Al^2Br^3$. It absorbs ammonia and hydrosulphuric acid, forming compounds which are decomposed by heat. (R. Weber, Pogg. Ann. ciii. 254.)

Chloride of Aluminium, Al^2Cl^3.—The finely divided metal heated to redness in a current of dry chlorine gas, takes fire and is converted into the chloride, which sublimes (Wöhler). The compound is also produced by passing dry chlorine over an ignited mixture of alumina and charcoal: and this is the method adopted for preparing it. Hydrate of aluminium precipitated from a hot solution of alum by an alkaline carbonate is made up into small pellets with oil and lampblack, and the mixture is strongly ignited in a crucible: the oil is then decomposed and an intimate mixture of alumina and charcoal remains. This is introduced into a porcelain tube or tubulated earthen retort placed in a furnace, and connected at one end with an apparatus for evolving chlorine, and at the other with a dry receiver. On raising the heat to bright redness, and passing chlorine through the apparatus, chloride of aluminium is formed and condenses in a solid mass in the receiver.

A similar process is adopted in preparing the compound on the large scale. Alumina or clay is mixed with coal, pitch, tar, resin, or any organic substance that will decompose by heat and leave a considerable quantity of charcoal, and the mixture, after being well calcined, is heated to redness in a cylinder of earthenware or cast iron, through which a current of dry chlorine is made to pass. The vapours of chloride of aluminium pass into a condensing chamber lined with plates of glazed earthenware, on which the chloride collects in the solid state. If clay containing a considerable proportion of iron is used in the preparation, it must first, after ignition with carbonaceous matter — whereby the iron is reduced to the metallic state — be treated with a dilute acid to dissolve out the iron, then washed and dried.

Chloride of aluminium is a transparent waxy substance having a crystalline structure like talc. It is colourless when pure, but generally exhibits a yellow colour, due perhaps to the presence of iron. It is fusible in large masses, and according to Liebig, boils at about 180° C. A small quantity volatilises immediately when heated. It fumes in the air, and smells of hydrochloric acid. It is decomposed at a heat below redness by potassium or sodium, aluminium being set free. When it is distilled with sulphuric anhydride, sulphurous anhydride and chlorine are given off and sulphate of aluminum remains. (H. Rose.)

$$2\mathrm{Al^2Cl^3} + 6\mathrm{SO^3} = \mathrm{Al^4(SO^4)^3} + 3\mathrm{SO^2} + 6\mathrm{Cl}.$$

Chloride of aluminium is very deliquescent, and dissolves readily in water. The solution left to evaporate in a warm dry place, yields the hydrated chloride $\mathrm{Al^2Cl^3.6H^2O}$ in six-sided prisms. The same solution is formed by dissolving alumina in hydrochloric acid. The anhydrous chloride cannot be obtained by heating the hydrated chloride, because the latter is thereby resolved into alumina and hydrochloric acid.

Chloride of Aluminium and Sodium, $\mathrm{NaCl.Al^2Cl^3}$, is obtained by fusing together the component chlorides in the proper proportions; by passing the vapour of chloride of aluminium over fused chloride of sodium; or by adding the proper quantity of chloride of sodium to the mixture of alumina or aluminiferous matter and carbon used for the preparation of chloride of aluminium, and igniting the mass in an atmosphere of dry chlorine or hydrochloric acid, and condensing the vapour in the same manner as that of the simple chloride. It is a crystalline mass which melts at 200° C., and crystallises on cooling. It is perfectly colourless when pure, much less deliquescent than chloride of aluminium, and being quite fixed at ordinary temperatures, may be handled with facility. These qualities render it much more convenient than the simple chloride for the preparation of aluminium. When ignited with sodium, it yields nearly the theoretical quantity (14 p. c.) of aluminium.

Fluoride of Aluminium, $\mathrm{Al^2F^3}$, is produced by the action of gaseous fluoride of silicon on aluminium. The product is at first mixed with reduced silicon, but this may be easily removed by digestion with a mixture of hydrofluoric and nitric acids. Fluoride of aluminium then remains in a colourless mass of cubical crystals, which have but little refracting power. It volatilises at a bright red heat, is insoluble in water, and resists the action of all acids. (Deville, Compt. rend. xliii. 49.)

Fluoride of Aluminium and Potassium, $\mathrm{3KF.Al^2F^3}$, is obtained as a gelatinous precipitate by dropping a solution of fluoride of aluminium into a solution of fluoride of potassium, till the latter remains in only slight excess. A precipitate of similar character, but consisting of $\mathrm{2KF.Al^2F^3}$, is obtained by stirring up a solution of fluoride of aluminium with a quantity of fluoride of potassium not quite sufficient for complete saturation. Both precipitates dry up to white powders, and give off the whole of their fluorine as hydrofluoric acid when heated with sulphuric acid. (Berzelius.)

Fluoride of Aluminium and Sodium, $\mathrm{3NaF.Al^2F^3}$.—Found native as *Cryolite*, and prepared artificially by pouring hydrofluoric acid in excess on a mixture of calcined alumina and carbonate of sodium in the proportions indicated by the formula, then drying and fusing the mixture. Cryolite belongs to the quadratic or dimetric system. It is colourless and transparent, softer than felspar, of specific gravity 2·96, melts below a red heat, and forms an opaque glass on cooling: so likewise does the artificially prepared salt. It is found in large quantity at Evigtok in Greenland, but has not hitherto been discovered in any other locality. It is used, as already described, for the preparation of aluminium, and also in Germany for the manufacture of soda for the use of soap-boilers.

Iodide of Aluminium, $\mathrm{Al^2I^3}$, is obtained by heating the metal with iodine or iodide of silver in sealed tubes. After repeated sublimation over metallic aluminium, it forms a snow-white crystalline mass, which melts at about 185° C., and boils at a temperature above the boiling-point of mercury. It resembles the bromide in most of its properties. With water it forms the hydrate $\mathrm{Al^2I^3.6H^2O}$, which may also be obtained by dissolving hydrated alumina in hydriodic acid. It forms double salts with the alkaline iodides, and absorbs ammonia, forming a snow-white powder. It does not appear to combine with hydrosulphuric acid. (Weber, Pogg. Ann. cvii. 264.)

Oxide of Aluminium. *Alumina*, $\mathrm{Al^2O^3}$, or Al^2O^3.—This, which is the only known oxide of aluminium, is formed by the direct combination of the metal with oxygen. Aluminium in the massive state does not oxidise, even at a strong red heat; but in the state of powder it burns brightly when heated to redness in the air or in oxygen gas, and is converted into alumina, 53·3 pts. of the metal taking up 46·69 pts. of oxygen to form 100 pts. of alumina. The atomic constitution of alumina cannot be determined from this or any other direct experiment, because there is no other oxide of aluminium with which to compare it; but it is inferred to be a sesquioxide, because it is isomorphous with the sesquioxides of iron and chromium, and is capable of replacing those oxides in combination in any proportion.

Alumina occurs native, and very nearly pure, in the form of *corundum*, varieties of which, distinguished chiefly by their colour, are the *sapphire*, *ruby*, *oriental topaz*, *oriental amethyst*, &c. The colourless variety is called *hyaline corundum*. The crystalline forms of these gems all belong to the rhombohedral or hexagonal system, the primary form being a rather acute rhombohedron. Alumina in the crystalline state has a specific gravity of about 3·9, and is, next to the diamond, the hardest substance known. An opaque variety of corundum called *emery*, which has a brown red colour, arising from oxide of iron, is much used in the state of powder for polishing glass and precious stones.

Alumina is prepared artificially: 1. By precipitating a boiling solution of common alum (sulphate of aluminium and potassium), free from iron, with carbonate of ammonium, washing the precipitate with water, and igniting it to expel the combined water.—2. By igniting sulphate of aluminium or ammonia-alum. In the former case, sulphuric anhydride is given off; in the latter, that compound, together with sulphate of ammonium, and alumina remains:

$$Al^4.3SO^4 = Al^4O^3 + 3SO^3$$

$$\text{and} \qquad 2(Al^2.NH^4.2SO^4) = Al^4O^3 + (NH^4)^2.SO^4 + 3SO^3.$$

Alumina thus prepared is apt however to retain a small quantity of sulphuric acid, and if the original salt contained iron, the whole of that impurity remains in the residue.—3.* By digesting clays, felspathic rocks, or other minerals containing alumina in a strong solution of caustic potash or soda, assisting the action, if necessary, by boiling under pressure, or by heating the same minerals with kelp or soda-ash in a reverberatory furnace, and lixiviating the fused product with water. A solution of aluminate of potassium or sodium is thus obtained, a silico-aluminate of the alkali generally remaining undissolved—and the alumina may be precipitated from the solution as a hydrate by passing carbonic acid through the liquid; by treating it with acid carbonate of sodium, or with neutral or acid carbonate of ammonium; by saturating with an acid (using by preference the last vapours of hydrochloric acid evolved in the manufacture of that compound); by treating it with chloride of ammonium, whereupon, ammonia is evolved, chloride of potassium or sodium remains in solution, and alumina is precipitated; or by mixing the solution of the alkaline aluminate with chloride of aluminium, the result being the precipitation of the alumina from both compounds:

$$\underbrace{Al^2K^3O^3}_{\text{Aluminate of potassium.}} + Al^2Cl^3 = Al^4O^3 + 3KCl.$$

4. By mixing cryolite with rather more than $\frac{3}{4}$ of its weight of quick lime, adding a small quantity of water to slake the lime, then a larger quantity, and heating the mixture by a current of steam. The products of this operation are fluoride of calcium and aluminate of sodium:

$$\underbrace{Al^2Na^3F^6}_{\text{Cryolite.}} + 3Ca^2O = 6CaF + \underbrace{Al^2Na^3O^3}_{\text{Aluminate of sodium.}}$$

The aluminate of sodium is decanted from the heavy deposit of fluoride of calcium, and decomposed by carbonic acid as above. If any insoluble aluminate of calcium should be formed, it may be decomposed by digestion with carbonate of sodium. (Deville.) 5. The slag obtained in the preparation of aluminium from chloride of aluminium and sodium, with fluor-spar or cryolite as a flux (p. 150), contains about 40 per cent. of fluoride of aluminium, together with soluble chlorides; and the residue of the extraction of sodium by Deville's process (see SODIUM), which consists in igniting a mixture of carbonate of sodium, carbonaceous matter and chalk, contains about 14·5 p. c. carbonate of sodium, 8·3 p.c. caustic soda, and 29·8 p.c. carbonate of calcium. Now, by heating to redness a mixture of 5 or 6 pts. of the sodium-residue with 1 pt. of the aluminium-slag, freed by washing from the soluble constituents, and lixiviating the product after cooling, a solution of aluminate of sodium is obtained which may be decomposed by carbonic acid as above. (Deville.)

Alumina prepared by any of the preceding processes contains iron. From this it may be purified by dissolving it in caustic alkali and precipitating the iron by a stream of sulphuretted hydrogen (Deville). It may then be reprecipitated by carbonic acid. The alumina thus precipitated always contains a certain quantity of

---

* This process, the invention of M. Le Chatelier of Paris, is patented in this country in the name of H. F. Newton, 1858, No. 1988, and 1859, No. 957.

alkaline carbonate, which cannot be removed by washing with water. It may, however, be separated by digestion, with the aid of heat, in a small quantity of dilute hydrochloric or nitric acid, or by digestion with chloride of aluminium in excess. (Le Chatelier.)

Artificially prepared alumina is white, and if it has been exposed only to a moderate red heat, is very light and soft to the touch; but after strong ignition, it cakes together, becomes so hard as scarcely to be scratched with a file, and emits sparks when struck with steel. According to H. Rose (Pogg. Ann. lxxiv. 430), the specific gravity of alumina ignited over a spirit-lamp is between 3·87 and 3·90; after six hours' ignition in an air furnace, it is between 3·725 and 3·75; and after ignition in a porcelain furnace, 3·999, which agrees very nearly with that of native corundum.

Alumina is infusible at all temperatures below that of the oxy-hydrogen flame; but at that degree of heat, it melts into transparent globules which assume a crystalline structure on cooling. If a small quantity of chromate of potassium be added before fusion, the melted alumina on cooling retains a deep red colour, and resembles the natural ruby. When a mixture of 1 pt. of alumina and 3 or 4 pts. of anhydrous borax is exposed for a considerable time to the high temperature of a porcelain furnace, the alumina dissolves in the fused borax, and as the borax is volatilised by the heat, remains in crystals resembling corundum; in this case also, the addition of a very small quantity of chromate of potassium causes the crystals to exhibit the colour of the ruby. This method is applicable to the artificial formation of a great number of crystallised minerals. (Ebelmen, Ann. Ch. Phys. [3] xxii. 211.)

Alumina is not decomposible by heat alone. Potassium at a white heat deoxidises it partially, forming an alloy of potassium and aluminium which decomposes water. It is not decomposed by chlorine at any temperature, unless it be mixed with charcoal, in which case a chloride of aluminium is produced.

Anhydrous alumina is perfectly insoluble in water. After strong ignition, it is likewise insoluble in most acids, concentrated hydrochloric or sulphuric acid being alone able to dissolve it. In the crystallised state it is insoluble in all acids. It may, however, always be rendered soluble by fusion with hydrate of potassium or sodium.

HYDRATES OF ALUMINIUM, OR OF ALUMINA. These compounds are three in number, viz.:

Monohydrate	Al^2HO^2	or	$Al^2O^3.HO$.
Dihydrate	$Al^4H^4O^5$	„	$Al^2O^3.2HO$.
Trihydrate	$Al^2H^3O^3$	„	$Al^2O^3.3HO$.

The monohydrate is found native as *Diaspore*, a mineral which forms translucent granular masses of specific gravity 3·43, and crumbles to powder when heated, but does not give off the whole of its water below 360° C. It is insoluble in water, and even in boiling hydrochloric acid.

The *trihydrate* is the ordinary gelatinous precipitate, obtained by treating solutions of aluminium-salts, alum, for example, with ammonia or alkaline carbonates; it is also thrown down from the same solutions by sulphide of ammonium, the aluminium not entering into combination with the sulphur. When dried at a moderate heat, it forms a soft friable mass, which adheres to the tongue and forms a stiff paste with water, but does not dissolve in that liquid. At a strong red heat, it parts with its water, and undergoes a very great contraction of volume. It dissolves with great facility in acids, and in the fixed caustic alkalis. When a solution of alumina in caustic potash is exposed to the air, the potash absorbs carbonic acid, and the trihydrate of aluminium is then deposited in white crystals which are but sparingly soluble in acids.

The trihydrate of aluminium has a very powerful attraction for organic matter, and when digested in solutions of vegetable colouring matter, combines with and carries down the colouring matter, which is thus removed entirely from the liquid if the alumina is in sufficient quantity. The pigments called *lakes* are compounds of this nature. The fibre of cotton impregnated with alumina acquires the same power of retaining colouring matters; hence the great use of aluminous salts as *mordants* to produce fast colours. (See DYEING.)

Trihydrate of aluminium occurs native as *Gibbsite*, a stalactitic, translucent, fibrous mineral, easily dissolved by acids.

Dihydrate of Aluminium, $Al^4H^4O^5$, or $Al^4O^3,2H^2O$.—When a dilute solution of diacetate of aluminium is exposed for several days to a temperature of 100° C. in a close vessel, the acetic acid appears to be set free, although no precipitation of alumina takes place. The liquid acquires the taste of acetic acid, and if afterwards boiled in an open vessel, gives off nearly the whole of its acetic acid, the alumina nevertheless remaining in solution. This solution is coagulated by mineral acids and by most vegetable acids, by alkalis, and by decoctions of dye-woods. The alumina contained in it is, however, no longer capable of acting as a mordant. Its coagulum with dye-woods has the colour of the infusion, but is translucent and totally different from the dense opaque lakes which ordinary alumina forms with the same colouring matters. On evaporating the solution to dryness at 100° C. the alumina remains in the form of dihydrate, retaining only a trace of acetic acid. In this state, it is insoluble in the stronger acids, but soluble in acetic acid, provided it has not been previously coagulated in the manner just mentioned. Boiling potash converts it into the trihydrate (Walter Crum, Chem. Soc. Qu. J. vi. 225). The dihydrate is said to occur native at Béaux (Berthier, Schw. J. xxxiv. 154). *Hydrargyllite*, a mineral occurring in regular six-sided prisms is also a hydrate of aluminium, but its exact composition is not known. (G. Rose, Pogg. Ann. xlviii. 564; l. 656.)

Aluminates.—The hydrogen in trihydrate of aluminium, may be replaced by an equivalent quantity of various metals; such compounds are called *aluminates*. According to Frémy, a solution of alumina in potash slowly evaporated [out of contact of air?] deposits granular crystals of aluminate of potassium, Al^2KO^2, or Al^4O^3, K^2O. Similar compounds occur native; thus *Spinell* is an aluminate of magnesium, Al^2MgO^2; *Gahnite*, an aluminate of zinc, Al^2ZnO^2.

Oxygen-Salts of Aluminium.—The general characters of these salts have already been described (p. 154). The most important of them are the sulphate $Al^4(SO^4)^3$, with its double sulphates, especially common alum, the sulphate of aluminium and potassium, and the silicates and double silicates. [For the detailed descriptions of these salts, see the several Acids.]

Phosphide of Aluminium.—Obtained by heating pulverulent aluminium to redness in phosphorus vapour. It is a dark grey mass, which acquires metallic lustre by burnishing, and is decomposed by water, with evolution of non-spontaneously inflammable phosphoretted hydrogen. (Wöhler.)

Silicide of Aluminium.—Aluminium combines readily, and in all proportions, with *silicon*. When strongly heated in contact with any silicious substances, such as glass or porcelain, it reduces the silicon and unites with it. Nevertheless aluminium may be fused in glass or earthen vessels, without undergoing the slightest alteration, provided no flux be used, because it does not then come into intimate contact with the substance of the vessel; but the addition of a flux produces instant decomposition. The properties of the compound vary with the proportion of silicon. An alloy containing 10·3 per cent. of silicon, called *cast* aluminium (*fonte d'aluminium*) is grey and very brittle. A compound containing 70 per cent. silicon, still exhibits metallic properties. All the compounds of aluminium and silicon are much more easily altered by exposure to the air, or by the action of acids and alkalies, than either pure aluminium or pure silicon.

Selenide of Aluminium, Al^4Se^3, or Al^2Se^3—Produced with incandescence when aluminium is heated in selenium vapour. It is a black powder, which acquires a dark metallic lustre by burnishing, and is readily decomposed by water or by a moist atmosphere, with formation of alumina and hydroselenic acid.

Sulphide of Aluminium, Al^4S^3, or Al^2S^3.—Sulphur may be distilled over aluminium without combining with it; but when thrown upon the red-hot metal, it is absorbed with vivid incandescence (Wöhler). The sulphide may be prepared by passing the vapour of disulphide of carbon over red-hot alumina. It is fusible, decomposes water at ordinary temperatures, yielding hydrate of aluminium and hydrosulphuric acid, and thus perhaps contributes to the formation of natural sulphur springs. (Frémy.)

ALUMO-CALCITE. A mineral from Erbenstock, in the Saxon Harz, having the appearance of opal. Specific gravity 2·1 to 2·2, scarcely harder than mica. Contains, according to Kersten's analysis, 6·25 per cent. lime, 2·23 alumina, and 40 water. It is probably a mere residue of decomposition.

ALUM-EARTH. A massive variety of aluminous schist, found in the neighbourhood of tertiary lignites, as in several parts of the valley of the Oder, on the Rhine, in Picardy, and other localities. It has not a distinct slaty structure, but is a soft, friable, usually dark brown mass.

ALUM-SLATE. A clay slate, containing bitumen and sulphide of iron, generally found in the transition-strata, but sometimes in more recent formations. It is found in the north of England and in Scotland, in Scandinavia, in the Harz, in the Ural, the Vosges, the lower Rhine, and other localities. There are two varieties of it, viz. 1. *Common.* This mineral occurs both massive and in insulated balls of a greyish-black colour, dull lustre, straight slaty fracture, tubular fragments, streak coloured like itself. Though soft, it is not very brittle. Effloresces, acquiring the taste of alum.

2. *Glossy Alum-slate.* A massive mineral of a bluish-black colour. The rents display a variety of lively purple tints. It has a semi-metallic lustre in the fracture,

which is straight, slaty, or undulating. There is a soft variety of it, approaching in appearance to slate clay. By exposure to air its thickness is prodigiously augmented by the formation of a saline efflioresence, which separates its thinnest plates. These afterwards exfoliate in brittle sections, causing entire disintegration.

ALUNITE, or **ALUM-STONE.** A basic sulphate of aluminium and potassium, $Al^2K.2SO^4 + 3Al^2H^3O^3$ or $\left.\begin{matrix}K^2O\\ Al^4O^3\end{matrix}\right\} 4SO^3 + 3(Al^4O^3.3H^2O)$, found chiefly in volcanic districts, viz. at Tolfa, near Civita Vecchia, at Solfatara, near Naples, at Puy de Garcey, in Auvergne, and other localities. Used for the preparation of Roman alum.

It is either massive or crystallised; the former is usually greyish white, and sometimes red. It is translucent, easily frangible, scratches calcareous spar, but is scratched by fluor spar. The crystals are generally situated in the cavities of the massive substance, they are small, shining, sometimes externally brownish, their form is an obtuse rhomboid, variously modified. The crystals have the composition above given: the massive variety contains in addition a considerable quantity of silica.

ALUNOGEN. Native sulphate of aluminium. (See SULPHATES.)

AMALGAM. A combination of mercury with another metal. (See MERCURY.)

AMALGAMATION. The process of extracting gold and silver from their ores by dissolving them out with mercury. (See GOLD and SILVER.)

AMALIC ACID (from ἀμαλός, *soft*, on account of its feeble acid reaction.)—A product of the decomposition of caffeine by chlorine (see CAFFEINE), discovered by Rochleder. Its composition is that of alloxantin, having the whole of its hydrogen replaced by methyl: $C^4(CH^3)^4N^4O^7 + H^2O$.

It forms transparent colourless crystals, which do not give off their water at 100° C. At a higher temperature, it melts and volatilises, leaving scarcely a trace of charcoal, but giving off ammonia, and yielding an oil and crystallised body. It slightly reddens litmus, and produces red stains on the skin, imparting to it an unpleasant odour, like alloxantin. It reduces silver-salts like alloxantin. Nitric acid converts it into a crystalline substance. When exposed to vapour of ammonia, it gradually assumes a deep violet colour, and forms a compound which dissolves in water with the colour of murexide: the solution yields a crystalline body, to which Rochleder gives the name *murexoin.* With baryta, potash, and soda, it forms compounds of a deep violet colour.

AMANITINE. An organic base obtained by Letellier from the fly agaric (*Agaricus muscarius*, or *Amanita muscaria*), and from *Agaricus bulbosus*, and supposed by him to be the poisonous principle of these agarics. According to Apaiger and Wiggers, on the other hand, the fly agaric contains a peculiar acid (muscaric acid), as well as a base, and it is to the acid that the poisonous action is due. (Handw. d. Chem. 2te Aufl. i. 663.)

AMARINE. $C^{21}H^{18}N^2$. *Benzoline, Pikramin, Hydrure d'azobenzoiline.*—(Laurent, Ann. Ch. Phys. [3] i. 306; Fownes, Ann. Ch. Pharm. liv. 363; Gössmann, Ann. Ch. Pharm. xciii. 329; Gm. xii. 193.)

This compound was discovered simultaneously by Laurent and by Fownes. It is isomeric with hydrobenzamide, from which it is generally prepared. 1. When hydrobenzamide is heated for three or four hours to 120°—130° C., the vitreous mass, when cool, dissolved in boiling alcohol, and excess of hydrochloric acid added, white crystals of hydrochlorate of amarine separate out (Bertagnini). — 2. Hydrobenzamide is boiled for some hours with caustic potash, the resulting resin dissolved in dilute sulphuric acid, the solution precipitated by ammonia, and the precipitate washed with water and crystallised from hot alcohol (Fownes). — 3. A solution of bitter-almond oil in alcohol, when saturated with gaseous ammonia, solidifies in 24—48 hours into a crystalline mass. This is boiled with water, and saturated while hot with hydrochloric acid, when an oily substance separates out, together with crystals of a peculiar acid (see BENZIMIC ACID). The hot solution is decanted, and the residue again extracted with boiling water, until all the hydrochlorate of amarine is dissolved out. The solution is precipitated by ammonia; and the precipitate is washed, dissolved in boiling alcohol, mixed with hydrochloric acid, and reprecipitated by ammonia: pure amarine then crystallises out (Laurent). — 4. When the dry compound of bitter-almond oil and acid sulphite of ammonium is heated in a large retort to 180°—200° with 3 or 4 times its volume of slaked lime, amarine and lophine distil over. The former, which collects partly in the receiver, partly in the lower part of the neck of the retort, is dissolved in alcohol, and purified as in the former process. (Gössmann.)

Amarine crystallises from alcohol in shining six-sided prisms. It melts at 100° C. and solidifies to a vitreous mass on cooling: when heated more strongly, it volatilises almost completely, ammonia being evolved: an oil smelling like benzol distils over, and a sublimate collects in the neck of the retort, which Fownes calls *pyrobenzoline*, and which, according to Laurent, is identical with lophine. Amarine is inodorous, tasteless at first, but afterwards slightly bitter. It is insoluble in water, soluble in alcohol and ether; the alcoholic solution is strongly alkaline. Amarine becomes strongly electrical by friction. Unlike its isomer, hydrobenzamide, it exerts a poisonous action on animals.

Amarine is readily attacked by bromine, hydrobromate of amarine being formed together with a resinous mass. When it is boiled with a mixture of sulphuric and chromic acids and water, a brisk action takes place, and benzoic acid is abundantly formed. Nitric acid acts similarly, but less violently. Fused potash does not attack it, save at a very strong heat.

Amarine-salts are formed by the direct combination of amarine with acids. With the exception of the acetate, they are all but slightly soluble. The *hydrochlorate*, $C^{21}H^{18}N^2,HCl$, crystallises in small shining needles, which effloresce in vacuo, or when heated to 100°. When hydrochloric acid is poured upon amarine, a colourless oil is formed, which gradually solidifies on drying, and may be drawn into threads when heated. It distils without decomposition, passing over as an oil which solidifies to a transparent mass. It is soluble in alcohol and ether. The *chloroplatinate* separates in yellow needles, when boiling alcoholic solutions of the hydrochlorate and of dichloride of platinum are mixed together. Fownes found in it 19·8 per cent. platinum; the formula $PtCl^2.C^{21}H^{19}N^2$ requires 19·58 per cent. The *sulphate* crystallises from an acid solution in small colourless prisms resembling oxalic acid. The *nitrate* is obtained by treating amarine with hot dilute nitric acid; a soft, amorphous mass is produced, which dissolves in boiling water, and on cooling deposits small crystals, which remain unaltered in vacuo. The *acetate* is very soluble, and yields on evaporation a gummy non-crystalline mass.

Diethylamarine, $C^{21}(C^2H^5)^2H^{16}N^2$.—Amarine heated with iodide of ethyl, yields a crystalline salt, which is the hydriodate of this base. The base itself is obtained by distilling the hydriodate with potash. It crystallises readily in oblique rhombic prisms, is nearly insoluble in water, but dissolves readily in alcohol and ether. It melts between 110° and 115° C. but does not solidify again till cooled down to 70°. At a stronger heat it decomposes. The *hydrochlorate* crystallises in oblique rhombic prisms. The *platinum-salt* is a yellow powder, insoluble in water and in ether, but soluble in alcohol, from which it crystallises in small prisms. (Borodine, Ann. Ch. Pharm. cx. 78.)

Diethylamarine treated with iodide of ethyl yields the hydriodate of another crystalline base, probably triethylamarine, which however has not yet been analysed, and this base again treated with iodide of ethyl, yields a third crystalline base. (Borodine.)

Trinitramarine, $C^{21}H^{15}(NO^2)^3N^2$ (Bertagnini, Ann. Ch. Pharm. lxxix. 275).—This compound is formed from trinitrohydrobenzamide, with which it is isomeric, just as amarine is from hydrobenzamide. Trinitrohydrobenzamide is boiled with 1 vol. caustic potash of 46° Baumé, and 50 vols. water; the resulting brown resinous mass (which becomes brittle on cooling) is dissolved in hot alcohol; a little ether added; and the solution is precipitated by hydrochloric acid. The hydrochlorate is redissolved in alcohol, alcoholic ammonia added to the solution, and the precipitated trinitramarine is washed with water, and recrystallised from alcohol. Trinitramarine is also obtained by heating trinitrohydrobenzamide in an oil-bath to 125°—130° C.

It crystallises slowly from its alcoholic solution in white hard nodules. It melts in boiling water, and dissolves slightly, forming an alkaline solution. It is soluble in boiling alcohol or ether, most readily in a mixture of the two. A hot saturated solution deposits it on cooling as an amorphous powder.

Its salts are but slightly soluble in water. The *hydrochlorate* separates in small shining needles when hydrochloric acid is added to an alcoholic solution of trinitramarine; it is nearly insoluble in cold, slightly soluble in boiling alcohol. The *nitrate* crystallises in needles from boiling alcohol. An alcoholic solution of trinitramarine forms with *dichloride of platinum*, small, yellow, heavy nodules insoluble in alcohol; and with *mercuric chloride*, a somewhat crystalline precipitate.—F. T. C.

AMARONE. $C^{16}H^{11}N$ (Laurent, Rev. Scient. xviii. 207, &c).—A compound formed by the dry distillation of azobenzoyl, benzoylazotide, or hydrobenzamide. The sublimate obtained by heating benzoylazotide is washed with ether, and then freed from lophine by boiling in alcohol containing hydrochloric acid; the residue is washed with alcohol, dried, crystallised from boiling rock-oil, and washed with ether. It forms small, colourless, inodorous needles, which melt at 233° C., and solidify to a radiated mass on cooling. It is insoluble in water, slightly soluble in alcohol, more readily in ether. It dissolves in cold sulphuric acid, with a fine blood-red colour, which disappears on addition of water, the amarone separating out. It dissolves sparingly in hot nitric acid, and crystallises unchanged on cooling. It is not decomposed by boiling with alcoholic potash.—F. T. C.

AMARYL. A name given by Laurent to a substance which he afterwards found to be impure nitrate of lophine.

AMARYTHRIN. Syn. with ERYTHRIN-BITTER or PICRO-ERYTHRIN.

AMASATIN. Syn. with ISAMIDE.

AMAUSITE. Compact FELSPAR.

AMAZON-STONE. A variety of orthoclase, coloured green by copper. It is found chiefly in the shores of Lake Ilmen in Russia, also in Norway. It is used for making trinkets.

AMBER. *Succin, Electrum, Ambra flava, Bernstein, Agtstein, gelbes Erdharz.*—A hard brittle tasteless substance, sometimes perfectly transparent, but mostly semi-transparent or opaque, and of a glassy surface; it is found of all colours but chiefly yellow or orange, and often contains leaves or insects. Its specific gravity varies from 1·065 to 1·070; hardness 2 to 2·5; slightly brittle; fracture conchoidal. It is susceptible of a fine polish, and becomes electric by friction: hence the word electricity (from ἤλεκτρον, amber). When rubbed or heated, it emits a peculiar smell. It is insoluble in water and alcohol, though the latter, when highly rectified, extracts a reddish colour from it. It is soluble in sulphuric acid, to which it imparts a reddish purple colour, but is reprecipitated on addition of water. No other acid dissolves it, nor is it soluble in essential or expressed oils without decomposition; but pure alkalis dissolve it.

According to Berzelius, amber contains a volatile oil, succinic acid, and two resins soluble in alcohol and ether. According to Schroetter and Forchammer, amber when deprived by ether of all its soluble constituents, possesses the composition of camphor viz. $C^{10}H^{16}O$.

The dry distillation of amber presents three distinct phases, characterised by the nature of the products. When submitted to the action of heat, amber softens, fuses, intumesces considerably, and gives off succinic acid, water, oil, and a combustible gas. If now the residue (*Colophony of Amber*) be more strongly heated, a colourless oil passes over. Lastly, when the residue is completely charred, and the heat is raised till the glass nearly fuses, a yellow substance sublimes of the consistence of wax.

The oil thus produced is a mixture of several hydrocarbons. The more volatile portion which passes over between 110° and 260° C., is decomposed in the cold by sulphuric acid, and coloured blue by hydrochloric acid, and by chlorine; the less volatile portion produced by a heat approaching redness, begins to boil at 140°, and then rises to 300°; sulphuric and hydrochloric acid and chlorine do not alter it. According to Pelletier and Walter (Ann. Ch. Phys. [3] ix. 89), these oils present the composition of oil of turpentine, containing 88·7 per cent. of carbon, and 11·3 of hydrogen.

The crude mixture of the two oils is used in pharmacy under the name of oil of amber, being in fact one of the constituents of *Eau de Luce*, a preparation sometimes used as a remedy for the bites of venomous animals, and consisting of 1 part of oil of amber, 24 of alcohol, and 96 of caustic ammonia.

The wax-like solid which passes over in the dry distillation of amber is a mixture of oil, yellow matter, a white crystalline substance, and a brown bituminous substance; these bodies are separated by treatment with ether and alcohol. The yellow matter appears to be identical with chrysene (C 94·4, H 5·8). It is scarcely soluble in boiling alcohol and ether, is pulverulent rather than crystalline, and requires for fusion a temperature of 240° C.

The white matter (*succisterene*) is tasteless and inodorous, it is scarcely soluble in cold alcohol, but little soluble in ether, but more soluble than the yellow matter; it melts between 160° and 162°, and distils above 300°. Nitric acid resinises it in the cold. It contains, according to Pelletier and Walter, 95·6 per cent. of carbon and 5·6 of hydrogen.

When amber is treated with fuming nitric acid, a resin is formed (artificial musk) which is soluble in an excess of nitric acid, and contains $C^{15}H^{16}N^2O^2$.

When powdered amber is distilled with a strong solution of potash, a watery liquid passes over, together with a white substance which exhibits all the properties of common camphor.

Amber occurs plentifully in regular veins in some parts of Prussia, especially between Palmnicken and Grosz-Hubenicken. In East and West Prussia there is scarcely a village where it has not been found. and thence it extends into Mecklenburg and Holstein and in fact along the whole Baltic plain. It has likewise been found in southern Germany, in France, Italy, Spain, Sweden and Norway; also on the shores of the

Caspian, in Siberia, Kamtschatka, China, Hindoostan, Madagascar, North America and Greenland. In Britain it is thrown out by the sea on the shores of Norfolk, Suffolk and Essex, and has also been found in the sands at Kensington. In the Royal Cabinet at Berlin there is a mass of 18 lbs. weight, supposed to be the largest ever found.

Haüy has pointed out the following characters by which amber may be distinguished from mellite and copal, the bodies which most closely resemble it. Mellite is infusible by heat; a bit of copal heated at the end of a knife takes fire, melting into drops, which flatten as they fall; whereas amber burns with spitting and frothing, and when its liquefied particles drop, they rebound from the plane which receives them.

Various frauds are practised with this substance. Neumann states as the common practices of workmen the two following: The one consists in surrounding the amber with sand in an iron pot, and cementing it with a gradual fire for forty hours, some small pieces placed near the sides of the vessel being occasionally taken out for judging of the effect of the operation. The second method, which he says is that most generally practiced, is to digest and boil the amber about twenty hours with rapeseed oil, by which it is rendered both clear and hard.

The chemical properties and mode of occurrence of amber leave no doubt of its being the produce of extinct coniferæ. It has been found encrusting or penetrating fossil wood exactly like resin at the present day, and enclosing the cones and leaves of the trees. Numerous insects, the inhabitants of these ancient forests have been embalmed in it. To the tree which principally produced it, Göppert gives the name of *Pinites succinifer*, but there was probably more than one species. Amber is often stated to occur in the brown coal beds of Northern Germany, but Göppert states that he knows of no instance of this, the substance found in those beds being retinite. (Handw. d. Chem. 2te Aufl. ii. 972; Dana, ii. 466; Gerh. iv. 394).

AMBERGRIS. (*Ambra, Ambra grisca*), is found in the sea, near the coasts of various tropical countries; and has also been taken out of the intestines of the spermaceti whale (*Physeter macrocephalus*). As it has not been found in any whales but such as are dead or sick, its production is generally supposed to be owing to disease, though some have a little too positively affirmed it to be the cause of the morbid affection. As no large piece has ever been found without a greater or smaller quantity of the beaks of the *sepio octopodia*, the common food of the spermaceti whale, interspersed throughout its substance, there can be little doubt of its originating in the intestines of the whale: for if it were merely occasionally swallowed by the animal, and then caused disease, it would much more frequently be without these bodies, when it is met with floating in the sea, or thrown upon the shore.

Ambergris is found of various sizes, generally in small fragments, but sometimes so large as to weigh near two hundred pounds. When taken from the whale, it is not so hard as it afterwards becomes on exposure to the air. Its specific gravity ranges from 0·780 to 0·926. If good, it adheres like wax to the edge of a knife with which it is scraped, retains the impression of the teeth or nails, and emits a fat odoriferous liquid on being penetrated with a hot needle. It is generally brittle; but, on rubbing it with the nail, it becomes smooth, like hard soap. Its colour is either white, black, ash-coloured, yellow, or blackish; or it is variegated, namely, grey with black specks, or grey with yellow specks. Its smell is peculiar, and not easy to be counterfeited. At 62·2 C. it melts, and at 100 C. is volatilised in the form of a white vapour; on a red-hot coal it burns, and is entirely dissipated. Water has no action on it; acids, except nitric acid, act feebly on it; alkalis combine with it, and form a soap; ether and the volatile oils dissolve it; so do the fixed oils, and also ammonia, when assisted by heat; alcohol dissolves a portion of it.

The principal constituent of ambergris is ambrein (*q. v.*) Succinic and benzoic acids are said to be sometimes found among the products of its destructive distillation. Its inorganic constituents are carbonate and phosphate of calcium, with traces of ferric oxide and alkaline chlorides.

An alcoholic solution of ambergris, added in minute quantity to lavender water, tooth powder, hair powder, wash balls, &c. communicates its peculiar fragrance. Its retail price being in London a guinea per oz. leads to many adulterations. These consist of various mixtures of benzoin, labdanum, meal, &c. scented with musk. The greasy appearance and smell which heated ambergris exhibits, afford good *criteria*, joined to its solubility in hot ether and alcohol.

It has occasionally been employed in medicine, but its use is now confined to the perfumer. Swediaur took thirty grains of it without perceiving any sensible effect. — U.

AMBLYGONITE. A greenish-coloured mineral of different pale shades, marked on the surface with reddish and yellowish-brown spots. It occurs massive and crystallised in oblique four-sided prisms. Lustre vitreous; cleavage parallel to the sides of an oblique four-sided prism of 106° 10′ and 77° 50′; fracture uneven; fragments rhomboidal; translucent; hardness as felspar; brittle; specific gravity 3·0: intumesces with the blowpipe, and fuses with a reddish-yellow phosphorescence into a white enamel. It occurs in granite, with green topaz and tourmaline, at Chursdorf and Arnsdorf, near Pinig, in Saxony. A specimen from Arsndorf analysed by Rammelsberg gave 47·15 phosphoric anhydride, 88·43 alumina, 7·03 lithia, 3·29 soda, 0·43 potash and 8·11 fluorine, agreeing very nearly with the formula:

$$(5Al^4O^3.3P^2O^5 + 5M^2O.3P^2O^5) + 2\,(Al^2F^3 + MF.)$$

(Handwört. d. Chem. 2te Aufl. i. 665; Dana, ii. 409.)

AMBREIN. By digesting ambergris in hot alcohol, specific gravity 0·827, the peculiar substance, called *ambrein* by Pelletier and Caventou, is obtained. The alcohol, on cooling, deposits the ambrein in very bulky and irregular crystals which still retain a very considerable portion of alcohol. Thus obtained, it has the following properties: — It is of a brilliant white colour, has an agreeable odour, of which it is deprived by repeated solution and crystallisation. It is destitute of taste, and does not act on vegetable blues. It is insoluble in water, but dissolves readily in alcohol and ether; and in much greater quantity in these liquids when hot than when cold. It melts at 30° C. (86° F.) softening at 25° C. When heated above 100° C., it is partly volatilised and decomposed, giving off a white smoke. It does not seem capable of combining with an alkali, or of being saponified. When heated with nitric acid, it becomes green and then yellow, eliminates nitrous gas, and is converted into an acid, which has been called *ambreic* acid. This acid is yellowish white, has a peculiar odour, reddens vegetable blues, does not melt at 100° C., and does not evolve ammonia when decomposed at higher temperatures. It is soluble in alcohol and ether; but slightly so in water. Ambreate of potassium forms yellow precipitates with chloride of calcium, protosulphate of iron, nitrate of silver, acetate of lead, corrosive sublimate, protochloride of tin and chloride of gold. (J. Pharm. v. 49.)

Ambrein is perhaps impure cholesterin, which substance it greatly resembles in its properties. Pelletier (Ann. Ch. Pharm. vi. 24) found it to contain 83·3 p. c. C, 13·3 H, and 3·32 O, which is nearly the composition of cholesterin: if this be so, ambreic acid is probably identical with cholesteric acid.

AMETHANES. A name applied to the ethers of the amic acids, *e. g.* oxamethane to oxamate of ethyl. (See AMIC ACIDS.)

AMETHYST. The amethyst is a gem of a violet colour, and great brilliancy, said to be as hard as the ruby or sapphire, from which it differs only in colour. This is called the oriental amethyst, and is very rare. When it inclines to the purple or rose colour, it is more esteemed than when it is nearer to the blue. These amethysts have the same figure, hardness, specific gravity, and other qualities, as the best sapphires or rubies, and come from the same places, particularly from Persia, Arabia, Armenia, and the West Indies. The occidental amethysts are merely coloured crystals of quartz. — U. (See QUARTZ and SAPPHIRE.)

AMIANTHOID. A variety of Hornblende (*q. v.*)

AMIANTHUS. Mountain flax. (See ASBESTOS.)

AMIC ACIDS. By this name are designated a class of nitrogenised acids, which differ from the acid ammonium-salts of polybasic acids by the elements of one or more atoms of water; and which, under certain circumstances, are capable of taking up the elements of water, and regenerating ammonia and the original non-nitrogenised polybasic acid. They bear a considerable resemblance to amides in their modes both of formation and of decomposition: but they differ from these bodies in possessing invariable and decided acid properties, and in not deriving from the type NH^3.

With regard to their constitution, amic acids are best regarded as deriving from the double type NH^3,H^2O. They represent this type in which 2, 3, or 4 atoms of hydrogen are replaced by other radicles, one of which must be the radicle of a *polybasic* acid: and they may be divided into 3 classes, according as 2, 3, or 4 atoms of hydrogen are so replaced. In class 1, therefore, it is obvious that 2 atoms of hydrogen in the type must be replaced by 1 diatomic acid radicle; in class 2, three atoms of hydrogen may be replaced by 1 triatomic, or by 1 diatomic and 1 monatomic acid radicle; and so on. No amic acid is formed by the substitution of an acid radicle of less than 2 atoms of hydrogen in the type: if 1 atom of hydrogen in NH^3,H^2O be replaced by the radicle of a monobasic acid, the only result is the formation of the ammonium-salt of that acid, *e. g.*:

$$\underset{\text{Acetyl.}}{NH^2(C^2H^3O)HO} = \underset{\text{Acetate of ammonium}}{C^2H^3O.NH^4.O}$$

Neither can an amic acid be formed by replacing 2 atoms hydrogen in the type by 2 monatomic acid radicles; for when benzoic anhydride is treated with ammonia, the 2 atoms of benzoyl, each equivalent to H, do not remain combined, forming an amic acid, but separate, forming 2 distinct compounds, benzamide and benzoate of ammonium:

$$\underset{\text{Benzoic anhyd.}}{(C^7H^5O)^2.O} + 2NH^3 = \underset{\text{Benzamide.}}{N.C^7H^5O.H^2} + \underset{\text{Benzoate of amm.}}{C^7H^5O.NH^4.O}$$

But when a dibasic anhydride is treated with ammonia, the acid radicle, equivalent to H^2, being indivisible, is incapable of separating so as to form two distinct compounds; so that a single compound is necessarily formed, the ammonium-salt of an amic acid:

$$\underset{\text{Sulphuric anhyd.}}{SO^2.O} + 2NH^3 = \underset{\text{Sulphamate of amm.}}{N\overbrace{H^2.S}^{'''}\overbrace{O^2.H}^{''}.O}$$

Hence it follows that a monobasic acid is incapable of forming an amic acid: in fact the possession of this property is perhaps one of the most distinguishing characteristics of polybasic acids.

We now proceed to describe the modes of formation, properties, and reactions of amic acids, dividing them into 3 classes, according as 2, 3, or 4 atoms of hydrogen are replaced in the type.

Class 1. They represent the type $\overbrace{NHHH}^{'''}\ \overbrace{HHO}^{''}$ in which 2 atoms of hydrogen are replaced by one diatomic acid radicle:

Sulphamic acid	$\overbrace{NH.H.S}^{'''}\overbrace{O^2.H}^{''}.O$
Carbamic acid	$\overbrace{NH.H.C}^{'''}\overbrace{O.H}^{''}.O$
Oxamic acid	$\overbrace{NH.H.C^2}^{'''}\overbrace{O^2.H}^{''}.O$
Succinamic acid	$\overbrace{NH.H.C^4}^{'''}\overbrace{H^4O^2.H}^{''}.O$

They are formed—1. By action of heat on the acid ammonium-salt of a dibasic acid:

$$\underset{\text{Acid oxalate of amm.}}{C^2O^2.(NH^4)H.O^2} - H^2O = \underset{\text{Oxamic acid.}}{N.\overbrace{H^2.C^2}^{'''}\overbrace{O^2.H}^{''}.}$$

In some cases, *e. g.* comenamic acid, $NH^2.C^6H^2O^3.H.O$, prolonged boiling of the ammonium-salt with water is sufficient.

2. By action of ammonia on anhydrides:

$$\underset{\text{Camphoric anhyd.}}{C^{10}H^{14}O^2.O} + NH^3 = \underset{\text{Camphoramic acid.}}{N\overbrace{H^2.C^{10}}^{'''}\overbrace{H^{14}O^2.H}^{''}.O}$$

The best mode is to dissolve the anhydride in absolute alcohol, and to lead dry ammonia into the solution. The reaction takes place with 2 atoms of ammonia, an amate of ammonium being formed.

3. By action of ammonia on acid salts of organic radicles:

$$\underset{\substack{\text{Acid salicylate of methyl.}\\ \text{(Methyl-salicylic acid.)}}}{C^7H^4O.(CH^3)H.O^2} + NH^3 = \underset{\text{Salicylamic acid.}}{N\overbrace{H^2.C^7}^{'''}\overbrace{H^4O.H}^{''}.O} + \underset{\substack{\text{Methylic}\\ \text{alcohol.}}}{CH^3.H.O}$$

4. By action of aqueous ammonia on ethers of dibasic acids. (Gerhardt, Chim. org. iv. p. 668.)

$$C^{10}H^{16}O^2.(C^2H^5)^2.O^2 + NH^3 + H^2O = \underset{\text{Sebamic acid.}}{N\overbrace{H^2.C^{10}}^{'''}\overbrace{H^{16}O^2.H}^{''}.O} + 2\left(\underset{\text{Alcohol.}}{C^2H^5.H.O}\right)$$

5. Imides, boiled with dilute ammonia, take up H^2O, and form amic acids: some alkalamides exhibit the same reaction:

$$\underset{\text{Succinimide.}}{N.C^4H^4O^2.H} + H^2O = \underset{\text{Succinamic acid.}}{N\overbrace{H^2.C^4}^{'''}\overbrace{H^4O^2.H}^{''}.O}$$

$$N.C^4H^4O^2.Ag. + H^2O = N\overbrace{H^2.C^4H^4}^{'''}\overbrace{O^2.Ag}^{''}.O$$

Argento-succinimide. Succinamate of silver.

6. Some primary diamides, boiled with mineral acids or alkalis, take up H^2O, and form amic acids, or amates of ammonium:

$$N^2.C^4H^4O^3.H^4 + H^2O = N\overbrace{H^2.C^4H^4}^{'''}\overbrace{O^3}^{''}.H.O + NH^3$$

Malamide. (Asparagine.) Malamic acid. (Aspartic acid.)

7. Some amic acids are formed by the action of hydrosulphuric acid on nitro-conjugated acids:

$$C^7H^4(NO^2)O.H.O + 3H^2S = N\overbrace{H^2.C^7H^4}^{'''}\overbrace{O.H}^{''}.O + 2H^2O + 3S$$

Nitrobenzoic acid. Oxybenzamic acid.

The acid thus formed is commonly called benzamic acid; an impossible name, as benzoic acid is monobasic. We regard it as the amic acid of oxybenzoic acid, $C^7H^4O.H^2.O^2$, a diatomic acid, although it does not form acid salts. Strecker regards this amic acid as phenylcarbamic acid, $NH.C^6H^5.CO.H.O$.

Class 2. They represent the type $N\overbrace{HHH}^{'''}\ \overbrace{HH}^{''}O$ in which 3 atoms hydrogen of are replaced; (a) by 1 triatomic acid radicle, (b) by 1 diatomic and 1 monatomic acid radicle, (c) by 1 diatomic acid, and 1 monatomic basic radicle.

a. 3H *are replaced by* 1 *triatomic acid radicle:*

Phosphamic acid, $N\overbrace{H.PO}^{'''}\overbrace{.H}^{''}.O$, formed by the action of ammonia on phosphoric anhydride:

$$P^2O^5 + 2NH^3 = 2(N.HPO.H.O) + H^2O.$$

b. 3H *are replaced by* 1 *diatomic and* 1 *monatomic acid-radicle:*

Benzoylsalicylamic acid . . . . $N\overbrace{H.C^7H^5O.C^7H^4}^{'''}\overbrace{O.H}^{''}.O$

Sulphophenyl-succinamic acid . . . $N\overbrace{H.C^6H^5SO^2.C^4H^4}^{'''}\overbrace{O^2.H}^{''}.O.$

Obtained by boiling certain tertiary amides with aqueous ammonia (Gerhardt and Chiozza):

$$N.C^6H^5SO^2.C^4H^4O^2 + NH^4.H.O = N\overbrace{H.C^6H^5SO^2.C^4H^4}^{'''}\overbrace{O^2.NH^4}^{''}.O.$$

Sulphophenyl-succinamide. Sulphophenyl-succinamate of amm.

c. 3H *are replaced by* 1 *basic monatomic and* 1 *acid diatomic radicle:*

Ethyloxamic acid . . . . $N\overbrace{H.C^2H^5.C^2}^{'''}\overbrace{O^2.H}^{''}.O$

Phenylsulphamic (sulphanilic) acid . . . $N\overbrace{H.C^6H^5.}^{'''}\overbrace{SO^2.H}^{''}.O$

Phenylsuccinamic (succinanilic) acid . . . $N\overbrace{H.C^6H^5.C^4}^{'''}\overbrace{H^4O^2.H}^{''}.O.$

These compounds (which may be called *alkalamic* acids) are obtained by the same reactions that serve for the formation of acids of class 1, a primary amine being substituted for ammonia:

1. By heating the acid salts of organic alkalis:

$$\overset{''}{C^2}O^2.N(CH^3)H^4.O^2 - H^2O = N\overbrace{H.CH^3.C^2}^{'''}\overbrace{O^2.H}^{''}.O.$$

Acid oxalate of methylium. Methyloxamic acid.

2. By action of primary amines on dibasic anhydrides:

$$C^5\overset{''}{H^6}O^2.O + N.C^6H^5.H^2 = N\overbrace{H.C^6H^5.C^5H^6}^{'''}\overbrace{O^2.H}^{''}.O.$$

Pyrotartaric anhyd. Phenylamine. Phenylpyrotartramic acid.

3. By heating alkalimides with dilute ammonia:

$$\underset{\text{Phenylmalamide.}}{N.C^6H^5.C^4\overset{''}{H}^4O^2} + H^2O = \underset{\text{Phenylmalamic acid.}}{N\overbrace{H.C^6H^5.C^4H^4}^{'''}\overbrace{O^2.H}^{''}.O}.$$

Class 3. They represent the type NH^3,H^2O in which four atoms of hydrogen are replaced by other radicles, one of which must be a polyatomic acid radicle. The only known members of this class are a few phenyl-compounds: phenylcitramic acid, $N.\overbrace{C^6H^5.C^6H^5}^{'''}\overbrace{O^4.H}^{''}.O$, is an example.

There are also certain nitrogenised acids, which either exist ready formed in nature, or are products of the decomposition of other compounds, which we may regard as amic acids. Thus glycocoll, $C^2H^5NO^2$, is the amic acid of glycollic acid, $C^2H^2O.H^2.O^2$, and may be written $NH^2.C^2H^2O.H.O$. Hippuric, choleic, and other acids may also be regarded as amic acids; but their constitution is as yet but imperfectly understood.

Amic acids are distinct monobasic acids: they form well defined salts, which are generally more soluble than those of the corresponding dibasic acids. They are mostly solid, crystalline, not volatile without decomposition. When heated, many of them lose the elements of 1 atom of water, and are converted into imides: others are decomposed into a dibasic anhydride and a primary amine. When boiled with mineral acids or alkalis, they mostly take up the elements of 1 atom of water, and regenerate the corresponding dibasic acid, and ammonia or a primary amine: in some cases, the mere boiling of their aqueous solutions suffices for this reaction; in others, fusion with solid potash is required:

$$\underset{\text{Phenylsuccinamic acid.}}{N\overbrace{H.C^6H^5.C^4H^4}^{'''}\overbrace{O^2.H}^{''}.O} + H^2O = \underset{\text{Succinic acid.}}{C^4\overset{''}{H}^4O^2.H^2.O^2} + \underset{\text{Phenylamine.}}{N.C^6H^5.H^2}$$

With nitrous acid, many amic acids regenerate the corresponding dibasic acid, with evolution of nitrogen:

$$\underset{\text{Malamic acid.}}{\overbrace{NH^2.C^4H^4}^{'''}\overbrace{O^3.H}^{''}.O} + NHO^2 = \underset{\text{Malic acid.}}{C^4\overset{''}{H}^4O^3.H^2.O^2} + N^2 + H^2O.$$

Like all decided acids, amic acids form ethers, *i. e.* salts of alcohol-radicles. These amic ethers are sometimes called *urethanes* (or amethanes), the former name having been applied to the earliest discovered, carbamic ether. They are formed by the incomplete action of ammonia on the ethers of dibasic acids:

$$\underset{\text{Oxalic ether.}}{C^2O^2.(C^2H^5)^2.O^2} + NH^3 = \underset{\text{Oxamic ether.}}{\overbrace{NH^2.C^2}^{'''}\overbrace{O^2.C^2H^5}^{''}.O} + \underset{\text{Alcohol.}}{C^2H^6.H.O}.$$

They are isomeric with alkalamic acids. When boiled with water, acids, or alkalis, they are converted into dibasic acids, alcohol, and ammonia:

$$\underset{\text{Oxamic ether.}}{NH^2.C^2O^2.C^2H^5.O} + 2H^2O = \underset{\text{Oxalic acid.}}{C^2O^2.H^2.O^2} + \underset{\text{Alcohol.}}{C^2H^5.H.O} + NH^3.$$

Excess of ammonia converts them into primary diamides (*q. v.*) — F. T. C.

Amic Bases. This name may be given to a class of bodies produced by the action of ammonia on the oxides, or chloro- or bromo- hydrates of polyatomic alcohol-radicles, and which are related to the polyatomic alcohols in the same way as the *amic acids* to the polyatomic acids. Their leading properties may be expressed by representing them as derived from a combination of the types NH^3 and H^2O.

The following bodies belonging to this class are already known:

$$\text{Anisamine, } C^8H^{11}NO = \left.\begin{matrix}(C^8\overset{''}{H}^8)\\H^3\end{matrix}\right\}\begin{matrix}N\\O\end{matrix};\ \text{type}\left\{\begin{matrix}H^3N\\H^2O\end{matrix}\right.$$

$$\left.\begin{array}{ll}
\text{Dianisamine, } C^{16}H^{19}NO^2 = & \left.\begin{matrix}(C^8\overset{''}{H}^8)^2\\H^3\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}\\
\text{Diglycolamine, } C^4H^{11}NO^2 = & \left.\begin{matrix}(C^2\overset{''}{H}^4)^2\\H^3\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}\\
\text{Glyceramine, } C^3H^9NO^2 = & \left.\begin{matrix}(C^3\overset{'''}{H}^5)\\H^4\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}\\
\text{Diglyceramine, } C^6H^{11}NO^2 = & \left.\begin{matrix}(C^3\overset{'''}{H}^5)^2\\H\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}
\end{array}\right\};\ \text{type}\left.\begin{matrix}H^3N\\2(H^2O)\end{matrix}\right\}$$

$$\text{Triglycolamine, } C^6H^{15}NO^3 = \left.\begin{matrix}(C^2\overset{''}{H}^4)^3\\H^3\end{matrix}\right\}\begin{matrix}N\\O^3\end{matrix};\ \text{type}\left.\begin{matrix}H^3N\\3(H^2O)\end{matrix}\right\}$$

AMIDES. Ammonia, NHHH, is capable, under certain circumstances, of exchanging each atom of its hydrogen successively for a metal, or for a compound radicle, acid or basic, — thus giving rise to a numerous class of compounds, all deriving from the same type, NHHH. The earliest discovered of these compounds were some of those in which *one* atom of hydrogen was thus replaced, *e. g.* NHHK, which was regarded as a compound of NH^2 (*amidogen*) with potassium, NH^2K, and called *amide* of potassium, analogous to the cyanide, CNK. In process of time, compounds came to be discovered, deriving from the type NHHH, in which 2 or 3 atoms of hydrogen were replaced by metals or compound radicles, to which the name amide in its original sense of a compound containing amidogen, NH^2, was plainly inapplicable; accordingly these compounds were designated by other names, *imides*, *nitriles*, &c., the introduction of which has caused considerable confusion, since they in no way indicate the common derivation of all these compounds.

Of late years attempts have been made, chiefly by Gerhardt, to remedy this confusion, by assigning to this numerous class of compounds a rational constitution which shall render evident their common derivation, and a nomenclature by which this constitution is at once expressed. These attempts have been attended with considerable success: and the classification adopted in this article is based upon that given by Gerhardt and Chiozza (Ann. Ch. Phys. [3] xlvi.), certain modifications being introduced where greater clearness seems thereby to be attained.

Since the hydrogen in ammonia is capable of being replaced either by acid- or by base-radicles (simple or compound), the first obvious division of the compounds thus formed is one based upon the *nature* of the radicle which has been substituted for hydrogen. These compounds thus fall into three great divisions:

1. Ammonias in which 1 or more atoms of hydrogen are replaced by an *acid*-radicle. To this division we propose to confine the name of amides. In the case of each individual member of the class, the generic name is preceded by a prefix, which indicates the particular acid radicle or radicles contained in the compound, *e. g.* acetamide $N.C^2H^3O.H^2$, diacetamide $N.(C^2H^3O)^2H$, &c.

2. Ammonias in which 1 or more atoms of hydrogen are replaced by *base*-radicles. This division we call amines. For examples of the nomenclature of individuals, we may take potassamine, $N.K.H^2$, ethylamine, $N.C^2H^5.H^2$, methylethylamine, $N.CH^3.C^2H^5.H$, &c.

3. Ammonias in which 2 or more atoms of hydrogen are replaced by *acid*- and *base*-radicles. This division we call alkalamides. Examples are ethylacetamide, $N.C^2H^5.C^2H^3O.H$, phenyldibenzamide, $N.C^6H^5.(C^7H^5O)^2$.

This primary classification enables us to perceive in compounds deriving from the type ammonia, NHHH, the same seriation of properties which was first pointed out by Gerhardt in the compounds deriving from the type oxide, OHH. As in the latter case, we have metallic oxides (bases) occupying the positive extreme, acids the negative extreme, while the middle place is filled up by salts, containing at once an acid- and a base-radicle; so in the former case, we have amines at the positive extreme, amides at the negative, and alkalamides between the two extremes.

A further ground for division is furnished by the fact that amides, amines, and alkalamides may derive from 1, 2, or 3 molecules of ammonia, according as they contain monatomic, diatomic, or triatomic radicles. Hence we have a further division of amides into

1. *Monamides* (or amides), deriving from 1 mol. ammonia NHHH.
2. *Diamides* „ „ 2 mols. „ $N^2H^2H^2H^2$.
3. *Triamides* „ „ 3 mols. „ $N^3H^3H^3H^3$.

The same subdivision applies to amines and alkalamides.

In each of these types, NHHH, $N^2H^2H^2H^2$, $N^3H^3H^3H^3$, one third, two thirds, or the whole of the hydrogen may be replaced by acid- or base-radicles: hence arises a further division of amides, diamides, and triamides into:

1. *Primary*, in wh. $\frac{1}{3}$ of the hydrogen is replaced, NAHH, $N^2A''H^2H^2$, $N^3A'''H^3H^3$.
2. *Secondary*, in wh. $\frac{2}{3}$ of the hydrogen is replaced, NA^2H, $N^2(A'')^2H^2$, $N^3(A''')^2H^3$.
3. *Tertiary*, in wh. the whole of the hydrogen is replaced, NA^3, $N^2(A'')^3$, $N^3(A''')^3$.

The same subdivision applies to amines, and (partially) to alkalamides.

Having thus indicated the general principles of classification which we adopt, we now proceed to the more detailed consideration of amides, amines, and alkalamides. It is not our purpose to give a complete list of these compounds, but merely to cite a sufficient number of them to illustrate our classification; and to enumerate the principal reactions by which the formation and decomposition of each group is effected.

AMIDES.

I. Monamides or Amides.

1. *Primary Amides.* They represent 1 molecule of ammonia, in which 1 atom of hydrogen is replaced by a monatomic acid-radicle (of a monobasic acid):

Acetamide	$N.C^2H^3O.H^2$
Propionamide	$N.C^3H^5O.H^2$
Benzamide	$N.C^7H^5O.H^2$
Cyanamide	$N.CN.H^2$
Sulphophenylamide	$N.C^6H^5SO^2.H^2$.

They differ from the ammonium-salt of their acids in containing the element of 1 atom of water less:

$$\underset{\text{Acet. amm.}}{C^2H^3O^2(NH^4)} - H^2O = \underset{\text{Acetamide.}}{N.C^2H^3O.H^2}$$

They are formed: 1. By the action of ammonia on anhydrides (Gerhardt).

$$\underset{\text{Benzoic anhyd.}}{(C^7H^5O)^2O} + NH^3 = \underset{\text{Benzoic acid.}}{C^7H^5O.H.O} + \underset{\text{Benzamide.}}{N.C^7H^5O.H^2}$$

2. By the action of ammonia (Liebig and Wöhler), or of carbonate of ammonium (Gerhardt) on the chlorides of acid-radicles:

$$\underset{\substack{\text{Chloride of}\\ \text{cyanogen.}}}{CNCl} + NH^3 = HCl + \underset{\text{Cyanamide.}}{N.CN.H^2}$$

This method is especially adapted to the formation of those amides which are insoluble or nearly so, in water.

3. By the action of ammonia on ethers:

$$\underset{\text{Acetic ether.}}{C^2H^3O.C^2H^5.O} + NH^3 = \underset{\text{Alcohol.}}{C^2H^6O} + \underset{\text{Acetamide.}}{N.C^2H^3O.H^2}$$

This method is peculiarly adapted to the formation of soluble amides. Glycerides, with ammonia, also yield an amide, and glycerin. (Berthelot.)

4. Some primary amides have special methods of formation: *e. g.* benzamide is formed by oxidising hippuric acid with peroxide of lead:

$$C^9H^9NO^3 + 3O = N.C^7H^5O.H^2 + 2CO^2 + H^2O$$

Primary amides are mostly solid and crystalline, easily fusible, neutral to test paper, volatile without decomposition. Some of them, *e. g.* acetamide, combine with acids: others *e. g.* benzamide, can exchange 1 atom of hydrogen for a metal, forming metallic salts, or alkalamides. They are generally soluble in alcohol or ether: some in water.

Reactions.—1. Boiled with acids or with alkalis (some with water), they take up H^2O and regenerate the acid and ammonia.

2. Treated with phosphoric anhydride, they lose H^2O, and yield the corresponding nitrile. The same reaction frequently takes place when they are passed in the state of vapour over caustic lime.

$$\underset{\text{Acetamide.}}{N.C^2H^3O.H^2} - H^2O = \underset{\substack{\text{Aceto-}\\ \text{nitrile.}}}{N.C^2H^3}$$

3. Treated with pentachloride of phosphorus, they behave as though they were oxides, yielding oxychloride of phosphorus, and the chloride of the radicle which they may be supposed to contain, if derived from the type HHO (Gerhardt):

$$\underset{\text{Benzamide.}}{C^7H^6N.H.O} + PCl^5 = PCl^3O + HCl + \underset{\substack{\text{Chloride of}\\ \text{benzamyl.}}}{C^7H^6N.Cl}$$

The chloride thus formed is readily decomposed by heat, frequently below 100° C. into hydrochloric acid and the corresponding nitrile, $C^2H^4NCl = HCl + N.C^2H^3$ (aceto-nitrile).

4. With nitrous acid they yield their corresponding acid, with evolution of nitrogen:

$$\underset{\text{Benzamide.}}{N.C^7H^5O.H^2} + NO^2H = NN + H^2O + \underset{\substack{\text{Benzoic}\\ \text{acid.}}}{C^7H^6O^2}$$

2. *Secondary Amides.*—They represent 1 molecule of ammonia, in which 2 atoms of hydrogen are replaced: (*a*) by 2 monatomic acid-radicles. (*b*) by 1 diatomic acid-radicle of a (dibasic acid).

a. $\mathrm{H^2}$ *are replaced by* 2 *monatomic radicles:*

Diacetamide	$\mathrm{N.(C^2H^3O)^2.H}$
Sulphophenyl-benzamide	$\mathrm{N.C^6H^5SO^2.C^7H^5O.H}$

They are formed: 1. By the action of chlorides of acid-radicles on primary amides, or their metallic salts (Gerhardt):

$$\mathrm{N.C^6H^5SO^2.H^2 + C^7H^5O.Cl = HCl + N.C^6H^5SO^2.C^7H^5O.H.}$$

Sulphophenylamide — Chloride of benzoyl. — Sulphophenyl-benzamide.

2. By action of dry hydrochloric acid on primary amides, at a high temperature (Strecker):

$$\mathrm{2(N.C^2H^3O.H^2) + HCl = NH^4Cl + N.(C^2H^3O)^2.H}$$

Acetamide. — Diacetamide.

These amides are readily soluble in ammonia. They exhibit acid properties, reddening litmus, and exchanging their remaining atom of hydrogen for a metal: the metallic salts thus formed dissolve in ammonia, producing compounds which Gerhardt regards as dialkalamides, but which, as they contain only monatomic radicles, it is perhaps preferable to regard as monalkalamides containing a compound ammonium:

$$\mathrm{N.C^6H^5SO^2.C^7H^5O.Ag. + NH^3 = N.C^6H^5SO^2.C^7H^5O.NAgH^3}\ \text{(monalkalamide).}$$
$$\text{or } \mathrm{N^2.C^6H^5SO^2.C^7H^5O.Ag.H^3}\ \text{(dialkalamide).}$$

According to Gerhardt (Ann. Ch. Phys. [3] liii.); pentachloride of phosphorus acts on secondary amides in the same way as on primary amides:

$$\mathrm{N.C^6H^5SO^2.C^7H^5O.H + PCl^5 = PCl^3O + HCl + N(C^7H^5)(C^6H^5SO^2)Cl}$$

Sulphophenylbenzamide. — Chloride of sulphophenyl-bexamidyl.

and the chloride formed is decomposed by heat:

$$\mathrm{N(C^7H^5)(C^6H^5SO^2)Cl = N.C^7H^5 + C^6HSO^2.Cl}$$

Benzonitrile. — Chloride of sulphophenyl.

b. $\mathrm{H^2}$ *are replaced by* 1 *diatomic radicle.* These are the bodies generally called *imides*, being regarded as containing *imidogen*, NH. Though we reject this view of their constitution, we retain the name for convenience sake.

Carbimide (cyanic acid)	$\mathrm{N.(CO)''.H}$
Succinimide	$\mathrm{N.(C^4H^4O^2)''.H}$
Camphorimide	$\mathrm{N.(C^{10}H^{14}O^2)''.H.}$

They differ from the acid ammonium-salts of their acids by containing 2 atoms of water less:

$$\mathrm{C^4H^4O^4(NH^4)H - 2H^2O = N.C^4H^4O^2.H}$$

Acid succinate of ammonium. — Succinimide.

They are formed much more easily than secondary amides (*a*):

1. By heating the acid ammonium-salts of dibasic acids.
2. By heating primary diamides:

$$\mathrm{N^2.C^4H^4O^2.H^4 = N.C^4H^4O^2.H + NH^3.}$$

Succinamide. — Succinimide.

3. By heating amic acids (Laurent):

$$\mathrm{N.C^{10}H^{14}O^2.H^2.H.O = H^2O + N.C^{10}H^{14}O^2.H}$$

Camphoramic acid. — Camphorimide.

4. By heating dibasic anhydrides with ammonia:

$$\mathrm{C^4H^4O^2.O + NH^3 = H^2O + N.C^4H^4O^2.H}$$

Succinic anhydride. — Succinimide.

Imides possess decided acid properties, and readily exchange their basic hydrogen for a metal; carbimide in fact is identical with cyanic acid.

Reactions.—1. Boiled with acids or alkalis, they take up $\mathrm{2H^2O}$ and regenerate the dibasic acid and ammonia:

$$\mathrm{N.C^4H^4O^2.H + 2H^2O = C^4H^4O^4.H^2 + NH^3.}$$

Secondary amides (*a*) also exhibit this reaction.

2. Boiled with dilute ammonia, they form the ammonium-salt of the corresponding amic acid:

$$\mathrm{N.C^4H^4O^2.H + NH^4.HO = N.C^4H^4O^2.H^2.NH^4.O}$$

Succinamate of amm.

3. *Tertiary Amides.*—They represent 1 molecule of ammonia, in which all the hydrogen is replaced: (*a*) by 3 monatomic, (*b*) by 1 diatomic and 1 monatomic, (*c*) by 1 triatomic, acid-radicle:

a. H^3 *are replaced by* 3 *monatomic radicles:*

Sulphophenyl-benzoyl-acetamide . . $N.C^6H^5SO^2.C^7H^5O.C^2H^3O$.

b. H^3 *are replaced by* 1 *diatomic and* 1 *monatomic radicle:*

Sulphophenyl-succinamide . . . $N.C^6H^5SO^2.(C^4H^4O^2)''$.

They are formed by the action of chlorides of acid-radicles on the metallic salts of secondary amides (tertiary alkalamides):

$$N.C^6H^5SO^2.C^7H^5O.Ag + C^2H^3O.Cl = AgCl + N.C^6H^5SO^2.C^7H^5O.C^2H^3O$$
$$N.C^4H^4O^2.Ag + C^6H^5SO^2.Cl = AgCl + N.C^4H^4O^2.C^6H^5SO^2.$$

Their reactions are but little known. Boiled with dilute ammonia, the amides of class (*b*) give the ammonium-salt of the corresponding amic acid:

$$\underset{\text{Sulphophenyl-succinamide.}}{N.C^4H^4O^2.C^6H^5SO^2} + NH^4.H.O = \underset{\text{Sulphophenyl-succinamate of ammonium.}}{NC^4H^4O^2.C^6H^5SO^2.H.NH^4.O.}$$

c. H^3 *are replaced by* 1 *triatomic radicle.* To this group, by their reactions and mode of formation, the following mineral compounds belong:

$N.(PO)'''$.	Gerhardt's biphosphamide	(phosphorylamide)	$= PO^4(NH^4)H^2 - 3H^2O$
$N.N.'''$.	Free nitrogen	(Nitroso-nitrile)	$= NO^2.NH^4 - 2H^2O$
$N.(NO)'''$.	Nitrous oxide.	(Nitro-nitrile)	$= NO^3.NH^4 - 2H^2O.$

II. **Diamides.**

1. *Primary Diamides.*—They represent 2 molecules of ammonia in which 2 atoms of hydrogen are replaced by 1 diatomic acid-radicle.

Sulphamide	$N^2.(SO^2)''.H^4$
Oxamide	$N^2.(C^2O^2)''.H^4$
Succinamide	$N^2.(C^4H^4O^2)''.H^4$
Carbamide (urea)	$N^2.(CO)''.H^4$

They differ from the normal ammonium-salts of their acids in containing 2 atoms of water less:

$$\underset{\text{Oxalate of ammonium.}}{C^2O^4(NH^4)^2} - 2H^2O = \underset{\text{Oxamide.}}{N^2.C^2O^2.H^4}$$

They are formed—1. By the action of ammonia on ethers:

$$\underset{\text{Oxalic ether.}}{C^2O^4(C^2H^5)^2} + 2NH^3 = 2C^2H^6O + \underset{\text{Oxamide.}}{N^2.C^2O^2.H^4}$$

2. By the action of ammonia on chlorides of acid-radicles:

$$\underset{\text{Chloride of succinyl.}}{C^4H^4O^2.Cl^2} + 2NH^3 = 2HCl + \underset{\text{Succinamide.}}{N^2.C^4H^4O^2.H^4}$$

3. By heating normal ammonium-salts of dibasic acids (Dumas).
4. By the action of ammonia on imides (Wöhler):

$$\underset{\text{Carbimide.}}{N.CO.H} + NH^3 = \underset{\text{Carbamide.}}{N^2.CO.H^4}$$

By the action of ammonia on dibasic anhydrides, not primary diamides, but amic acids, are generally formed.

Many primary diamides exhibit decidedly basic properties, combining with acids and forming definite salts: *e.g.* urea, asparagine, &c.

Reactions.—1. Many of them, when heated, evolve ammonia and yield imides. 2. Boiled with acids or alkalis, they take up $2H^2O$, and regenerate the acid and ammonia:

$$N^2.C^2O^2.H^4 + 2H^2O = C^2O^4.H^2 + 2NH^3.$$

3. With nitrous acid, they regenerate their dibasic acid, with evolution of nitrogen (Piria, Malaguti):

$$\underset{\text{Oxamide.}}{N^2.C^2O^2.H^4} + 2NO^2H = 2NN + \underset{\text{Oxalic acid.}}{C^2O^4.H^2} + 2H^2O.$$

Intermediate between primary and secondary diamides must be classed the bodies lately discovered by Zinin (Ann. Ch. Phys. [3] xliv. 57), which he describes as ureas, in which 1 atom of hydrogen is replaced by an acid radicle. They are of course diamides, in which 3 atoms of hydrogen are replaced, 2 by a diatomic, and 1 by a monatomic radicle.

Acetocarbamide (acetyl-urea) . .	$N^2.CO.C^2H^3O.H^3$
Benzocarbamide (benzoyl-urea) . .	$N^2.CO.C^7H^5O.H^3$.

They are formed by the action of chlorides of acid-radicles on urea:

$$\underset{\text{Carbamide.}}{N^2.CO.H^4} + \underset{\text{Chloride of acetyl.}}{C^2H^3O.Cl} = HCl + \underset{\text{Acetocarbamide.}}{N^2.CO.C^2H^3OH^3}$$

Attempts to replace more than 1 atom of hydrogen in urea by an acid-radicle, have hitherto failed.

These bodies are crystallisable, and do not combine with acids. They are not volatile, being decomposed by heat into cyanuric acid and a primary amide:

$$\underset{\text{Acetocarbamide.}}{3(N^2.CO.C^2H^3O.H^3)} = \underset{\text{Cyanuric acid.}}{C^3N^3O^3H^3} + \underset{\text{Acetamide.}}{3(N.C^2H^3O.H^2)}$$

Here too must be placed Gerhardt's phosphamide (Ann. Ch. Phys. [3] xviii.)—$N^2.(PO)'''.H^3$, formed by saturating pentachloride of phosphorus with ammonia, and boiling with water:

$$PCl^5 + 2NH^3 + H^2O = N^2.PO.H^3 + 5HCl.$$

It differs from monacid phosphate of ammonium by the elements of 3 atoms of water:

$$PO^4(NH^4)^2H - 3H^2O = N^2.PO.H^3.$$

2. *Secondary Diamides.*—They represent 2 molecules of ammonia, in which 4 atoms hydrogen are replaced by 2 diatomic acid-radicles, or by 1 diatomic and 2 monatomic radicles.

None of these have yet been formed. (Handwb.)

3. *Tertiary Diamides.*—They represent 2 molecules of ammonia, in which all the hydrogen is replaced by acid-radicles, one of which at least must be dibasic:

Trisuccinamide	$N^2.(C^4H^4O^2)^3$
Succinyl-disulphophenyl-dibenzamide .	$N^2.(C^4H^4O^2).(C^6H^5SO^2)^2.(C^7H^5O)^2$.

They are formed by the action of chlorides of acid-radicles on the silver-salts of secondary amides:

$$\underset{\text{Argentosuccinamide.}}{2(N.C^4H^4O^2.Ag)} + \underset{\text{Chloride of succinyl.}}{C^4H^4O^2.Cl^2} + \underset{\text{Trisuccinamide.}}{N^2.(C^4H^4O^2)^3} + 2AgCl.$$

III. **Triamides.**

1. *Primary Triamides.*—They represent 3 molecules of ammonia, in which 3 atoms of hydrogen are replaced by a triatomic acid-radicle:

Phosphamide	$N^3.(PO)'''.H^6$.
Citramide	$N^3.(C^6H^5O^4)'''.H^6$.

They differ from the normal ammonium-salts of their acids by containing $3H^2O$ less:

$$\underset{\text{Citrate of amm.}}{C^6H^5O^7(NH^4)^3} - 3H^2O = \underset{\text{Citramide.}}{N^3.C^6H^5O^4.H^6}.$$

Phosphamide is formed by the action of ammonia on oxychloride of phosphorus: $POCl^3 + 6NH^3 = 3NH^4Cl + N^3.PO.H^6$. (Schiff. Ann. Ch. Pharm. ci. 300.)

Citramide is formed by the action of ammonia on citric ether:

$$\underset{\text{Citric ether.}}{C^6H^5O^4.(C^2H^5)^3.O^3} + 3NH^3 = \underset{\text{Citramide.}}{N^3.C^6H^5O^4.H^6} + \underset{\text{Alcohol.}}{3(C^2H^5.H.O)}$$

Heated with acids or alkalis, they take up $3H^2O$, and regenerate their acid and ammonia.

2. *Secondary Triamides.*
3. *Tertiary Triamides.*

They represent respectively 3 mols. ammonia, in which two-thirds and the whole of the hydrogen is replaced by acid-radicles, one of which at least must be triatomic.

No member of either of these groups has yet been formed.

Gerhardt (Chim. org. iv. p. 767) regards melam, $C^3H^6N^6$, as a primary triamide, $N^3.C^3N^3.H^6$: and indeed we may admit the existence of a triatomic radicle, C^3N^3, and regard hydrocyanic acid as tribasic, $C^3N^3H^3$: otherwise such compounds as ferrocyanide of potassium, $C^6N^6FeK^2$, present the anomaly of bodies deriving from a triple type (H^3Cl^3), and yet containing only monatomic radicles.

AMINES.

I. **Monamines** or **Amines.**

1. *Primary Amines.*—They represent 1 molecule of ammonia, in which 1 atom of hydrogen is replaced by a monatomic base-radicle, whether a metal or an organic radicle. They are sometimes called *amide-bases.*

Potassamine	$N.K.H^2$
Platinamine	$N.Pt.H^2$.
Methylamine	$N.CH^3.H^2$
Ethylamine	$N.C^2H^5.H^2$
Phenylamine (Aniline) . . .	$N.C^6H^5.H^2$.

Primary amines containing metals are generally obtained by the action of ammonia on the metal or its oxide. Zincamine is formed by the action of ammonia on zinc-ethyl: $ZnC^2H^5 + NH^3 = H.C^2H^5 + NZnH^2$.—When treated with water or acids, they are mostly decomposed, like primary amides, yielding ammonia and the hydrate of the metal.

Primary amines containing organic radicles are formed:

1. By action of ammonia on hydrobromic or hydriodic ethers (Hofmann):

$$\underset{\text{Iodide of methyl.}}{CH^3I} + NH^3 = HI + \underset{\text{Methylamine.}}{N.CH^3.H^2}$$

2. By action of potash on cyanic or cyanuric ethers (Wurtz):

$$\underset{\text{Cyanate of methyl.}}{N.CO.CH^3} + K^2H^2O^2 = \underset{\text{Carbonate of potassium.}}{CO.K^2.O^2} + \underset{\text{Methyl-amine.}}{N.CH^3.H^2}$$

3. By action of reducing agents, viz. alkaline hydrosulphates (Zinin), acetate of iron (Béchamp), on certain nitro-conjugated hydrocarbons:

$$\underset{\text{Nitrobenzene.}}{C^6H^5(NO^2)} + H^6 = 2H^2O + \underset{\text{Phenylamine.}}{N.C^6H^5.H^2}$$

Their formation is also observed in the dry distillation of several nitrogenised organic substances. (For the various modes of formation of monamines in general, primary, secondary, and tertiary, see Kékulé, Lehrb. d. org. Chemie, pp. 451—456.)

These primary amines are mostly liquid, boiling at a low temperature, and volatile without decomposition. They strikingly resemble ammonia in all their properties: like it they have a strong alkaline reaction; they combine directly with acids, forming salts, whence they are expelled by the fixed alkalis; they precipitate metallic solutions; with anhydrides, ethers, and chlorides of acid-radicles, they react precisely like ammonia (forming alkalamides, *q. v.*), and with hydriodic ethers they form diamides. With nitrous acid they yield nitrous ether or alcohol, with evolution of nitrogen:

$$\underset{\text{Ethylamine.}}{N.C^2H^5.H^2} + 2NO^2H = NN + 2H^2O + \underset{\text{Nitrous ether.}}{NO^2.C^2H^5}$$

$$\underset{\text{Phenylamine.}}{N.C^6H^5.H^2} + NO^2H = NN + H^2O + \underset{\text{Phenylic alcohol.}}{C^6H^6O}$$

In this group must also be included those amines whose radicle contains chlorine, bromine, iodine, or nitryl (NO^2), substituted for 1, 2, or 3 atoms of hydrogen: *e. g.* Dichlorethylamine, $N.C^2H^3Cl^2.H^2$, Chlorophenylamine, $N.C^6H^4Cl.H^2$, Dichlorphenylamine, $N.C^6H^3Cl^2.H^2$, Trichlorphenylamine, $N.C^6H^2Cl^3.H^2$, Nitrophenylamine, $N.C^6H^4.(NO^2).H^2$, &c. Their alkaline properties are less marked, the greater the number of atoms of chlorine, &c. they contain. They are formed mostly either by the direct action of chlorine, &c. on amines, or by the metamorphoses of other conjugated compounds. Nitrophenylamine is formed by the reduction of dinitrobenzene by hydrosulphate of ammonium, just as phenylamine results from the reduction of nitrobenzene by the same agent.

2. *Secondary Amines.*—They correspond to 1 molecule of ammonia, in which 2 atoms of hydrogen are replaced by two monatomic base-radicles. They are sometimes called *Imide-bases.*

Dimethylamine	$N.(CH^3)^2.H$.
Methylethylamine	$N.CH^3.C^2H^5.H$.
Ethylphenylamine	$N.C^2H^5.C^6H^5.H$.

They are formed by the action of hydriodic ethers on primary amines:

$$\underset{\text{Methylamine.}}{N.CH^3.H^2} + \underset{\text{Iodide of ethyl.}}{C^2H^5I} = HI + \underset{\text{Methylethylamine.}}{N.CH^3.C^2H.^5H}$$

In properties and reactions, they closely resemble primary amines: but they are in general less volatile.

We must also regard as secondary amines two alkaloids, which have not yet been formed artificially:

Piperidine	$N.(C^5H^{10})''.H.$
Conine	$N.(C^8H^{14})''.H.$

The chemical relations of the radicles contained in these compounds are as yet unknown to us; and we cannot determine whether they are single diatomic radicles, or whether they are made up of two monatomic radicles.

3. *Tertiary Amines.*—They represent 1 molecule of ammonia, in which all the hydrogen is replaced: (*a*) by 3 monatomic, (*b*) by 1 diatomic and 1 monatomic, (*c*) by 1 triatomic base-radicle.

a. H^3 are replaced by 3 monatomic radicles (Nitrile-bases).

Tripotassamine	$N.K^3$
Trimercuramine	$N.Hg^3$
Trimethylamine	$N.(CH^3)^3$
Methyldiethylamine	$N.CH^3.(C^2H^5)^2.$
Methylethylphenylamine	$N.CH^3.C^2H^5.C^6H^5.$

Those containing organic radicles are formed—1. By the action of hydriodic ethers on secondary amines:

$$\underset{\text{Dimethylamine.}}{N.(CH^3)^2.H} + \underset{\text{Iodide of ethyl.}}{C^2H^5.I} = HI + \underset{\text{Dimethylethylamine.}}{N.(CH^3)^2.C^2H^5.}$$

2. By the distillation of the salts of organic ammonium-bases:

$$\underset{\text{Hydrate of tetrethylium.}}{N.(C^2H^5)^4.H.O} = \underset{\text{Triethylamine.}}{N.(C^2H^5)^3} + \underset{\text{Ethylene.}}{C^2H^4} + H^2O$$

$$\underset{\text{Iodide of tetrethylium.}}{N(C^2H^5)^4.I} = N.(C^2H^5)^3 + C^2H^5I.$$

3. By action of ethylate of potassium on cyanic ether:

$$\underset{\text{Cyanate of ethyl.}}{N.CO.C^2H^5} + \underset{\text{2 mol. ethylate of potassium.}}{(C^2H^5)^2.K^2.O^2} = \underset{\text{Triethylamine.}}{N.(C^2H^5)^3} + \underset{\text{Carbonate of potassium.}}{CO.K^2.O^2}$$

This reaction is analogous to that of hydrate of potassium on cyanic ethers. (See PRIMARY AMINES.)

Tertiary amines are generally similar in properties to primary and secondary amines: they are less volatile than either. They are however distinguished by one important reaction, which at the same time exhibits in the strongest light their analogy with the type from which they are derived. When acted upon by hydriodic ethers, direct combination takes place, an iodide of an organic ammonium-base being formed:

$$N.(C^2H^5)^3 + C^2H^5.I = \underset{\text{Iodide of tetrethylium.}}{N(C^2H^5)^4.I}$$

These iodides are usually crystalline, soluble in water and alcohol: when treated with oxide of silver, they yield iodide of silver, and a hydrate of the ammonium-base:

$$2[N(C^2H^5)^4.I] + Ag^2O + H^2O = 2AgI + 2[\underset{\text{Hydrate of tetrethylium.}}{N(C^2H^5)^4.H.O}]$$

These hydrates are crystalline and soluble in water: they are powerful alkalis; in some reactions they resemble the fixed alkalis, liberating ammonia from ammoniacal salts, and decomposing ethers into acid and alcohol. Precisely, therefore, as ammonia (nitride of hydrogen) NH^3, combines with hydriodic acid (iodide of hydrogen) HI, forming iodide of ammonium, NH^4I; so triethylamine (nitride of ethyl) $N(C^2H^5)^3$, combines with iodide of ethyl, C^2H^5I, forming iodide of tetrethylium, $N(C^2H^5)^4I$. Just as we have the hypothetical compound ammonium, NH^4, playing the part of potassium, sodium, and other metals, and replacing the basic hydrogen in acids to form salts—so we have the hypothetical compound tetrethylium, $N(C^2H^5)$, performing precisely the same metallic functions. The analogy could not be more complete.

b. H^3 are replaced by 1 diatomic and 1 monatomic radicle: Hofmann's ethylenephenylamine, $N.(C^2H^4)''.C^6H^5.$

c. H^3 are replaced by 1 triatomic radicle (Nitriles).

Acetonitrile (cyanide of methyl)	$N.(C^2H^3)'''$
Propionitrile (cyanide of ethyl)	$N.(C^3H^5)'''$
Benzonitrile (cyanide of phenyl)	$N.(C^7H^5)'''$.

They are formed—1. By the action of heat or dehydrating agents (*e.g.* phosphoric anhydride) on ammoniacal salts of monobasic acids:

$$\underset{\text{Acetate of amm.}}{C^2H^3O^2.NH^4} - 2H^2O = \underset{\text{Acetonitrile.}}{N.C^2H^3}.$$

These nitriles differ from primary amides in containing H^2O less.

2. By the action of cyanide of potassium on sulphate of ethyl and potassium (or a homologous salt), or on hydriodic ethers:

$$\underset{\substack{\text{Sulphate of ethyl}\\\text{and potassium.}}}{SO^2.(C^2H^5).K.O^2} + CN.K = \underset{\substack{\text{Sulphate of}\\\text{potassium.}}}{SO^2.K^2.O^2} + \underset{\substack{\text{Cyanide of}\\\text{ethyl or}\\\text{propio-nitrile.}}}{CN.C^2H^5}$$

This mode of formation shows that nitriles may also be regarded as cyanides ($N.C^2H^3 = CN.CH^3$), deriving from the type ClH: and it is in this light that they are usually considered. But, if we consider their formation from ammoniacal salts, and their behaviour when boiled with acids or alkalis, when they regenerate their acid and ammonia,—$NC^2H^3 + KHO + H^2O = C^2H^3O^2K + NH^3$,—we may fairly regard them as deriving from the same type with amides. And we are led to consider them as amines rather than as amides, by the fact that, in one of them at least, the radicle is clearly a basic one; in propio-nitrile, $N.C^3H^5$, the radicle is *glyceryl*, the triatomic radicle of the triatomic alcohol, glycerin, $C^3H^5.H^3.O^3$. Moreover, that they resemble amines in the property of combining with acids, is shown by the compounds which Gerhardt obtained by the action of pentachloride of phosphorus on primary amides (*q. v.*) $C^7H^6NCl = N.C^7H^5 + HCl$.

In order to show the connection between nitriles and the acids from whose ammonium-salts they are formed, *e.g.* of acetonitrile $N.C^2H^3$, with acetic acid, $C^2H^4O^2$, and acetic compounds generally, it may be observed that acetic compounds may be represented as containing the triatomic radicle C^2H^3. Thus acetic acid may be written $(C^2H^3)'''.H.O^2$, deriving from the double type H^4O^2: acetamide, $N.H.C^2H^3.H.O$, deriving from the double type $NH^3 + H^2O$: chloride of acetyl, $Cl.C^2H^3.O$, deriving from the double type $ClH + H^2O$: acediamine, $N^2.C^2H^3.H^3$, deriving from the double type N^2H^6.

We have already seen that, when an amine which contains any replaceable hydrogen (primary or secondary amines), is treated with the iodide of an organic basic radicle, the result is the replacement of the basic hydrogen by the organic radicle: but that when tertiary amines, in which all the basic hydrogen is already replaced, are similarly treated, the result is a direct combination of the iodide with the amine. Hence we are enabled to class as tertiary amines many natural organic alkalis, which combine directly with organic iodides; of whose constitution, as they cannot be formed artificially, we should otherwise be ignorant. Among these are the following homologous alkalis, obtained by the dry distillation of animal matter:

Pyridine	$N.C^5H^5$
Picoline	$N.C^6H^7$
Lutidine	$N.C^7H^9$
Collidine	$N.C^8H^{11}$
Parvoline	$N.C^9H^{13}$.

Also the numerous vegetable alkalis or alkaloids (quinine, strychnine, morphine, &c.), which have been extracted from plants. The majority of these latter compounds contain oxygen-radicles: as many of them contain 2 atoms of nitrogen, it is possible that they must be regarded as diamines. How many radicles they may contain, we have as yet no means of determining.

II. **Diamines.**

1. *Primary Diamines.* } They represent 2 molecules of ammonia, in which
2. *Secondary Diamines.* } 2 and 4 atoms of hydrogen are replaced by 1 and 2 diatomic base-radicles. The only representatives of these groups are the compounds lately obtained by Hofmann, by the action of bromide of ethylene on ammonia; they contain the diatomic radicle ethylene, C^2H^4:

Ethylenamine	$N^2.\overset{\prime\prime}{(C^2H^4)}.H^4$
Diethylenamine	$N^2.\overset{\prime\prime}{(C^2H^4)}{}^2.H^2$.

They are thus formed:

$$\underset{\text{Bromide of ethylene.}}{C^2H^4.Br^2} + N^2H^6 = 2HBr + \underset{\text{Ethylenamine.}}{N^2.\overset{''}{C^2}H^4.H^4}$$

$$2C^2H^4Br^2 + N^2H^6 = 4HBr + \underset{\text{Di-ethylenamine.}}{N^2.(\overset{''}{C^2}H^4)^2.H^2}$$

Intermediate between secondary and tertiary diamines, is Hofmann's diphenylformylamine, $N^2.(C^6H^5)^2.CH.H$, obtained by the action of chloroform on phenylamine; $2(N.C^6H^5.H^2) + CHCl^3 = N^2.(C^6H^5)^2.CH.H + 3HCl$.

3. *Tertiary Diamines.*—They represent 2 mols. ammonia, in which all the hydrogen is replaced; (*a*) by 3 diatomic, (*b*) by 2 diatomic, and 2 monatomic base-radicles.

a. Hofmann has obtained triethylenamine, $N^2.(\overset{''}{C^2}H^4)^3$, by the reaction:

$$3C^2H^4Br^2 + N^2H^6 = 6NHBr + N^2.(C^2H^4)^3.$$

In this group may be classed the compounds known as *hydramides:*

Benzhydramide (hydrobenzamide)	$N^2.(\overset{''}{C^7}H^6)^3$
Salhydramide	$N^2.(\overset{''}{C^7}H^6O)^3$.

They are obtained by the action of ammonia on certain aldehydes:

$$\underset{\text{Benzoic aldehyde.}}{3C^7H^6O} + N^2H^6 = 3H^2O + \underset{\text{Benzhydramide.}}{N^2.(C^7H^6)^3}$$

They are crystalline, insoluble in water, soluble in alcohol, not volatile without decomposition. They are decomposed by hydrosulphuric acid, yielding sulph-aldehydes. (Cahours.)

$$N^2.(C^7H^6)^3 + 3H^2S = N^2H^6 + 3C^7H^6S.$$

The view here taken of the constitution of hydrobenzamide is confirmed by its formation from chlorobenzol, $C^7H^6Cl^2$, and ammonia (Engelhardt), by the manner in which iodide of ethyl reacts upon it (Borodine), and by the existence of a number of bodies obtained from chlorobenzol, which may be regarded as the methylate, ethylate, acetate, valerate, benzoate, &c. of the diatomic radicle C^7H^6.

b. Hofmann has obtained diethylene-diphenylamine, $N^2.(C^2H^4)^2(C^6H^5)^2$, by the action of chloride of ethylene on phenylamine:

$$2(C^2H^4.Cl^2) + 2(N.C^6H^5.H^2) = 4HCl + N^2.(C^2H^4)^2.(C^6H^5)^2.$$

Here too should probably be classed cyanogen, or oxalo-nitrile, N^2C^2, which bears the same relation to normal oxalate of ammonium that acetonitrile does to acetate of ammonium:

$$C^2O^4.(NH^4)^2 - 4H^2O = N^2C^2.$$
$$C^2H^3O^2.NH^4 - 2H^2O = N.C\ H^3;$$

also nitride of boron, N^2B^2.

III. **Triamines.**

1. Primary.
2. Secondary.
3. Tertiary.

They represent 3 molecules of ammonia, in which 3, 6, or 9 atoms of hydrogen are replaced by 1, 2, or 3 triatomic basic radicles.

The only triamine known is Frankland and Kolbe's *Cyanethine*, $C^9H^{15}N^3$, which, according to Hofmann, should be regarded as triglycerylamine, $N^3.(\overset{'''}{C^3}H^5)^3$, a tertiary triamine.

Tetramines and **Pentamines.**—We know but little of any complex ammonia-molecules of a higher order than the triamines; nevertheless it appears that under certain circumstances, four, five, or even a greater number of atoms of ammonia are capable of coalescing into a complex molecule.

The only well characterised tetramines with which we are acquainted are *glycosine*, $N^4.C^6H^6$, a product of the action of ammonia on glyoxal, which may be regarded as $N^4(\overset{'''}{C^2}H^2)^3$, and *hexamethylenamine*, $N^4.C^6H^{12}$, formed by the action of ammonia on dioxymethylene, which may be written $N^4(C^2\overset{''''}{H^4})^3$ (Buttlerow, Bullet. de la Soc. Chim. de Paris, i. 221.) There are also some natural bases containing 4 at. nitrogen, *e.g.* *caffeine*, $C^8H^{10}N^4O^2$, and *theobromine*, $C^7H^8N^4O^2$, but we know nothing of the radicles which they contain.

Pentamines appear to be produced by the action of ammonia on certain metallic oxides. Some of the ammoniacal compounds of cobalt appear to be of this character; but further investigation is necessary to give accurate ideas of their constitution.

PHOSPHINES, ARSINES, STIBINES.—In connection with the basic derivatives of ammonium, we must also mention a class of bodies derived from phosphoretted hydrogen, PH^3, arsenetted hydrogen, AsH^3, and antimonetted hydrogen, SbH^3, by the substitution of alcohol-radicles for the hydrogen. All the compounds thus formed, are basic, like the alcoholic derivatives of ammonia, and form salts of exactly analogous character. Up to the present time, however, the only phosphines, arsines, and stibines, that have been obtained are those in which the whole of the hydrogen in the type is replaced by an equivalent quantity of an alcohol-radicle, *e. g.*:

Triethylphosphine	$P(C^2H^5)^3$
Trimethystibine	$Sb(CH^3)^3$

These bases have not yet been obtained by direct substitution from the hydrides of phosphorus, arsenic and antimony; but they are produced, either by submitting a metallic compound of phosphorus, arsenic, or antimony to the action of the iodides, bromides or chlorides of the alcohol radicles, *e.g.*:

$$\underset{\text{Trisodic arsenide.}}{Na^3As} + \underset{\text{Iodide of ethyl.}}{3C^2H^5I} = 3NaI + \underset{\text{Triethyl-arsine.}}{As(C^2H^5)^3}$$

or, better in most cases, by treating the metallic compounds of the alcohol-radicles with the iodides, bromides, and chlorides of phosphorus, arsenic and antimony; thus,

$$\underset{\text{Zinc-methyl.}}{3CH^3Zn} + PCl^3 = 3ZnCl + \underset{\text{Trimethyl-phosphine.}}{P(CH^3)^3}$$

These compounds, when treated with the bromides or iodides of the alcohol-radicles, behave exactly like the corresponding nitrogen-bases, producing the bromides or iodides of bases containing 4 at. of the alcohol-radicle and belonging to the ammonium type: *e. g.*:

$$\underset{\text{Triethyl-phosphine.}}{P(C^2H^5)^3} + \underset{\text{Iodide of ethyl.}}{C^2H^5I} = \underset{\text{Iodide of ethylphosphonium.}}{P(C^2H^5)^4I}$$

$$\underset{\text{Trimethyl-phosphine.}}{P(CH^3)^3} + C^2H^5I = \underset{\text{Iodide of trimethyl-ethyl-phosphonium.}}{P(CH^3)^3(C^2H^5)I.}$$

The phosphines treated with diatomic bromides (dibromide of ethylene, for example), yield, among other products, the monobromide of a phosphonium-molecule, in which the fourth atom of hydrogen is replaced by a brominated alcohol-radicle; thus triethylphosphine, treated with dibromide of ethylene, yields the *monobromide of bromethyl-triethyl-phosphonium*:

$$P(C^2H^5)^3 + C^2H^4Br^2 = P[(C^2H^4Br)'.(C^2H^5)^3]Br.$$

(See AMMONIUM-BASES.)

ALKALAMIDES.

I. **Monalkalamides** or **Alkalamides.**

1. *Secondary Alkalamides.*—They represent 1 vol. ammonia in which 2 atoms of hydrogen are replaced, one by an acid, the other by a base radicle.

Mercurobenzamide	$N.Hg.C^7H^5O.H.$
Argentosulphophenylamide	$N.Ag.C^6H^5SO^2.H.$
Ethylformamide	$N.C^2H^5.CHO.H.$
Ethylacetamide	$N.C^2H^5.C^2H^3O.H.$
Phenylbenzamide (benzanilide)	$N.C^6H^5.C^7H^5O.H.$
Ethylcyanamide	$N.C^2H^5.CN.H.$

Those which contain metals are formed by the action of primary amides on metallic oxides; they are decomposed by most acids, which remove their metal. Those containing silver are readily attacked by chlorides of acid-radicles, yielding secondary amides and chloride of silver:

$$\underset{\text{Argentosulphophenylamide.}}{N.Ag.C^6HSO^2.H} + \underset{\text{Chloride of benzoyl.}}{C^7H^5O.Cl} = AgCl + \underset{\text{Sulphophenylbenzamide.}}{N.C^6H^5SO^2.C^7H^5O.H.}$$

Those containing organic base-radicles, are formed by the same reactions as primary amides, a primary amine being substituted for ammonia:

1. By action of primary amines on monobasic anhydrides (Gerhardt):

$$\underset{\text{Phenylamine.}}{N.C^6H^5.H^2} + \underset{\text{Benzoic anhydride.}}{(C^7H^5O)^2O} = \underset{\text{Benzoic acid.}}{C^7H^5O.H.O} + \underset{\text{Phenylbenzamide.}}{N.C^6H^5.C^7H^5O.H.}$$

2. By action of primary amines on chlorides of acid-radicles (Gerhardt):

$$\underset{\text{Methylamine.}}{N.CH^3.H^2} + \underset{\text{Chloride of acetyl.}}{C^2H^3O.Cl} = HCl + \underset{\text{Methylacetamide.}}{N.CH^3.C^2H^3O.H}$$

3. By action of primary amines on ethers:

$$\underset{\text{Ethylamine.}}{N.C^2H^5.H^2} + \underset{\text{Acetic ether.}}{C^2H^3O.C^2H^5.O} = \underset{\text{Alcohol.}}{C^2H^5.H.O} + \underset{\text{Ethylacetamide.}}{N.C^2H^5.C^2H^3O.H.}$$

4. By action of monobasic acids on cyanic ethers (Wurtz):

$$\underset{\text{Formic acid.}}{CHN.H.O} + \underset{\text{Cyanate of ethyl.}}{N.C^2H^5.CO} = \underset{\text{Carbonic anhyd.}}{CO.O} + \underset{\text{Ethyl-formamide.}}{N.C^2H^5.CHO.H.}$$

They are crystalline, and generally do not combine with acids; boiled with acids or alkalis, they take up H^2O, and regenerate their acid and primary amine:

$$\underset{\text{Phenylacetamide.}}{N.C^6H^5.C^2H^3O.H} + H^2O = \underset{\text{Phenylamine.}}{N.C^6H^5.H^2} + \underset{\text{Acetic acid.}}{C^2H^3O.H.O.}$$

Those containing cyanogen act as weak alkalis, forming with concentrated acids compounds which are decomposed by water. By heat they are decomposed in rather a peculiar manner, yielding a tertiary alkalamide, and a kind of intermediate dialkalamide, which contains only monatomic radicles:

$$\underset{\text{Ethylcyanamide}}{3(N.C^2H^5.CN.H)} = \underset{\text{Diethylcyanamide.}}{N.(C^2H^5)^2.CN} + \underset{\text{Ethyldicyandiamide.}}{N^2.C^2H^5.(CN)^2.H^3}$$

According to Gerhardt (Ann. Ch. Phys. [3] liii. 307) secondary alkalamides are acted upon by pentachloride of phosphorus in the same way as primary and secondary amides:

$$\underset{\text{Phenyl-benzamide.}}{N.C^6H^5.C^7H^5O.H} + PCl^5 = \underset{\text{Chloride of phenyl-benzamidyl.}}{N(C^7H^5)'''(C^6H^5)Cl} + POCl^3 + HCl.$$

2. *Tertiary Alkalamides.*—They represent 1 molecule of ammonia in which all the hydrogen is replaced; (*a*) by 1 basic and 2 acid monatomic radicles; (*b*) by 2 basic and 1 acid monatomic radicles; (*c*) by 1 basic monatomic, and 1 acid diatomic radicle.

a. H^3 *are replaced by* 1 *basic and* 2 *acid monatomic radicles:*

Ethyl-diacetamide	$N.C^2H^5.(C^2H^3O)^2$
Phenyl-dibenzamide	$N.C^6H^5.(C^7H^5O)^2$

They are formed:—

1. By action of chlorides of acid-radicles on secondary alkalamides (Gerhardt and Chiozza):

$$\underset{\text{Phenylbenzamide.}}{N.C^6H^5.C^7H^5O.H} + \underset{\text{Chloride of benzoyl.}}{C^7H^5O.Cl} = HCl + \underset{\text{Phenyldibenzamide.}}{N.C^6H^5.(C^7H^5O)^2.}$$

2. By action of monobasic anhydrides on cyanic ethers (Wurtz):

$$\underset{\text{Acetic anhydride.}}{(C^2H^3O)^2.O} + \underset{\text{Cyanate of ethyl.}}{N.C^2H^5.CO} = CO.O + \underset{\text{Ethyldiacetamide.}}{N.C^2H^5.(C^2H^3O)^2}$$

They are neutral bodies, combining neither with acids nor with bases.

b. H^3 *are replaced by* 2 *basic and* 1 *acid monatomic radicle:*

Methyl-ethyl-cyanamide	$N.CH^3.C^2H^5.CN$
Diethyl-cyanamide	$N.(C^2H^5)^2.CN.$

The only members of this group hitherto formed, contain cyanogen as the acid-radicle. They are formed by the action of chloride of cyanogen on secondary amines (Cahours and Cloez):

$$\underset{\text{Ethylphenylamine.}}{N.C^2H^5.C^6H^5.H} + CN.Cl = HCl + \underset{\text{Ethylphenylcyanamide.}}{N.C^2H^5.C^6H^5.CN.}$$

They are liquid and volatile without decomposition. Heated with acids or alkalis, they regenerate a secondary amine and cyanic acid, which latter is further decomposed into carbonic anhydride and ammonia:

$$\underset{\text{Diethyl-cyanamide.}}{N.(C^2H^5)^2.CN} + HHO = \underset{\text{Diethylamine.}}{N.(C^2H^5)^2.H} + \underset{\text{Cyanic acid.}}{CN.H.O.}$$

$$\underset{\text{Cyanic acid.}}{N.CO.H} + H^2O = NH^3 + CO.O$$

c. H³ *are replaced by* 1 *monatomic basic, and* 1 *diatomic acid, radicle.*—As these compounds correspond to those secondary amides which are commonly called imides we will retain the same termination for them:

Phenyl-succinimide (succinanile) . . . . . $N.C^6H^5.(C^4H^4O^2)''$
Ethyl-carbimide (cyanic ether) . . . . . . $N.C\,H^5.(CO)''$

With the exception of cyanic ethers, the only members of this group that have been studied are those containing phenyl as their basic radicle; they are commonly called *aniles.* They are obtained by the action of phenylamine on dibasic anhydrides or acids (probably also on the corresponding chlorides):

$$N.C^6H^5.H^2 + \underset{\text{Camphoric anhydride.}}{C^{10}H^{14}O^2.O} = H^2O + \underset{\text{Phenylcamphorimide.}}{N.C^6H^5.C^{10}H^{14}O^2}$$

$$N.C^6H^5.H^2 + \underset{\text{Camphoric acid.}}{C^{10}H^{14}O^2.H^2.O^2} = 2H^2O + N.C^6H^5.C^{10}H^{14}O^2.$$

Boiled with dilute ammonia, they form the ammonium-salt of an amic acid:

$$\underset{\text{Phenylsuccinimide}}{N.C^6H^5.C^4H^4O^2} + NH^4.H.O = \underset{\text{Phenylsuccinamate of ammonium.}}{N.\overbrace{H.C^6H^5.C^4H^4}^{'''}\overbrace{O^2.NH^4}^{''}.O}$$

Fused with potash, they regenerate phenylamine and their acid:

$$N.C^6H^5.C^4H^4O^2 + K^2H^2O^2 = \underset{\text{Succinate of potassium.}}{C^4H^4O^2.K^2.O} + N.C^6H^5.H^2.$$

As cyanic acid may be regarded as carbimide, cyanic ethers may obviously be regarded as alkalimides. With potash they exhibit the same reaction as the foregoing alkalimides:

$$N.C^2H^5.CO + K^2H^2O^2 = CO.K^2.O^2 + N.C^2H^5.H^2.$$

By the action of water or ammonia, they form Dialkalamides (compound ureas):

$$\underset{\text{2 mol. cyanic ether.}}{N^2.(C^2H^5)^2.(CO)^2} + H^2O = CO.O + \underset{\text{Diethylcarbamide.}}{N^2.CO.(C^2H^5)^2.H^2.}$$

$$N.C^2H^5.CO + NH^3 = \underset{\text{Ethylcarbamide.}}{N^2.CO.C^2H^5.H^3.}$$

II. **Dialkalamides.**

There are no primary dialkalamides: but there exists a class of compounds occupying an intermediate place between primary and secondary dialkalamides. They represent 2 mols. of ammonia, in which 3 atoms of hydrogen are replaced, 2 by a diatomic acid-radicle, and 1 by a monatomic base-radicle. With the exception of phenyl-oxamide, $N^2.C^6H^5.C^2O^2.H^3$, the only members of this class are the *compound ureas,* representing urea or carbamide in which 1 H is replaced by a base-radicle:

Ethyl-carbamide (ethyl-urea) . . . . $N^2.(CO)''.C^2H^5.H^3$
Phenyl-carbamide (phenyl-urea) . . . . $N^2.(CO)''.C^6H^5.H^3.$

They are formed by the action of a primary amine on cyanic acid, or of ammonia on cyanic ethers:

$$\begin{aligned} N.C^2H^5.H^2 &+ N.CO.H &= N^2.CO.C^2H^5.H^3 \\ NH^3 &+ N.CO.C^2H^5 &= N^2.CO.C^2H^5.H^3 \end{aligned}$$

They are decomposed by potash, yielding carbonate, a primary amine and ammonia:

$$N^2.CO.C^6H^5.H^3 + H^2.K^2.O^2 = CO.K^2.O^2 + N.C^6H^5.H^2 + NH^3.$$

2. *Secondary Dialkalamides.*—They represent 2 molecules of ammonia in which 4 atoms of hydrogen are replaced by 2 monatomic base-radicles and 1 diatomic acid radicle:

Dimethyloxamide . . . . $N^2.(CH^3)^2.(C^2O^2)''.H^2$
Diphenylsuccinamide . . . . $N^2.(C^6H^5)^2.(C^4H^4O^2)''.H^2$
Diethylcarbamide (diethyl-urea) . . . . . $N^2.(C^2H^5)^2.(CO)''.H^2$

They are formed:

1. By heating the normal salts of organic alkalis:

$$\underset{\text{Oxalate of methylium.}}{C^2O^4(N.CH^3.H^3)^2} - 2H^2O = \underset{\text{Dimethyloxamide.}}{N^2.(CH^3)^2.C^2O^2.H^2}$$

2. By action of primary amines on ethers of dibasic acids:

$$\underset{\text{Oxalate of ethyl.}}{C^2O^2.(C^2H^5)^2.O^2} + \underset{\text{2 mol. methylamine.}}{N^2.(CH^3)^2.H^4} = \underset{\text{2 mol. alcohol.}}{(C^2H^5)^2.H^2.O^2} + \underset{\text{Dimethyloxamide.}}{N^2.(CH^3)^2.C^2O^2.H^2}.$$

3. By action of primary amines on chlorides of acid-radicles:

$$\underset{\text{2 mol. phenylamine.}}{N^2.(C^6H^5)^2.H^2.H^2} + \underset{\text{Chloride of carbonyl.}}{CO.Cl^2} = 2HCl + \underset{\text{Diphenylcarbamide.}}{N^2.(C^6H^5)^2.CO.H^2}.$$

The compound ureas (alkal-carbamides) belonging to this group are also formed by the action of water on cyanic ethers:

$$\underset{\text{Cyanate of ethyl.}}{2(N.CO.C^2H^5)} + H^2O = CO.O + \underset{\text{Diethylcarbamide.}}{N^2.(C^2H^5)^2.CO.H^2}.$$

All these secondary dialkalamides are decomposed by potash, yielding a primary amine, and the normal potassium-salt of their acid:

$$\underset{\text{Diethyloxamide.}}{N^2.(C^2H^5)^2.C^2O^2.H^2} + H^2K^2O^2 = \underset{\text{2 mols. ethylamine.}}{N^2.(C^2H^5)^2.H^4} + \underset{\text{Oxalate potass.}}{C^2O^2.K^2.O^2}$$

Hofmann regards melaniline, $C^{13}H^{13}N^3$, and a compound, $C^{19}H^{17}N^3$, which he has obtained by the action of dichloride of carbon on phenylamine, as cyan-diphenyldiamide, $N^2.CN.(C^6H^5)^2.H^3$, and cyantriphenyldiamide, $N^2.CN.(C^6H^5)^3.H^2$, respectively,—*i. e.* as dialkalamides containing only monatomic radicles. Considering the reaction by which the latter at least of these compounds is formed, it may perhaps be preferable to regard it as deriving from 3 molecules of ammonia, in which a portion of the hydrogen is replaced by the tetratomic radicle, C'''' viz. as $N^3.C.(C^6H^5)^3.H^2$.

Pebal has described the following compounds, intermediate between secondary and tertiary dialkalamides:

Diphenylcitrimide . . . . . . $N^2.(C^6H^5)^2.(C^6H^5O^4)'''.H$
Diphenylaconitimide . . . . . . $N^2.(C^6H^5)^2.(C^6H^3O^3)'''.H.$

They correspond to the monacid phenylium-salts of tribasic acids, less the elements of 3 atoms of water:

$$C^6H^5O^7(N.C^6H^5.H^3)^2H - 3H^2O = N^2.(C^6H^5)^2.C^6H^5O^4.H.$$

3. *Tertiary Dialkalamides.*—They represent 2 molecules of ammonia in which all the hydrogen is replaced by base- and acid-radicles, one of which at least must be polyatomic. This process is represented by compound-ureas, in which all the hydrogen is replaced by basic radicles,—*e.g.* Tetrethylcarbamide or tetrethyl-urea, $N^2.(CO)''.(C^2H^5)^4$. Also by Buff's sulphocyanide of ethylene (ethylene-disulphocarbamide) $N^2.(CS)^2.(C^2H^4)''$. obtained by boiling chloride of ethylene with an alcoholic solution of sulphocyanate of potassium (Proc. Roy. Soc. viii. 188), and by Hofmann's diphenylcarboxamide, $N^2.(CO)''.(C^2O^2)(C^6H^5)^{2''}$, obtained by the action of dilute hydrochloric acid on dicyanmelaniline.

$$C^{15}H^{13}N^5 + 3HCl + 3H^2O = 3NH^4Cl + N^2.CO.C^2O^2.(C^6H^5)^2$$

More might probably be obtained by the action of secondary amines on chlorides of acid radicles, or on ethers of dibasic acids:

$$2(N.(CH^3)^2.H) + C^4H^4O^2.Cl^2 = 2HCl + \underset{\text{Tetramethylsuccinamide.}}{N^2.(CH^3)^4.C^4H^4O^2}.$$

$$2[N.(C^2H^5)^2.H] + \underset{\text{Succinate of ethyl.}}{C^4H^4O^2.(C^2H^5)^2.O^2} = 2(C^2H^5.H.O) + \underset{\text{Tetrethylsuccinamide.}}{N^2.(C^2H^5)^4.C^4H^2O^2}$$

III. **Trialkalamides.**

1. *Secondary Trialkalamides.*—They correspond to 3 molecules of ammonia, in which 6 atoms of hydrogen are replaced by 1 triatomic acid-radicle and 3 monatomic base-radicles. Examples are Pebal's triphenylcitramide, $N^3.(C^6H^5)^3.(C^6H^5O^4)'''.H^3$, obtained by the action of citric acid on phenylamine:

$$C^6H^5O^4.H^3.O^3 + 3(N.C^6H^5.H^2) = N^3.(C^6H^5)^3.C^6H^5O^4.H^3 + 3H^2O$$

It corresponds to the normal citrate of phenylium, less the elements of 3 atoms of water. Also Schiff's triphenylphosphamide, $N^3.(C^6H^5)^3.PO.H^3$, and trinaphtylphosphamide, $N^3.(C^{10}H^7)^3.PO.H^3$, obtained by the action of phenylamine and naphtylamine respectively on oxychloride of phosphorus (Ann. Ch. Pharm. ci. 300):

$$POCl^3 + 3(N.C^6H^5.H^2) = N^3.(C^6H^5)^3.PO.H^3. + 3HCl.$$

2. *Tertiary Trialkalamides.*—The cyanuric ethers may be placed in this division, *e. g.* cyanurate of ethyl, $N^3.(\overset{''}{C}O)^3.(C^2H^5)^3$.—F. T. C.

AMMELIDE and **AMMELINE.** See CYANURAMIC ACIDS.

AMMIOLITE. A red earthy mass from Chile, containing 36·5 antimony, 14·8 tellurium, 12·2 copper, 22·2 mercury, and 2·5 quartz, besides oxygen; probably a mixture. (*Rammelsberg's Mineralchemie*, p. 426.)

AMMONIA. NH^3. (Synonymes, *Volatile alkali*, *Alkaline air*, *Ammoniacal gas*, *Ammoniaque*, *Ammoniak.*)

History. — The earliest mention of aqueous ammonia, which was known long before the gas itself, is made by Raymond Lully, in the thirteenth century: he prepared it from urine, and called it *Mercurius vel spiritus animalis.* Basil Valentine, in the fifteenth century, first prepared it from sal-ammoniac: he still retained the name *spiritus urinæ.* It was Bergman (1782) who first designated it by the name *ammonia.* Ammoniacal gas was discovered by Priestley, who describes it in 1774 by the name of *alkaline air;* he also observed its decomposition by the electric spark. Scheele, in 1777, ascertained that it contained nitrogen, regarding it as a compound of nitrogen and phlogiston. Its true composition was first ascertained by Berthollet (1785); and it was finally analysed with still greater exactness, by his son Am. Berthollet in 1808.

Natural Sources. — Ammonia exists in the air as carbonate of ammonium: in rain-water, especially in that of thunder-showers, as nitrate. In sea-water, and in many mineral springs. In most kinds of clay and soils: in sesquioxide of iron, and in the majority of iron-ores. Sal-ammoniac and ammonium-alum are found as minerals, the former chiefly in volcanic regions, and in some specimens of rock-salt. As ammoniacal-salts, in animal fluids and excrements (especially in urine), and in the juices of many plants.

Formation. — Ammonia cannot be formed by the direct combination of its elements in the free state. When 1 vol. nitrogen and 3 vols. hydrogen are passed through a red-hot tube, no ammonia is formed, not even if spongy platinum be present. But it is formed with great readiness by the combination of its elements, when one or both of them is in the *nascent* state: *i. e.* at the moment of its liberation from another compound: and in this manner ammonia may be formed from many substances, organic and inorganic.

1. *From inorganic substances.* — On igniting a mixture of oxygen, nitrogen, and excess of hydrogen, nitrate of ammonium is formed. (Th. Saussure.)

a. *Formation from nascent hydrogen and free nitrogen.* — Water containing atmospheric air yields nitric acid at the positive pole, and ammonia at the negative pole of a voltaic battery (Sir H. Davy). Moistened iron-filings, in contact with atmospheric air or nitrogen at the ordinary temperature, induce the formation of ammonia (Chevallier, Berzelius). (Will states that no ammonia is thus formed.) This reaction accounts for the existence of ammonia in rust of iron, and iron ores generally. When liver of sulphur is fused with an equal weight of iron-filings, and water dropped on the hot mass, ammonia is evolved (Hollunder). When certain metals which combine readily with oxygen (potassium, arsenic, lead, iron, &c.) are heated with the hydrates of potassium, sodium, barium, or calcium, in contact with air, ammonia is formed. Faraday states that this formation of ammonia takes place even in an atmosphere of hydrogen: a fact explained by Bischof as arising from the difficulty of obtaining hydrogen free from atmospheric air. Reiset also points out that the hydrogen will contain nitric oxide, if the sulphuric acid employed for its generation contains nitric acid or nitric oxide.

b. *Formation from nascent nitrogen and free hydrogen.*— A mixture of 2 vols. nitric oxide and 5 vols. hydrogen passed over gently heated spongy platinum, yields ammonia and water (Hare; Ville, Ann. Ch. Phys. [3] xlvi.) The same gases when passed through a red-hot tube, only yield ammonia when some porous substance is present; pumice-stone, or ferric oxide acts most energetically (Reiset). Nitrous oxide and hydrogen in excess yield ammonia when in contact with hot spongy platinum or platinum-black. Hydrogen saturated with nitric acid vapour acts in a similar manner.

c. *Formation from nascent hydrogen and nascent nitrogen.* — Moist nitric oxide passed over heated iron-filings yields ammonia. A mixture of nitric oxide and hydrosulphuric acid, passed over heated soda-lime, yields ammonia (Ville). Certain metals which decompose water at a high temperature (iron, zinc, &c.), when treated with dilute nitric acid, or the aqueous solutions of certain nitrates, yield ammonia. Ammonia is formed when nitric acid is added to zinc and sulphuric acid in a hydrogen apparatus, also by the decomposition of chloride, iodide, and phosphide of nitrogen, and of all bodies belonging to the class, amides, by water. When a mixture of baryta and carbonaceous matter is heated in contact with air, cyanide of barium is formed, a compound which is decomposed by steam at 300° C. into carbonate of barium and ammonia: Margueritte and Sourdeval have lately proposed to employ this process for the preparation of ammonia on the large scale. (Rep. Chim. App. ii. 170.)

2. *From organic substances.*—Many *non-nitrogenous* organic bodies form ammonia by prolonged contact with air and water: *e.g.* in the process of putrefaction. Sugar, oxalates, tartrates, &c. yield ammonia when heated with alkaline or alkaline-earthy hydrates, in contact with air. Oxygen-compounds of nitrogen, heated with organic reducing agents, *e.g.* nitric oxide with alcohol-vapour, nitric acid with gum, form ammonia. Most *nitrogenised* organic compounds yield ammonia, either free or combined, in the processes of putrefaction or of dry distillation: it is from this source that the ammonia existing in nature is chiefly derived.

Preparation.—Powdered sal-ammoniac is mixed with twice its weight of slaked lime, the mixture covered with a layer of coarsely powdered quick lime, about equal in weight to the sal-ammoniac used, and the whole heated gradually in a flask or retort: for the preparation of ammonia on a large scale, iron vessels are used. The gas is passed through a two-necked bottle, in which aqueous vapour is condensed, and any solid particles that may be carried over are arrested; it is then dried by passing over solid potash or quick lime—or better, a mixture of the anhydrous oxides of potassium and copper, obtained by heating nitrate of potassium with finely divided copper reduced from the oxide by hydrogen (Stas), (chloride of calcium absorbs the gas)—and collected over mercury. If the gas is pure, it should be entirely absorbed by water. In order to obtain perfectly dry ammonia, Vogel recommends saturating a concentrated aqueous solution of ammonia with solid chloride of calcium, heating gently, and passing the gas over solid potash.

Properties.—Colourless gas, of a pungent smell, and strong alkaline taste. Its specific gravity is (calculated) 0·5893; (H. Davy) 0·5901; (Thomson) 0·5931; (Biot and Arago) 0·5967. 1 litre at 0° C. and 760mm. barometric pressure weighs 0·7752 grm. (Biot and Arago). Its specific heat (water = 1) is 0·508 (Regnault). Its refractive power (air = 1) is 1·309 (Dulong).

It does not support either combustion or respiration: animals die when immersed in it. It is feebly combustible: when issuing in a thin stream into atmospheric air, it may be kindled, and burns with a pale flame. It colours turmeric paper brown, and reddened litmus blue: the colours disappear on exposure to the air.

It may be condensed by cold and pressure, and obtained both in the liquid and solid form. Faraday prepares liquid ammonia as follows: Ammonio-chloride of silver is introduced into a very strong glass tube, closed at one end, which is then bent at an acute angle, the chloride being in the longer limb. The shorter limb is then sealed and immersed in ice, and the chloride gradually heated: it fuses at 38° C., and between 112° and 119° C. gives off all its ammonia, which condenses to a liquid by its own pressure in the cool part of the tube. As the chloride of silver cools, the liquid ammonia boils violently, and is reabsorbed by the chloride. Guyton de Morveau and Bunsen have condensed ammonia without pressure by a mixture of chloride of calcium and ice, the former at 52° C., the latter at −40°. Liquid ammonia is a colourless, very mobile liquid, refracting light more powerfully than water; specific gravity 0·76: boiling-point at 749mm. barometic pressure, −33·7° C. (Bunsen.) Its tension at −17·78° C. = 2·48 atmospheres: at 0° C. = 4·44 atm.: at 10·8° C. = 6 atm.: at 19·44° C. = 7·60 atm.: at 28·31° C. = 10 atm.

Faraday has obtained solid ammonia by exposing the dry gas to a pressure of 20 atmospheres and to a cold of —75° C., produced by solid carbonic anhydride and ether. It is a white, transparent, crystalline body, which melts at −75° C., and has a higher specific gravity than liquid ammonia.

Decompositions.—Dry ammonia is decomposed by a succession of electric sparks: the resulting gas is double the volume of the original gas, and consists of 1 vol. nitrogen and 3 vols. hydrogen. Also by being passed through a red-hot porcelain tube containing copper or iron wire; gold-, silver-, or platinum-wire acts similarly, but less energetically. No change is produced in the gold and platinum-wire: the copper and iron wire are rendered brittle, and sometimes increased in weight, owing to the formation of a nitride.—2 vols. ammonia mixed with not less than 1, nor more than 6 vols. oxygen, are exploded by the electric spark: the products, if the oxygen be in excess, are water and nitrate of ammonium; if the ammonia be in excess, water, nitrogen, and hydrogen.—Aqueous ammonia, in contact with finely divided copper or platinum, and *oxygen* or *atmospheric air*, is converted into nitrite of ammonium, both its constituents undergoing oxidation (Handwb.)—Ammonia is decomposed by several of the oxygen-compounds of chlorine and nitrogen. Dry ammonia mixed with dry *hypo-*

chlorous anhydride explodes violently at the ordinary temperature, with separation of chlorine. Aqueous ammonia added gradually to aqueous *hypochlorous acid*, the mixture being kept cool, yields nitrogen, and chloride of nitrogen. Ammonia mixed with proper proportions of *nitrous or nitric oxide*, explodes by the electric spark, yielding water and nitrogen. Ammonia is violently decomposed at the ordinary temperature by *peroxide of nitrogen*, whether liquid or gaseous, with evolution of nitric oxide and nitrogen (Dulong).—In contact with *chlorine* in the cold, ammonia burns with a red and white flame, forming chloride of ammonium and free nitrogen ($4NH^3 + Cl^3 = 3NH^4Cl + N$); when chlorine is passed into strong aqueous ammonia or a solution of an ammoniacal-salt, chloride of nitrogen is also formed. — *Iodine* does not decompose dry ammonia: in presence of water, iodide of ammonium and an iodine-derivative of ammonia are formed.—With *bromine*, ammonia yields bromide of ammonium and free nitrogen.—Passed with vapour of *phosphorus* through a red-hot tube, ammonia yields phosphide of hydrogen and free nitrogen.—Passed over red-hot *charcoal*, ammonia yields cyanide of ammonium and free hydrogen.—With *bisulphide of carbon*, ammonia gives hydrosulphuric and sulphocyanic acids ($NH^3 + CS^2 = H^2S + CNSH$).—When *potassium* or *sodium* is heated in dry ammonia, hydrogen is evolved, its place being supplied by the metal, and nitride of potassium and hydrogen (potassamine), NKH^2, is formed.—In contact with zinc-ethyl, ammonia gives zinc-amine $NZnH^2$ and hydride of ethyl, C^2H^6. Many *metallic oxides* decompose ammonia with the aid of heat: the products are sometimes water, nitrogen, reduced metal, and more or less of an oxygen-compound of nitrogen; sometimes, water and a metallic nitride.—Ammonia reacts with anhydrous acids, chlorides of acid-radicles, and many compound ethers, giving *amic acids*, or *amides*. In like manner, it gives with many derivatives of the alcohols, *amic bases* or *amines*. (See AMIC ACIDS, AMIC BASES, AMIDES, AMINES.)

We have seen that ammonia is decomposed by certain metals and metallic oxides, hydrogen being liberated, and compounds formed representing ammonia in which a part or the whole of the hydrogen is replaced by a metal. There are certain organic compounds (*e. g.* monobasic anhydrides, compound ethers, &c.) which are capable of decomposing ammonia in a similar manner, with formation of compounds representing ammonia in which the hydrogen is wholly or partially replaced by an organic radicle, acid or basic. The numerous and interesting class of compounds which are thus formed from ammonia by the partial or total replacement of its hydrogen by other radicles, organic or inorganic, acid or basic, is known by the generic name of *amides*: under which name they are fully described.

Combinations.—1. *With Water* (*Solution of ammonia, Aqueous ammonia*, or simply *Ammonia, Spirits of hartshorn, Salmiakgeist, Liquor ammonii*).

Both water and ice absorb ammonia with great avidity, with considerable evolution of heat, and with great expansion. Davy found that 1 vol. water at 10° C. and 29·8 inches barometric pressure absorbs 670 vols. ammonia, or nearly half its weight: the specific gravity of this solution is 0·875. According to Dalton, water at a lower temperature absorbs even more ammonia, and the specific gravity of the solution is 0·85. According to Osann, 100 pts. water at 24° C. absorb 8·41 pts. at 55° C. 5·96 pts. ammonia. 1 vol. water by absorbing 505 vols. ammonia, forms a solution occupying 1·5 vols., and having specific gravity 0·9: this, when mixed with an equal bulk of water, yields a liquid of specific gravity 0·9455: whence it appears that aqueous ammonia expands on dilution. (Ure.)

Preparation.—1 part of sal-ammoniac in lumps is introduced into a glass flask, with $1\frac{1}{4}$ parts slaked lime, and from 1 to $1\frac{1}{2}$ parts water: and the flask is connected by bent tubes with three Woulfe's bottles. The first bottle, which is intended to arrest any solid particles that may be carried over mechanically, and any empyreumatic oil contained in the sal-ammoniac, as well as to condense aqueous vapour, contains a small quantity of water (Mohr prefers milk of lime). The second bottle contains the water to be saturated with ammonia: it should contain a quantity of water about equal in weight to the sal-ammoniac employed, and should not be more than three parts full, to allow for the expansion. These two bottles should be placed in cold water, and each provided with a safety tube. The third bottle contains a little water, to retain any ammonia that may pass through the second bottle. The flask is then heated in a sand-bath, care being taken that its contents do not boil over: and the operation continued till about half the water in the flask has distilled over into the first bottle. The first bottle then contains a weak and impure solution of ammonia: the second a pure and strong solution (if a perfectly saturated solution be required, the quantity of water in this bottle should not exceed $\frac{2}{3}$ the weight of the sal-ammoniac employed): the solution in the third bottle is weak, but pure.

The proportions of lime and water to be added to the sal-ammoniac in order to produce the largest yield of ammonia have been variously stated: those given above are now most generally received. According to the equation, $CaHO + NH^4Cl = NH^3 + CaCl + H^2O$, the amount of slaked lime should be to that of sal-ammoniac as 37 : 53·5, or 69 parts of the former to 100 parts of the latter. But in practice it is always found necessary to employ a larger proportion of lime; for not only is the lime of commerce always impure, but also it is impossible to bring the whole of it into such contact with the sal-ammoniac, as would ensure the completeness of their reaction. The object of adding water is to ensure the gradual solution of the sal-ammoniac, and consequently its more complete contact with the lime. There are also other disadvantages which attend the absence of water. If the lime and sal-ammoniac are mixed in a state of powder, a large quantity of ammonia is lost before the mixture is introduced into the flask; and the heated mass expands on cooling so as invariably to break the flask. These inconveniences are avoided by first placing the sal-ammoniac in lumps in the flask, and then covering it with the powdered lime: but in this case the heat required is sufficient to volatilise the sal-ammoniac, which is liable to stop up the delivery-tube and cause a dangerous explosion. Moreover a larger quantity of empyreumatic oil passes over with the ammonia: and the chloride of calcium formed in the flask obstinately retains a portion of the ammonia, which is consequently lost. On the other hand, the addition of too much water diminishes the product of ammonia, and hampers the operation in other ways.

In the preparation of aqueous ammonia on a large scale, the gas is generated in cast-iron or copper vessels: earthenware vessels are generally found not to answer, owing to the porosity of their structure.

The aqueous ammonia thus prepared may contain the following impurities, which are easily detected:

Carbonate of ammonium.—Occurs when the lime employed contains much carbonate, or when the solution has been exposed to the air. Causes turbidity when heated with chloride of barium.

Chlorine.—Owing to chloride of ammonium having been sublimed, or carried over mechanically. The solution, saturated with nitric acid, gives a cloudiness with nitrate of silver.

Lime.—Carried over mechanically. Gives a precipitate with oxalic acid: left as a solid residue on evaporation.

Copper or *Lead.*—Derived from the generating vessel. The former is detected by the solution becoming tinged with blue on evaporation; the latter by hydrosulphuric acid.

Empyreumatic oil.—From the sal-ammoniac. The solution has a yellow colour and a peculiar smell.

Properties.—Aqueous ammonia is a colourless transparent liquid, smelling of ammonia, and having a sharp burning, urinous taste. Its specific gravity varies from 1·000 to 0·85, according to the amount of ammonia it contains: its boiling-point varies similarly (see Dalton's table, *infra.*) A perfectly saturated solution freezes between −38° and −41° C., forming shining flexible needles: at −49° C. it solidifies to a grey gelatinous mass, almost without smell (Fourcroy and Vauquelin). It loses almost all its ammonia at a temperature below 100° C. The following tables have been constructed, showing the amount of real ammonia contained in aqueous ammonia of different densities:

By the aid of these tables, the strength of aqueous ammonia, like that of commercial alcohol, may be approximately ascertained by taking its specific gravity. (See also Griffin's Table given in *Ure's Dictionary of Arts, Manufactures, and Mines*, vol. i. p. 132, and Chem. Soc. Qu. J. iii. 260.)

Roscoe and Dittmar (Chem. Soc. Qu. J. xii. 147), have determined the amount of ammonia-gas absorbed by water at various pressures and temperatures. The results are given in the two following tables.

Table A shows the weight of ammonia-gas in grammes G absorbed by 1 gramme of water at 0° C. and various *partial* pressures P.*

---

* By partial pressure is meant the total pressure under which the absorption occurs, *minus* the tension of aqueous vapour at 0° C.

TABLE A.

P.	G.	P.	G.	P.	G.	P.	G.
0·00	0·000	0·25	0·465	0·85	0·937	1·45	1·469

0·02	0·084	0·35	0·561	0·95	1·001	1·55	1·584
0·03	0·120	0·40	0·607	1·00	1·037	1·60	1·645
0·04	0·149	0·45	0·646	1·05	1·075	1·65	1·707
0·05	0·175	0·50	0·690	1·10	1·117	1·70	1·770
0·75	0·228	0·55	0·731	1·15	1·161	1·75	1·835
0·100	0·275	0·60	0·768	1·20	1·208	1·80	1·906
0·125	0·315	0·65	0·804	1·25	1·258	1·85	1·976
0·150	0·351	0·70	0·840	1·30	1·310	1·90	2·046
0·175	0·388	0·75	0·872	1·35	1·361	1·95	2·120
0·200	0·411	0·80	0·906	1·40	1·415	2·00	2·195

From these numbers it appears: (1) that the quantity of ammonia absorbed by water at 0° C. is far from being proportional to the pressure; and (2) that for equal increments of pressure up to about 1 metre of mercury, the corresponding increments of absorbed ammonia continually diminish, but that above this point, the amount of dissolved gas increases in a more rapid ratio than the pressure.

Table B shows the weight in grammes of ammonia (column II.), absorbed by 1 gramme of water under the pressure of 0·76^m. and at various temperatures (column I).

TABLE B.

Aqueous ammonia possesses the property of dissolving many salts which are insoluble in water. Thus it dissolves chromic and stannic oxides, the protoxides of tin, cadmium, zinc, &c., the oxides of copper and silver. The compounds thus formed are decomposed by heat, losing ammonia, sometimes with explosive violence. Many other salts are also soluble in aqueous ammonia, *e. g.* phosphate, chloride, bromide of silver, &c.: in some cases, the original salt can be recovered unchanged by evaporating off the ammonia; in others a more intimate combination is effected.

2. *With alcohol.* (Liquor ammoniaci alcoholicus).

Alcohol, like water, absorbs ammonia in great quantity, with considerable expansion and evolution of heat. The alcoholic solution is prepared in precisely the same way as the aqueous solution, alcohol of 85—90 p. c. being substituted for water in the second bottle. The proportion of alcohol to the sal-ammoniac employed should be somewhat less than in the case of water. The specific gravity of the solution of course varies with the amount of alcohol and ammonia which it contains.

3. *With metallic salts.* Ammonia forms solid compounds with certain metallic oxides (of gold, silver, platinum, mercury, antimony, &c.) which are decomposed by heat, frequently with explosive violence. Certain metallic chlorides, bromides, and iodides (of silver, calcium, &c.) absorb ammonia, frequently with evolution of heat. Some of these compounds lose their ammonia when exposed to the air; others, but not all, when heated. Some dissolve in water without decomposition, forming solutions from which the whole of the ammonia is not precipitated by dichloride of platinum: the majority are decomposed by water, which sometimes dissolves the original salt and separates ammonia, sometimes precipitates the metal as hydrate. Similarly, certain crystalline salts, when freed from their water of crystallisation, absorb ammonia abundantly and in atomic proportion, forming compounds which are decomposed by heat or by water. Ammonia also combines with metallic cyanides, with fluoride of silicon, and other bodies.

4. *With acids*, forming *ammoniacal salts.* (See AMMONIACAL SALTS.)

5. *With polybasic anhydrides*, forming the ammonium-salts of amic acids. (See AMIC ACIDS.)

F. T. C.

AMMONIACAL SALTS. *Ammonium-salts, Sels ammoniacaux, Ammoniaksalze.*

Ammonia combines very readily with acids, which it neutralises completely, forming definite crystalline salts, known by the name of ammoniacal or ammonium-salts. These salts are isomorphous with those of potassium, and are in their general properties so closely analogous to metallic salts, that they are universally regarded as belonging to this class of bodies. There is, however, a characteristic difference in their mode of formation. While other metallic salts are formed by the substitution of a metal for the hydrogen of an acid, *e.g.* chloride of zinc, $ZnCl = HCl + Zn - H$: ammoniacal salts are formed by the direct combination of ammonia with the acid, without elimination of hydrogen,—*e.g.* chloride of ammonium, $NH^4Cl = NH^3 + HCl$.

Among the various theories by which it has been proposed to represent the constitution of these salts, that which most clearly expresses their analogy with other metallic salts is unquestionably the *Ammonium Theory* of Berzelius. According to this theory, ammoniacal salts contain a compound metal, *ammonium*, NH^4, analogous to potassium, sodium, and other metals, the salts of which, *ammonium-salts*, are analogous to other metallic salts. Thus, chloride of ammonium, $ClNH^4$, is analogous to chloride of potassium, ClK; sulphate of ammonium, $SO^4(NH^4)^2$, to sulphate of potassium, SO^4K^2, &c. This hypothetical metal has never been isolated. An amalgam of mercury and ammonium is, however, known to exist, which affords strong corroborative evidence, not only of the existence of ammonium, but also of its metallic nature, metals being the only bodies which are capable of forming amalgams with mercury. This singular substance, discovered simultaneously in 1808, by Seebeck, at Jena, and by Berzelius and Pontin, at Stockholm, was originally prepared by the action of electricity upon aqueous ammonia in contact with mercury. A strong solution of aqueous ammonia in which mercury is placed, is brought into the voltaic circle, the negative pole dipping into the mercury, and the positive pole into the liquid. Another method is to dip the negative wire into mercury, which is placed in a cavity hollowed out of a fragment of a solid ammonium-salt, carbonate, sulphate, phosphate, or chloride, the positive wire being inserted into the salt itself, or connected with a metallic plate on which the salt rests. Oxygen, or, if chloride of ammonium be employed, chlorine, is evolved at the positive pole, but scarcely any gas at the negative pole; while the mercury increases very largely in volume, and assumes the consistence of butter. When completely saturated with ammonium, the amalgam is lighter than water: obtained by the former method, it has frequently a crystalline structure. It is a very unstable compound, decomposing spontaneously as soon as it is removed from the voltaic circle, being resolved into liquid mercury, and a mixture of 2 vols. ammonia, NH^3, and 1 vol. hydrogen, H. When cooled below 0° C., it solidifies and crystallises in cubes. At a very low temperature, it contracts, and becomes brittle; decomposition does not begin till the temperature rises to 29° C. According to Sir H. Davy, it contains 1 atom NH^4 to 753 atoms mercury. The amalgam may also be prepared without the intervention of electricity, by bringing potassium- or sodium-amalgam — the latter is more energetic in its action—into contact with an ammonium-salt, either solid and moistened with water, or as a concentrated aqueous solution. The amalgam thus prepared contains, according to Gay-Lussac and Thénard, 1 part nitrogen and hydrogen to 1800 parts mercury. It contains a certain portion of potassium or sodium, and on this account is less unstable than the amalgam prepared by either of the former methods: it may be preserved for a considerable time in anhydrous rock-oil, or in an atmosphere of hydrogen.

Formation.—Ammonium-salts are formed by bringing ammonia or carbonate of ammonium directly into contact with acids.

Properties.—Ammonium-salts are isomorphous with potassium-salts. They have mostly a pungent, saline, somewhat urinous taste. They are all soluble in water, generally with facility: less soluble in alcohol or ether. Ammonium-salts of colourless acids are colourless.

Reactions of Ammonium-salts. Tests for Ammonia.—Ammonium-salts are variously affected by heat: all, however, are wholly or partially volatilised, with or without decomposition. The carbonate, and those which contain no oxygen (chloride, iodide, &c.), are volatilised undecomposed. All others lose their ammonia when heated. Some, *e.g.* the phosphate, and borate, evolve ammonia undecomposed, leaving the acid. Others, *e.g.* sulphate, evolve nitrogen, the acid being more or less completely reduced by the hydrogen of the ammonia: the nitrate is decomposed into nitrous oxide and water. Their aqueous solution, when exposed to the air (still more rapidly when evaporated), generally loses ammonia, an acid salt, or a normal salt mixed with excess of acid, being formed: hence, in crystallising an ammonium-salt, ammonia must be occasionally added during evaporation. When treated with *chlorine*, their aqueous solution yields hydrochloric acid and nitrogen; or, if the salt contains a powerful acid, hydrochloric acid and chloride of nitrogen (Dulong). With a solution of *hypochlorous acid*, dry ammonium-salts yield water, chloride of nitrogen, and nitrogen, while nitrogen and chlorine remain in solution (Balard). In solution they are decomposed by *protoxides*, with liberation of ammonia; not by sesquioxides. When heated, either solid or in solution, with a fixed alkali, baryta, lime, oxide of lead, &c., they evolve ammonia: magnesia expels only half the ammonia, forming a double salt.

The reaction by which ammonium-salts are generally detected, is their decomposition when heated with *fixed alkalis* or *alkaline earths*. If the ammonia evolved be in so minute a quantity that its characteristic smell cannot be perceived, it is easily recognised by its property of restoring the blue colour to reddened litmus-paper, and of forming dense white fumes by contact with a glass rod moistened with dilute hydrochloric acid. If the evolved ammonia be brought into contact with a strip of paper moistened with a dilute neutral solution of subnitrate of mercury, sulphate of copper, or sulphate of manganese, in the first case a black stain is produced on the paper, in the second a blue, in the third a brown.—A solution of *molybdate of sodium containing phosphoric acid* (phosphomolybdate of sodium), gives with ammonium-salts, a yellow precipitate, soluble in alkalis and non-volatile organic acids, insoluble in mineral acids: in very dilute ammonium solutions, the formation of the precipitate is gradual; it is accelerated by heat. When a solution containing an ammonium-salt or free ammonia is mixed with potash, and a solution of *iodide of mercury in iodide of potassium* added, a brown precipitate or coloration is immediately produced (Nessler). ($NH^3 + 4HgI = NHg^4I + 3HI$). This is by far the most delicate test for ammonia.—With *dichloride of platinum*, ammonium-salts give a yellow crystalline precipitate of chloroplatinate of ammonium, $PtCl^3NH^4$, slightly soluble in water, insoluble in alcohol or acids. When ignited, the precipitate is converted into pure metallic platinum, perfectly free from chlorine. With *acid tartrate of sodium* (or *tartaric acid*), they give a white precipitate of acid tartrate of ammonium, slightly soluble in cold water, readily soluble in alkaline solutions and in mineral acids. The carbonaceous residue left on igniting this precipitate has no alkaline reaction.—A not too dilute solution of an ammonium-salt gives with a concentrated solution of *sulphate of aluminium*, a crystalline precipitate of ammonium-alum.—Only very concentrated solutions of ammonium-salts give precipitates with *perchloric* or *fluosilicic acid*.—*Subnitrate of mercury* gives a brown colour in solutions containing free ammonia.—A slightly alkaline solution of an ammonium-salt gives a white precipitate with *chloride of mercury*.—Alcoholic solutions of ammonium-salts burn with a blue or violet flame.

Reactions very similar to those just described, *e. g.* with phosphomolybdate of sodium, iodomercurate of potassium, dichloride of platinum, chloride of mercury, &c., are likewise produced by the salts of methylamine, ethylamine, and other compound ammonias. These organic bases may, however, be distinguished with certainty from ammonia itself by igniting the substance under examination with oxide of copper, and passing the evolved gases into baryta water, when, if carbon is present, a precipitate of carbonate of baryta will be produced. (See ANALYSIS, ORGANIC, p. 225.)

Separation and Estimation of Ammonium.—Ammonium is separated from all other metals except the alkaline metals, by its non-precipitation by hydrosulphuric acid, sulphide or carbonate of ammonium, or phosphate of sodium, in presence of chloride of ammonium. From sodium and lithium it is separated by dichloride of platinum and alcohol, which precipitates potassium and ammonium as chloroplatinates, while sodium and lithium remain in solution. The mixed chloroplatinates are converted by ignition into a mixture of metallic platinum and chloride of potassium, the latter of which is dissolved out by water, the solution evaporated to dryness, gently ignited, and weighed. The weight of platinum corresponding to the amount of potassium thus obtained being deducted from the total weight of metallic platinum, the remaining platinum represents the ammonium present: 1 atom of platinum corresponds to 1 atom of ammonium. This method is applicable only when the metals are present as salts which are soluble in alcohol, *e. g.* as chlorides. Sulphates are best converted into chlorides by adding carbonate of barium, and saturating the filtrate with hydrochloric acid.

The best method for the separation of ammonium from all other metals is to heat the compound under examination in a combustion-tube with excess of soda-lime, and to collect the ammonia evolved in a bulb-apparatus containing hydrochloric acid. The chloride of ammonium thus obtained is mixed with excess of dichloride of platinum (perfectly free from nitric acid), and evaporated to dryness on a water-bath. The residue is treated with alcohol, which dissolves excess of the dichloride: the chloroplatinate of ammonium is collected on a weighed filter, dried at 100° C., and weighed; or converted by ignition in a porcelain crucible into metallic platinum, from the weight of which the amount of ammonia is readily calculated. This method is not applicable to the separation of ammonia from other volatile organic bases.

Ammonium-salts may occasionally be estimated by loss. This is the case when the ammonium-salt is entirely volatile, and when no other volatile or decomposible compound is present. The substance under examination is heated in a water-bath until it ceases to lose weight: it is then moderately ignited and weighed again, when the loss of weight represents the amount of ammonium-salt present. This is a convenient method for the estimation of chloride, nitrate, or normal sulphate of ammonium, in presence of the corresponding fixed alkaline salts.

Ammonia may also be estimated by distilling it into a known quantity of dilute acid, and determining volumetrically by a standard alkaline solution the excess of free acid.

The following are the principal ammonium-salts:

1. ACETATES OF AMMONIUM. *a. Normal acetate*, $C^2H^3O^2.NH^4$.—A white odourless salt, obtained by saturating glacial acetic acid with dry ammonia.

b. Acid acetate, $C^2H^3O^2.NH^4 + C^2H^4O^2$.—Obtained as a white crystalline sublimate, when dry powdered chloride of ammonium is treated with an equal weight of acetate of potassium or calcium, ammonia being given off simultaneously. (See ACETATES, p. 12.)

2. CARBONATES OF AMMONIUM.—H. Rose (Pogg. Ann. xlviii. 352) admits the existence of a considerable number of carbonates of ammonium, to which he assigns very various and complicated formulæ. But, according to H. Deville (Compt. rend. xxxiv. 880; Ann. Ch. Phys. [3] xl. 87), there exist only two carbonates of ammonium of definite composition.

a. Normal carbonate, $CO^3(NH^4)^2$ [or $CO^2.NH^4O = CO^2.NH^3.HO$].—This salt has never been isolated. The salt which crystallises from an alcoholic solution of sesquicarbonate of ammonium saturated with ammonia, is simply sesquicarbonate. Neither can it be obtained from a saturated solution of commercial sesquicarbonate in strong aqueous ammonia. It may be obtained in aqueous or alcoholic solution, or, as sesquicarbonate, in combination with the acid carbonate (*b*). (Pelouze et Fremy, Traité de Chimie, ii. 222.)

b. Acid carbonate, $CO^3.NH^4.H$ [or $CO^2.NH^4O + CO^2.HO$.]—Obtained by saturating an aqueous solution of ammonia or sesquicarbonate of ammonium with carbonic anhydride. Or by treating the commercial sesquicarbonate finely powdered, with alcohol of 90 per cent., which dissolves out normal carbonate, leaving a residue of acid carbonate. Sesquicarbonate of ammonium is similarly decomposed by cold water; but in this case, a larger quantity of the acid carbonate is dissolved. All carbonates of ammonium, when left to themselves, are gradually converted into acid carbonate. It forms large crystals, belonging to the right prismatic or trimetric system. According to Deville, it is dimorphous, but never isomorphous with acid carbonate of potassium. When exposed to the air, it volatilises slowly, without becoming opaque, and gives off a slight ammoniacal odour. At the ordinary temperature, it is soluble in 8 parts of water; if this solution be heated above 36° C. it is decomposed, evolving carbonic anhydride. Even at ordinary temperatures, the solution, whether concentrated or dilute, gradually becomes ammoniacal on keeping (Gmelin). It is insoluble in alcohol; but when exposed to the air under alcohol, it dissolves as normal carbonate, evolving carbonic anhydride.

It has been found native in considerable quantity in the deposits of guano on the western coast of Patagonia, in the form of white crystalline masses, with a strong ammoniacal smell. (Ulex. Ann. Ch. Pharm. lxvi. 44.)

c. Sesquicarbonate, $C^3O^9N^4H^{16} + 2H^2O$ [$= 3CO^2.2NH^4O + 3HO$.]—Obtained by dissolving commercial carbonate of ammonium in strong aqueous ammonia, at about 30° C., and crystallising the solution. It forms large transparent crystals, representing a right rectangular prism, with the faces of the corresponding rhombic octahedron resting on the angles. These crystals decompose very rapidly in the air, losing water and ammonia, and being converted into di-acid carbonate. This salt may be regarded as a mixture or compound of 1 atom of normal carbonate with 2 of atoms acid carbonate [$CO^3.(NH^4)^2 + 2(CO^3.NH^4.H) = C^3O^9N^4H^{16}$]: a view which is confirmed by its behaviour with water and alcohol; which, when added in quantity insufficient for the complete solution of the salt, dissolves out normal carbonate, leaving a residue of acid carbonate: 100 pts. water at 13° C. dissolve 25 pts. sesquicarbonate, at 17°, 30 pts.; at 32°, 37 pts.; at 41°, 40 pts.; at 49°, 50 pts. (Berzelius): above this temperature, carbonic anhydride is evolved, and a solution of normal carbonate formed.

Commercial carbonate of ammonium (*sal volatile, salt of hartshorn*, &c.) consists of sesquicarbonate, more or less pure. It is prepared on a large scale by the dry distillation of bones, hartshorn, and other animal matter. The product thus obtained is contaminated with empyreumatic oil, from which it is purified by subliming it once or twice with 1½ times its weight of animal charcoal, in cast-iron vessels over which glass receivers are inverted. By repeated sublimation, the salt is partially decomposed. Another method of preparing it is by heating to redness a mixture of 1 pt. chloride or sulphate of ammonium, and 2 pts. carbonate of calcium (chalk), or carbonate of potassium, in a retort to which a receiver is luted: ammonia and water are first disengaged, and then the sesquicarbonate distils over and solidifies in the neck of the retort and the receiver. On a small scale, glass vessels are employed: on a large scale, an earthenware or cast-iron retort, and an earthenware or leaden receiver, which, when filled by repeated distillations, is broken or cut in two: 10 pts. sal-ammoniac yield from 7 to 8 pts. sesquicarbonate. (See *Dictionary of Arts, Manufactures and Mines*, i. 135.) The salt thus prepared is liable to contain the following impurities:

Hyposulphite of ammonium: when sulphate of ammonium, or chloride containing sulphate, is employed in the preparation. The salt neutralised with acetic acid gives a white precipitate which turns black on addition of nitrate of silver.—*Sulphate of ammonium*, from the same causes: detected by hydrochloric acid and chloride of barium. —*Sal-ammoniac:* detected by nitric acid and nitrate of silver.—*Lead*, from the receiver: the salt has a grey colour, and when dissolved in dilute nitric acid, gives the reactions of lead.—*Lime* and *chloride of calcium*, carried over mechanically: from these and other fixed impurities the salt is freed by re-sublimation.

The sesquicarbonate obtained as above is a white, transparent, fibrous mass, with a pungent caustic taste, and a strong ammoniacal smell. Exposed to the air, it is gradually converted into acid carbonate. It is completely volatile, though not without partial decomposition. Its aqueous solution is strongly alkaline: from a hot saturated solution, the acid carbonate crystallises on cooling, but not in the ordinary crystalline form. (Deville.)

The aqueous solution of this salt (*spiritus salis ammoniaci*), is extensively employed in medicine as a stimulant. It is also a very valuable reagent. The solid salt is employed in the manufacture of other ammoniacal salts.

3. CHLORIDE OF AMMONIUM, $ClNH^4$. (*Hydrochlorate* or *muriate of ammonia*, *Sal-ammoniac*, *salzsaures Ammoniak*, *Salmiak*, *Chlorure d'ammonium*, or *Chlorure ammonique*.)

Hydrochloric acid gas and ammonia combine volume for volume, with great evolution of heat, forming solid chloride of ammonium. This salt forms colourless feathery crystals, which, when examined by a lens, are found to consist of an aggregation of cubes or octahedrons. It has no smell, but a pungent taste; its specific gravity is 1·5. It dissolves in 2·72 pts. water at 18·75° C., with great reduction of temperature; and in about its own weight of water at 100°. It is less soluble in alcohol. When exposed to the air, it loses ammonia, and becomes acid to test-paper. When heated, it volatilises undecomposed, without previous fusion. After sublimation, it forms white crystalline masses, which are exceedingly tough and difficult to powder: to obtain it in a pulverulent state, a hot saturated solution is evaporated to dryness very rapidly, with continual agitation, when the salt is left as a crystalline powder.

Chloride of ammonium is decomposed by several metals, potassium, iron, &c., a metallic chloride being formed, and ammonia and hydrogen separated. It is also decomposed by many salts; by some, *e. g.* alkaline and alkaline-earthy hydrates, completely, ammonia being evolved; by others, as by cupric and ferric salts, partially, double salts being formed. Some salts, *e. g.* platinic chloride, combine with it directly, forming double salts (chloroplatinates). Some metallic hydrates are soluble in a solution of sal-ammoniac, especially those of zinc and magnesium.

Sal-ammoniac is found native in many volcanic regions; also in small quantities in sea-water. It is readily formed by heating nitrogenised animal matter containing chloride of sodium, or with which that salt has been mixed. Until the middle of the last century, sal-ammoniac was obtained almost exclusively from Egypt, where it was prepared in this manner, by subliming the soot obtained by the combustion of camel's dung. It is now largely manufactured in Europe, chiefly from the impure carbonate of ammonium which is obtained in gas-works, or by the dry distillation of animal matter. This carbonate is converted into chloride by the addition of hydrochloric acid, or of the mother-liquor from salt-works, containing the chlorides of magnesium and calcium, and by evaporating the solution (ammonia being added from time to time), crystals of sal-ammoniac are obtained. These are contaminated with empyreumatic oil, which is destroyed by heating the crystals to a temperature a little below their subliming point. They are then dissolved in water, the solution decolorised by boiling with animal charcoal, and again crystallised. The salt is finally purified by sublimation, which is performed at a brisk heat, in large glass or earthenware bottles, the neck of which must be carefully kept unobstructed, to avoid the risk of explosion: the bottles are then broken and the sal-ammoniac removed in cakes. Metallic receivers are sometimes employed in the sublimation; in this case, the outer surface of the sal-ammoniac is dark-coloured, owing to metallic impurities, and must be scraped off.

In some manufactories, the carbonate of ammonium is first converted into sulphate, and subsequently into chloride. This is generally done by filtering the solution of carbonate through a stratum of powdered gypsum (sulphate of calcium), when insoluble carbonate of calcium is formed, and a solution of sulphate of ammonium obtained. This solution is mixed with chloride of sodium, evaporated to dryness, and the sal-ammoniac separated from the residue by sublimation. Or the solution of the two salts is evaporated at the boiling heat, when sulphate of sodium, being less soluble at a high than at a lower temperature, mostly crystallises out and is removed. The solution is then cooled, when the sal-ammoniac crystallises out, since its solubility diminishes rapidly with decrease of temperature. The crystals thus obtained are purified as above described. Ferrous sulphate may be employed instead of gypsum to convert the carbonate of ammonium into sulphate; this is a more expensive process, but it possesses the advantage of removing the greater part of the empyreumatic oil, which is carried down by the precipitated iron-salt. (Berzelius.)

In the factory at Buxweiler, in Alsace, sal-ammoniac, phosphorus, and gelatin are prepared by the following ingenious process. Bones are digested in hydrochloric acid, which dissolves out the bone-earth, leaving the cartilage insoluble: the latter is employed for the preparation of gelatin. The hydrochloric solution is mixed with crude carbonate of ammonium, when sal-ammoniac is formed, and phosphate of calcium precipitated in the finely-divided state in which it is best adapted for the preparation of phosphorus. [For further details of the manufacture of sal-ammoniac, see *Dictionary of Arts, Manufactures and Mines*, i. 141.]

Sal-ammoniac is employed in medicine. In the laboratory it serves for the preparation of ammonia, and carbonate of ammonium, and for frigorific mixtures. It is employed in dyeing; also in metal-works, as a deoxidising agent, especially for copper. A solution of chloride of silver in chloride of ammonium is employed for plating copper and brass. It enters into the composition of a cement used for fixing iron in stone: this cement is formed by moistening with a solution of sal-ammoniac, iron-filings mixed with 1 or 2 per cent. sulphur. Impure sal-ammoniac has recently been employed as manure.

4. HYDRATE OF AMMONIUM, $NH^4.H.O.$—This compound has never been isolated. The aqueous solution of ammonia behaves in many respects like a solution of hydrate of ammonium.

5. NITRATE OF AMMONIUM, $NO^3.NH^4$ [or $NO^5.NH^4O = NO^5.NH^3.HO$]. (*Nitrum flammans.*)—Obtained by crystallising a mixture of nitric acid with a slight excess of aqueous ammonia. It forms long flexible needles: if the crystallisation be effected very slowly, it may be obtained in six-sided prisms. When the solution is evaporated to a very small bulk, the salt solidifies into a dense amorphous mass. It has a pungent taste. It is soluble in about half its weight of water at 18° C., and in still less at 100°: its saturated solution boils at 164° C., and contains 47·8 per cent. salt: when dissolved in water it produces great cold. It is soluble in alcohol. Exposed to the air, it deliquesces slightly, loses ammonia, and becomes acid. When heated, it fuses perfectly at 108° C., and boils without decomposition at 180°. Between 230° and 250° it is decomposed into water and nitrous oxide, ($NO^3.NH^4 = N^2O + 2H^2O$). If it be heated too rapidly, ammonia, nitric oxide, and nitrite of ammonium are also formed. (Berzelius). When thrown into a red-hot crucible, it burns with a slight noise, and a pale yellow flame. In presence of spongy platinum, it is decomposed at about 170° C. into nitrogen and nitric acid. (Millon and Reiset.)

Nitrate of ammonium is formed when a mixture of nitrogen, oxygen, and excess of hydrogen is submitted to the electric current; also when hydrosulphuric acid is passed into a dilute solution of nitric acid. It is also formed by the action of nitric acid on several metals, especially tin.

6. NITRITE OF AMMONIUM, $NO^2.NH^4$ [$= NO^3.NH^3.HO$].—Obtained by double decomposition of nitrite of lead and sulphate of ammonium, or of nitrite of silver and chloride of ammonium: the solution is evaporated in vacuo. Or by passing nitrous fumes into aqueous ammonia, and evaporating over lime (Millon). It forms an imperfectly crystallised mass. It is decomposed by heat into nitrogen and water, ($NO^2.NH^4 = N^2 + 2H^2O$). Its aqueous solution is similarly decomposed, suddenly if acid, gradually if alkaline.

7. OXALATES OF AMMONIUM. —*a. Normal oxalate.* $C^2O^4(NH^4)^2 + H^2O$.—Obtained by neutralising oxalic acid with ammonia, and crystallising. It forms long prisms united in tufts, belonging to the rhombic, right prismatic or trimetric system: soluble in 3 pts. cold water, insoluble in alcohol. It is very slightly volatile at ordinary temperatures. When carefully heated to 220° C. it is entirely decomposed into carbonic oxide and carbonate of ammonium; when it is heated more strongly, some oxamide is formed. Its solution is employed as a reagent for precipitating calcium-salts.

b. Acid oxalate, $C^2O^4.NH^4.H + H^2O$. — Obtained in the crystalline form by adding oxalic, sulphuric, nitric, or hydrochloric acid to a solution of the normal salt. It crystallises in the trimetric system. It reddens litmus, and is less soluble than the normal salt. It is decomposed by heat, yielding, among other products, oxamide, $\mathrm{C^2O^2N^2H^4}$, and oxamic acid, $\mathrm{C^2O^3NH^3}$.

c. Quadroxalate, Hyper-acid oxalate, $\mathrm{C^2O^4.NH^4.H + C^2O^4H^2 + 2H^2O}$. — Obtained by crystallising a solution of equal parts of acid oxalate and oxalic acid. The crystals belong to the triclinic or doubly oblique prismatic system, and are isomorphous with the corresponding potassium salt. They are very soluble in hot water. At 100° C. they effloresce slightly, and lose their water of crystallisation.

8. PHOSPHATES OF AMMONIUM. — *a. Normal phosphate*, $\mathrm{PO^4(NH^4)^3}$ [or $PO^5.3NH^4O.$] —When a solution of monacid phosphate of ammonium is mixed with ammonia, this salt separates as a crystalline magma: it cannot be dried without losing ammonia, being converted into *b*.

b. Diammonic phosphate, $\mathrm{PO^4.(NH^4)^2.H}$ [or $PO^5.2NH^4O.HO$]. (*Ordinary phosphate of ammonium*, formerly called *neutral phosphate.*)—Obtained by adding a slight excess of ammonia or carbonate of ammonium to acid phosphate of calcium (solution of bone-earth in hydrochloric or dilute sulphuric acid); when phosphate of calcium is precipitated, and monacid phosphate of ammonium remains in solution. It forms large, colourless, transparent crystals, belonging to the monoclinic or oblique prismatic system. It has a cooling, saline taste, and an alkaline reaction. Exposed to the air, it effloresces slightly, losing ammonia. It is soluble in 4 pts. cold, and in a smaller quantity of boiling water; insoluble in alcohol. By a red heat, it is converted into metaphosphoric acid, $\mathrm{PO^4.(NH^4)^2.H = PO^3H + 2NH^3 + H^2O}$).

c. Monammonic phosphate, $\mathrm{PO^4.(NH^4).H^2}$ [or $PO^5.NH^4O.2HO$]. (Formerly called *acid phosphate.*) — Obtained by adding phosphoric acid to aqueous ammonia, till the solution is strongly acid, and no longer precipitates chloride of barium; or by boiling a dilute solution of *b* and evaporating it to crystallisation. It crystallises in the dimetric or square prismatic system. It is somewhat less soluble in water than *b*, and is similarly decomposed by heat.

The phosphates of ammonium are employed for the preparation of metaphosphoric acid. As the residue of their ignition always retains ammonia, it must be moistened with nitric acid, and again calcined. Gay-Lussac has proposed to preserve muslins and other inflammable textures from ignition by steeping them in a solution of these salts; the salt being decomposed by heat, the tissue is covered with a film of metaphosphoric acid, which preserves it from contact with the air, and prevents its breaking into flame. These salts cannot, however, be applied to fabrics which have to be washed and ironed, because the heat of the iron would decompose them, expelling the ammonia. The same objection applies to sulphate of ammonium, which is otherwise efficacious in diminishing the inflammability of light tissues. From recent experiments by Versmann and Oppenheim (Pharm. J. Trans. [2] i. 385), it appears that the only salt universally applicable for rendering such fabrics non-inflammable, is the neutral tungstate of sodium. (See TUNGSTATES.)

Some of the double phosphates of ammonium and other metals are of considerable importance. The phosphate of sodium, ammonium and hydrogen, $\mathrm{PO^4.Na.NH^4.H}$, commonly called *microcosmic salt*, or *phosphorus salt*, is much used as a blow-pipe flux, being converted by heat into transparent metaphosphate of sodium, which dissolves many metallic salts with characteristic colours.

9. SULPHATES OF AMMONIUM. — *a. Normal Sulphate*, $\mathrm{SO^4(NH^4)^2}$ [or $SO^3.NH^4O.$] (Glauber's *Sel secretum.*) — Obtained by neutralising dilute sulphuric acid with ammonia or carbonate of ammonium. It forms crystals belonging to the trimetric or right prismatic system, isomorphous with potassic sulphate. It is colourless, and has a very bitter taste; it is soluble in twice its weight of cold, and in its own weight of boiling water; insoluble in alcohol. It fuses at 140° C: above 280°, it is decomposed, ammonia, nitrogen, and water being given off, and acid sulphite of ammonium sublimed.

It is found native as *Mascagnine*. It is manufactured on a large scale (as already described under Sal-ammoniac) by neutralising with sulphuric acid, or decomposing by gypsum, the impure carbonate of ammonium obtained in gas-works, &c. and crystallising the solution. The crystals are heated, to destroy animal matter, and purified by recrystallisation. Sulphate of ammonium is employed in the manufacture of ammonium-alum: also as manure.

b. Acid sulphate, $\mathrm{SO^4.NH^4.H}$, [or $2SO^3.NH^4O.HO$].—Obtained by treating a solution of *a* with sulphuric acid. It crystallises in thin rhombohedrons. It is soluble in its own weight of cold water, and in alcohol. It deliquesces slowly in the air.

10. SULPHIDES OF AMMONIUM.—*a. Sulphide*, $\mathrm{(NH^4)^2S}$.—When a mixture of dry hydrosulphuric acid and ammonia, the latter in excess, is exposed to a temperature of − 18° C. 2 vols. ammonia combine with 1 vol. hydrosulphuric acid, and form sulphide of ammonium. The same compound is formed when sulphide of potassium is distilled

with chloride of ammonium, provided the receiver be cooled to −18° C. It forms colourless crystals, which have a strong alkaline reaction. At the ordinary temperature, it is at once decomposed, losing ammonia, and being converted into sulphydrate (*b*). This decomposition takes place even in an atmosphere of ammonia. Its aqueous solution, which is much employed as a reagent, is prepared by dividing a saturated solution of ammonia into 2 equal parts, saturating one with hydrosulphuric acid, and then adding the other. It forms a colourless solution, which becomes yellow on keeping, owing to the formation of a higher sulphide; by further exposure to the air, sulphur is separated, hyposulphite, sulphite, and finally sulphate of ammonium being successively formed.

b. Sulphydrate or *Hydrosulphate*, $NH^4.H.S.$—Obtained by mixing dry hydrosulphuric acid and ammonia, in any proportions, at a temperature above −18° C. It is a combination of the two gases in equal volumes. It forms colourless crystals, which have an alkaline reaction, and volatilise undecomposed, even at ordinary temperatures. Its aqueous solution is obtained by saturating aqueous ammonia with washed hydrosulphuric acid, out of contact with the air. It forms a colourless solution, which, by exposure to the air, is decomposed in the same manner as the sulphide.

c. Polysulphides.—Besides the above, there are several other compounds of sulphur and ammonium described, which may be regarded as combinations of the monosulphide with sulphur, or as polysulphides of ammonium. These are—1. The *disulphide*, $(NH^4)^2S^2$; 2. The *trisulphide*, $(NH^4)^2S^3$; 3. The *tetrasulphide*, $(NH^4)^2S^4$; 4. The *pentasulphide*, $(NH^4)^2S^5$; 5. The *heptasulphide*, $(NH^4)^2S^7$. The most general method of preparing these compounds is by distilling the corresponding sulphide of potassium with excess of chloride of ammonium. In the wet way, they are prepared by adding sulphur to a solution of the monosulphide, and saturating the mixture alternately with ammonia and hydrosulphuric acid. The heptasulphide, to which there is no corresponding sulphide of potassium, is formed by the spontaneous decomposition of the pentasulphide:

$$3(NH^4)^2S^5 = 2(NH^4)^2S^7 + NH^3 + NH^4.H.S.$$

It forms ruby-red crystals. It is the most stable of the polysulphides of ammonium, not being decomposed at temperatures below 300° C., and but very slowly by water or hydrochloric acid.

The substance known as *fuming liquor of Boyle*, or *volatile liver of sulphur*, is a mixture of two or more sulphides of ammonium. It is obtained by distilling a mixture of 1 pt. sulphur, 2 pts. sal-ammoniac, and 2 to 3 pts. quick lime. It is a dark yellow liquid, of penetrating smell: it fumes strongly in the air, or in any gas containing oxygen, not in gases free from oxygen. It is capable of taking up more sulphur, forming a syrupy fluid, which no longer fumes on contact with air.—F. T. C.

AMMONIUM. A hypothetical metal, whose composition is expressed by the formula NH^4: it is supposed to be contained in ammoniacal salts. (See AMMONIACAL SALTS, p. 188.)

AMMONIUM-AMALGAM. (p. 188.)

AMMONIUM-BASES. In very many cases, the watery solution of ammonia behaves with other bodies exactly like a solution of potash or soda. We cannot express this similarity in our chemical formulæ, if we regard liquid ammonia as a mere solution of ammonia, NH^3, in water: it only becomes comparable to the fixed alkalis when we regard it as containing a compound of ammonia with water, $NH^3.H^2O$. In order to express this relation still more precisely, Berzelius proposed to represent aqueous ammonia as containing the hydrated oxide of the compound group, NH^4,—($NH^3.H^2O = \left.\begin{matrix}NH^4\\H\end{matrix}\right\}O$), to which he gave the name *Ammonium*, and by means of which the ammonia-salts can be represented as exactly analogous to those of potassium, sodium, or the metals generally (see AMMONIUM-SALTS, p. 188). In the article AMIDES, it is shown that a very large number of bodies may be formed from ammonia, by replacing a part or the whole of its hydrogen by other radicles, simple or compound. When the hydrogen of ammonia is replaced by the alcohol-radicles (methyl, ethyl, &c.), or by other bodies which more or less resemble hydrogen in their general chemical characters, the resulting compounds (*Amines*) retain the most important property of ammonia itself, namely, the property of forming definite salts by direct union with acids. It is evident that, if it is wished to express the analogy of the salts of these derivatives of ammonia with the metallic salts, they may be represented as containing ammonium in which part of the hydrogen is replaced by other radicles: for instance, hydrochlorate of triethylamine, $NC^6H^{16}Cl$, may be viewed as chloride of triethylammonium, $[N(C^2H^5)^3H]Cl$, analogous to chloride of ammonium, $(NH^4)Cl$, and chloride of potassium, KCl.

But since only three-fourths of the hydrogen of the ammonium in ammonia-salts is derived from ammonia, the other fourth belonging to the acid, it is plain that the compounds of the derived ammonias with acids never represent ammonium-salts in which more than three-fourths of the hydrogen is replaced. But, by the combination of tertiary amines (derivatives of ammonia by the replacement of all three atoms of hydrogen by methyl, ethyl, or similar radicles), with the chlorides, bromides, or iodides of the alcohol-radicles, compounds are formed which represent ammonium-salts in which all the hydrogen is replaced by other radicles (see Amides, p. 175): *e. g.*

$$\underset{\text{Triethylamine.}}{N.(C^2H^5)^3} + \underset{\substack{\text{Iodide of}\\\text{ethyl.}}}{C^2H^5.I} = \underset{\substack{\text{Iodide of}\\\text{tetrethylium.}}}{N.(C^2H^5)^4I}$$

Notwithstanding the obvious analogy of this mode of formation to the formation of the salts of amines by the action of the iodides, &c, of alcohol-radicles on ammonia — *e. g.*:

$$NH^3 + \underset{\substack{\text{Iodide of}\\\text{ethyl.}}}{C^2H^5I} = \underset{\substack{\text{Hydriodate of}\\\text{ethylamine.}}}{N.(C^2H^5.H^3)I};$$

the seriation which connects this class of bodies with the ammonium-salts: —

$N.H \;.\; H \;.\; H \;.\; H \;.\; I,$	hydriodate of ammonia, or iodide of ammonium,
$N.C^2H^5 \;.\; H \;.\; H \;.\; H \;.\; I,$	„ ethylamine, „ ethylium,
$N.C^2H^5 \;.\; C^2H^5 \;.\; H \;.\; H \;.\; I,$	„ diethylamine „ diethylium,
$N.C^2H^5 \;.\; C^2H^5 \;.\; C^2H^5 \;.\; H \;.\; I,$	„ triethylamine „ triethylium,
$N.C^2H^5 \;.\; C^2H^5 \;.\; C^2H^5 \;.\; C^2H^5 \;.\; I,$	iodide of tetrethylium;

and the applicability of the ammonium-theory to express the nature of the salts of the amines, as pointed out above — the derivatives of the ammonium-salts by the replacement of all the hydrogen of the ammonium, nevertheless exhibit some important general differences from the salts of the amines. For example, when caustic potash or lime is added to a salt of ammonia, or of an amine, the salt is decomposed, even in the cold, and ammonia, or a derivative, is set at liberty; on the other hand, iodide of tetrethylium, or a similar compound, is not decomposed by potash; it can however be decomposed by hydrate of silver; but, even then, there is no separation of a derivative of ammonia, but hydrate of tetrethylium, $N.(C^2H^5)^4.H.O$, or a similar body, is formed:

$$\underset{\substack{\text{Iodide of}\\\text{tetrethylium.}}}{N(C^2H^5)^4I} + AgHO = \underset{\substack{\text{Hydrate of}\\\text{tetrethylium.}}}{N(C^2H^5)^4.H.O} + AgI.$$

In the first case, the hydrate of ammonium, which may be supposed to be formed in the first stage of the reaction, is decomposed into ammonia and water: in the second case, the substance which represents hydrate of ammonium is stable and has the properties of a strong alkali. This difference makes it convenient to have some general term to distinguish such bodies as hydrate of tetrethylium from such basic hydrates as decompose, at the moment of their formation, into a representative of ammonia and water. The former class of substances are therefore often spoken of as *ammonium-bases*, in contradistinction to the *amine-* or *ammonia-bases.*

The formation of the ammonium-bases is specially interesting in connection with the theory of ammonium. It is impossible to isolate the hydrate of ammonium, which, according to that theory, exists in solution of ammonia, or to obtain a corresponding compound from any of the compound ammonias; but the ammonium-bases are representatives of hydrate of ammonium, which correspond to the hydrates of potassium and sodium, not only in their formulæ, but very closely in their properties. Their concentrated solution is caustic to the touch; by evaporation, they are obtained as crystalline substances, very soluble in water, which liberate ammonia from its salts, dissolve most of the metallic oxides which are soluble in potash, and decompose compound ethers into the corresponding acid and alcohol. At a high temperature, they are decomposed, with formation of a tertiary amine:

$$\underset{\substack{\text{Hydrate of}\\\text{tetrethylium.}}}{N.(C^2H^5)^4.H.O} = \underset{\substack{\text{Triethyl-}\\\text{amine.}}}{N.(C^2H^5)^3} + \underset{\substack{\text{Ethy-}\\\text{lene.}}}{C^2H^4} + H^2O.$$

Their iodides, or similar salts, are similarly decomposed by heat:

$$\underset{\substack{\text{Iodide of}\\\text{tetrethylium.}}}{N(C^2H^5)^4I} = \underset{\substack{\text{Triethyl-}\\\text{amine.}}}{N(C^2H^5)^3} + \underset{\substack{\text{Iodide}\\\text{of ethyl.}}}{C^2H^5.I.}$$

The tertiary derivatives of phosphide, arsenide, and antimonide of hydrogen, give rise to precisely similar compounds by combination with hydriodic ethers and subsequent decomposition of the iodide so formed, by hydrate of silver. The decomposition by heat of the hydrates of the *phosphonium-bases*, differs from that of the corresponding ammonium-bases: *e. g.*

$$\underset{\substack{\text{Hydrate of}\\ \text{tetrethyl-}\\ \text{phosphonium.}}}{P(C^2H^5)^4H.O} = \underset{\substack{\text{Oxide of}\\ \text{triethylphos-}\\ \text{phine.}}}{P(C^2H^5)^3O} + \underset{\substack{\text{Hydride of}\\ \text{ethyl.}}}{C^2H^5.H.}$$

POLYAMMONIUM-BASES.—These compounds bear to the monammonium-bases just described, the same relation that the diamines and triamines bear to the monamines: they may be considered as representing two or more molecules of hydrate of ammonium in which the whole or part of the hydrogen is replaced by polyatomic radicles. As in the case of the monammonium-bases, there is a difference between the polyammonium-bases in which only part of the hydrogen is replaced, and those in which it is all replaced: the former cannot be obtained in the isolated state; the latter are stable compounds and possess strong alkaline properties. But both these classes of hydrates have been less studied, and are therefore hitherto less important, than the corresponding salts, which are for the most part equally stable, whether still containing replaceable hydrogen, or no. We shall therefore in this article treat of the polyammonium compounds generally, making no essential distinction between hydrates and other salts, or between those compounds in which the hydrogen of ammonium is wholly, and those in which it is partially replaced. Moreover, as the bodies of this class containing phosphorus and arsenic have been at least as much studied as those containing nitrogen, it will be most convenient to speak of the action of polyatomic compounds on the basic derivatives of ammonia generally, taking as special examples of the various reactions hitherto known, compounds containing nitrogen, phosphorus, or arsenic, as these or those happen to be best known.

A. ACTION OF DIATOMIC CHLORIDES, BROMIDES, OR IODIDES: —

1. *On Ammonia.*

The experiments which have been made in this direction are almost confined to the action of bromide of ethylene on ammonia. The products thus formed are the following:

Dibromide of ethylene-diammoniuum . . .	$N^2(\overset{\prime\prime}{C}{}^2H^4)H^6Br^2$
Dibromide of diethylene-diammonium . . .	$N^2(\overset{\prime\prime}{C}{}^2H^4)^2H^4Br^2$
Dibromide of triethylene-diammonium . . .	$N^2(\overset{\prime\prime}{C}{}^2H^4)^3H^2Br^2$.

These compounds, when distilled with potash, give, respectively, ethylenamine, $N^2(\overset{\prime\prime}{C}{}^2H^4)H^4$, diethylenamine, $N^2(\overset{\prime\prime}{C}{}^2H^4)^2H^2$, and triethylenamine, $N^2(\overset{\prime\prime}{C}{}^2H^4)^3$, bodies which are likewise acted on by bromide of ethylene, the final product being a substance very analogous to bromide of tetrethylium, and which is probably dibromide of tetrethylene-diammonium, $N^2(\overset{\prime\prime}{C}{}^2H^4)^4Br^2$.

2. *On Primary derivatives of ammonia, primary amines.*

Bromide of ethylene gives with ethylamine and phenylamine:

Dibromide of ethylene-diethyl-diammonium . .	$N^2(\overset{\prime\prime}{C}{}^2H^4)(C^2H^5)^2H^4Br^2$
Dibromide of diethylene-diethyl-diammonium .	$N^2(\overset{\prime\prime}{C}{}^2H^4)^2(C^2H^5)^2H^2Br^2$.

and similar phenyl-compounds.

3. *On Tertiary derivatives of ammonia.*

Just as dibasic acids can combine with one or with two atoms of ammonia, so likewise can diatomic ethers (such as chloride or bromide of ethylene, or iodide of methylene) combine with one or with two atoms of the tertiary derivatives of ammonia.[*] Thus triethylphosphine with bromide of ethylene gives the compounds —

$\left.\begin{array}{r}(C^2H^4)''Br^2\\ (C^2H^5)^3P\end{array}\right\}$	"Bromide of bromethyl-triethylphosphonium" (Hofmann).
$\left.\begin{array}{r}(C^2H^4)''Br^2\\ 2[(C^2H^5)^3P]\end{array}\right\}$	"Bromide of ethylene-hexethyl-diphosphonium" (Hofmann).

The condition of the bromine contained in these compounds is worth noticing. The addition of nitrate of silver to a solution of the first compound precipitates only half the bromine contained in it, but nitrate of silver precipitates all the bromine contained in the second. This difference is explained by Hofmann, by supposing that 1 atom of

---

[*] Bromide of ethylene and iodide of methylene combine directly with only 1 atom of the tertiary amines, but the compounds with two atoms can be obtained by the action of hydrobromic, or hydriodic ethers on ethylenamine.

bromine in the first compound is contained in the form of *bromethyl*, C^2H^4Br: his view of the constitution of the two compounds is expressed in the names quoted above. It is not, however, difficult to account for the difference in the behaviour of the two bromides without making this supposition. When we remember that the bromine in bromide of ethyl is not precipitated by nitrate of silver, but that it becomes so immediately bromide of ethyl is combined with ammonia or an analogous body, it does not seem surprising that *one* of the two atoms of bromine in bromide of ethylene should become saline (or accessible to ordinary reagents) when that body is combined with *one* molecule of a representative of ammonia, and that *both* atoms should become saline when it is combined with two molecules of an ammonia-derivative. In all compounds formed upon the model of the first compound, only 1 atom of the salt-radicle is precipitable by nitrate of silver; in all those formed upon the model of the second, both atoms are precipitable.

The following are the most important transformations of the above or similar bodies.

a. The compound $\left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P\end{matrix}\right\}$ is decomposed by heat thus:—

$$\left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P\end{matrix}\right\} = HBr + \underset{\text{Bromide of vinyl-triethylphosphonium.}}{\left.\begin{matrix}C^2H^3Br \\ (C^2H^5)^3P\end{matrix}\right\}}$$

b. When a dilute solution is treated with hydrate of silver, it loses all its bromine and gives $\left.\begin{matrix}(C^2H^4)''H^2.O^2 \\ (C^2H^5)^3P\end{matrix}\right\}$, which may be regarded as a compound of triethylphosphine with glycol. This substance is a strong base, but, as in the bromine compound, only one half of the elements combined with the ethylene, are directly replaceable by acid radicles (*e. g.* hydrochloric acid gives $\left.\begin{matrix}C^2H^4.HO.Cl \\ (C^2H^5)^3P\end{matrix}\right\}$): with bromide of phosphorus, it regenerates the original bromine-compound. In a concentrated solution, hydrate of silver gives $\left.\begin{matrix}(C^2H^4)''O \\ (C^2H^5)^3P\end{matrix}\right\}$, differing from the last substance by the elements of an atom of water. This compound may be regarded as containing oxide of ethylene and triethylphosphine, and belongs to the same class of bodies as the bases * which Wurtz obtained by the action of ammonia on oxide of ethylene:—

$$\underset{\text{Ethylene-triethylhydorphosphine.}}{\left.\begin{matrix}C^2H^4.O \\ (C^2H^5)^3P\end{matrix}\right\}} \qquad \underset{\text{Diethylene-dihydoramine.}}{\left.\begin{matrix}2(C^2H^4.O) \\ H^3N\end{matrix}\right\}} \qquad \underset{\text{Triethylene-trihydoramine.}}{\left.\begin{matrix}3(C^2H^4.O) \\ H^3N\end{matrix}\right\}}$$

c. The same compound is converted by acetate of silver at 100° C. into acetate of vinyl-triethylphosphonium, $P(C^2H^5)^3C^2H^3.C^2H^3O^2$. This reaction probably has two stages:—

$$1^\circ \quad \left.\begin{matrix}C^2H^4.Br^2 \\ (C^2H^5)^3P\end{matrix}\right\} + 2(C^2H^3AgO^2) = \left.\begin{matrix}C^2H^4.(C^2H^3O^2)^2 \\ (C^2H^5)^3P\end{matrix}\right\} + 2AgBr$$

$$2^\circ \quad \left.\begin{matrix}C^2H^4.(C^2H^3O^2)^2 \\ (C^2H^5)^3P\end{matrix}\right\} = \left.\begin{matrix}C^2H^3.C^2H^3O^2 \\ (C^2H^5)^3P\end{matrix}\right\} + C^2H^4O^2$$

If this be so, the second stage of the reaction is precisely similar to the decomposition already mentioned of the bromine-compound by heat.

d. By nascent hydrogen it is converted into bromide of tetrethylphosphonium:—

$$\left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P\end{matrix}\right\} + H^2 = \left.\begin{matrix}C^2H^5Br \\ (C^2H^5)^3P\end{matrix}\right\} + HBr$$

e. With derivatives of ammonia, it gives bodies of the type of the second compound. The following bodies have been so obtained.

$$\left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P \\ H^3N\end{matrix}\right\}, \left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P \\ CH^3.H^2N\end{matrix}\right\}, \left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P \\ C^2H^5.H^2N\end{matrix}\right\}, \left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P \\ (CH^3)^3N\end{matrix}\right\}, \left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P \\ (CH^3)^3P\end{matrix}\right\}, \left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P \\ (C^2H^5)^3P\end{matrix}\right\}, \left.\begin{matrix}C^2H^4Br^2 \\ (C^2H^5)^3P \\ (C^2H^5)^3As\end{matrix}\right\}$$

It has already been stated that bodies of this class part with all their bromine to salts of silver. Hydrate of silver gives $\left.\begin{matrix}C^2H^4.H^2.O^2 \\ 2[(C^2H^5)^3P]\end{matrix}\right\}$ and similar bodies. These are strong bases and give the corresponding salts by the action of acids. $\left.\begin{matrix}C^2H^4.H^2.O^2 \\ 2[(C^2H^5)^3P]\end{matrix}\right\}$ is decomposed by heat into $\left.\begin{matrix}C^2H^4O \\ (C^2H^5)^3P\end{matrix}\right\}$, a compound already mentioned, and oxide of

---

* As rational names for bodies deriving from the mixed type $\left.\begin{matrix}\text{[illegible]}O \\ mH^3N\end{matrix}\right\}$, namely *amic bases* and *amic acids*, the terms *hydoramines* and *hydoramides* (not to be confounded with hydramides) may be used (see further, art. NOMENCLATURE).

triethylphosphine, $P(C^2H^5)^3O$.—$\left.\begin{matrix}C^2H^4Br^2\\(C^2H^5)^3P\\(C^2H^5)^3As\end{matrix}\right\}$ is decomposed by heat into $\left.\begin{matrix}C^2H^4Br^2\\(C^2H^5)^3P\end{matrix}\right\}$ and triethylarsine, $(C^2H^5)^3As$.

B. Action of Triatomic Chlorides, Bromides, or Iodides: —

1. *On Ammonia.*

Tribromide of glyceryl, $(\overset{\prime\prime\prime}{C^3}H^5)Br^3$, gives with ammonia a base containing $NC^6H^9Br^2$, and bromide of ammonium. The reaction probably takes place according to the following stages: —

$$1^\circ \qquad C^3H^5Br^3 = C^3H^4Br^2 + HBr.$$
$$2^\circ \quad 2(C^3H^4Br^2) + NH^3 = NC^6H^9Br^2 + 2HBr,$$

the hydrobromic acid which is formed of course combining with ammonia. The first stage of the reaction is analogous to the conversion of bromide of ethylene into bromethylene by the action of alcoholic potash: the compound, $C^3H^4Br^2$ may be regarded as dibrom-propylene, or as bromide of brom-allyl, $(C^3H^4Br)'Br$. In the latter case, the product of its action on ammonia becomes $N\left\{\begin{matrix}(C^3H^4Br)'\\(C^3H^4Br)'\\H\end{matrix}\right.$ *dibrom-diallylamine.* (Maxwell Simpson).

2. *On Primary derivatives of ammonia.*

Chloroform, $(\overset{\prime\prime\prime}{C}H)Cl^3$, reacts on phenylamine, forming the hydrochlorate of a monoacid base, containing, $C^{13}H^{12}N^2$, and which may be considered as representing two molecules of phenylamine in which the radicle $(\overset{\prime\prime\prime}{C}H)$ replaces H^3; thus $\left.\begin{matrix}(\overset{\prime\prime\prime}{C}H)\\(C^6H^5)^2H\end{matrix}\right\}N^2$.

3. *On Tertiary derivatives of ammonia.*

Iodoform, $(\overset{\prime\prime\prime}{C}H)I^3$, combines with three molecules of triethylphosphine, giving $\left.\begin{matrix}CH.I^3\\3[(C^2H^5)^3P]\end{matrix}\right\}$. This compound parts with all its iodine to silver-salts, which accords with what is said above respecting the compounds of bromide of ethylene with triethylphosphine. Its solution treated with hydrate of silver does not give a corresponding hydrate, but hydrate of methyl-triethylphosphonium and oxide of triethylphosphine.

$$\begin{matrix}(\overset{\prime\prime\prime}{C}H)I^3\\3[(C^2H^5)^3P]\end{matrix} + 3AgHO = \left.\begin{matrix}CH^3.HO\\(C^2H^5)^3P\end{matrix}\right\} + 2[(C^2H^5)^3P.O] + 3AgI.$$

C. Action of Tetratomic Chlorides, Bromides, or Iodides on Derivatives of Ammonia.

Bichloride of carbon, $(\overset{iv}{C})Cl^4$, reacts on phenylamine thus: —

$$\underset{\text{3 mol. phenylamine.}}{3(C^6H^7N)} + CCl^4 = 3HCl + C^{19}H^{17}N^3.HCl.$$

The product of this reaction may be regarded as the hydrochlorate of a base deriving from three molecules of phenylamine by the substitution of $(\overset{iv}{C})$ for H^4: viz.

$$\left.\begin{matrix}(\overset{iv}{C})\\(C^6H^5)^3\\H^3\end{matrix}\right\}N^3.$$

(For details, see various papers by Hofmann, Proc. Roy. Soc. vols. ix. and x., also the Articles Phosphorus, Arsenic, Antimony.)

Ammonium-bases containing Metals.—A very large number of compounds have been obtained by treating different metallic salts with ammonia. Some of these compounds are apparently of similar constitution to the salts of the organic ammonium-bases, or to easily conceivable derivatives of them. But it is impossible to reduce the greater number of them to any consistent system, before they have themselves been more thoroughly examined, and we have more definite notions as to the atomicity of the metals contained in them. The following are examples of some of these compounds which can be written as analogous to known or conceivable organic compounds.

Metallic Compounds.	*Organic Analogues.*
$N.H^3CuCl$	$N.H^3.C^6H^5.Cl$
$NH^2(\overset{''}{Hg})Cl$	$N.H^2(C^2H^5)^2Cl.$
(or $N^2H^4(\overset{''}{Hg})^2Cl^2$(?)	$N^2H^4(C^2\overset{''}{H}{}^4)^2.Cl^2.$
$N(\overset{''}{Hg})^2Cl$	$N(C^2H^5)^4Cl.$
(or $N^2(\overset{''}{Hg})^4Cl^2$ (?)	$N^2(C^2\overset{''}{H}{}^4)^4Cl^2.$
$NH^3\overset{''}{Hg}Cl^2$	$N(CH^3)^3(C^2\overset{''}{H}{}^4)Br^2.$
$\left.\begin{array}{l}N\\O\\I\end{array}\right\{\begin{array}{l}H^3\\(\overset{''}{Hg})\\(\overset{''}{Hg})\end{array}$	$\left.\begin{array}{l}N\\O\\I\end{array}\right\{\begin{array}{l}H^3\\(C^2\overset{''}{H}{}^4)\\(C^2\overset{''}{H}{}^4).\end{array}$ (unknown.)
$NH^3(\overset{''}{Pt})Cl^2.$	$P(C^2H^5)^3(C^2\overset{''}{H}{}^4)Br^2.$
$N^2H^6(\overset{''}{Pt})Cl^2$	$P^2(C^2H^5)^6(C^2\overset{''}{H}{}^4)Br^2.$

*** $Hg = 200$

The attempts which have been made by some chemists to make formulæ for many other metallic derivatives of the ammonium-salts, by supposing ammonium capable of replacing hydrogen in ammonium, or by assuming the existence of such radicles as PtCl or Pt*O*, may be described in words used with reference to another subject, by the author of one such attempt, as "unwissenschaftliche Spielereien, die hier keine Berücksichtigung verdienen." — G. C. F.

AMNIOTIC LIQUID. (See ALLANTOIC and AMNIOTIC LIQUIDS.)

AMOIBITE. A mineral allied to nickel-glance, and probably identical with it.

AMORPHISM. (Gm. i. 102.)—Solid bodies which do not exhibit any crystalline or regular structure, even in their minutest particles, are said to be *amorphous* (α, privative, and μορφη form). Such are opal and other forms of silica, also glass, obsidian, pumice stone, bitumen, resins, coal, albuminous substances, and numerous precipitates. Such bodies have a smooth conchoidal fracture, never exhibiting a granulated appearance on the broken surface; they have no particular planes of cleavage, such as are found in crystals, but require the same amount of force to separate them in all directions: they also conduct heat equally in all directions, and never exhibit double refraction, excepting when pressed or otherwise brought into a forced state. In short, the essential character of an amorphous body is perfect uniformity of structure in every direction, each particle being similarly related to all those which surround it, the character of a fluid without its mobility, whereas in crystallised or organised* bodies, the molecular forces act with greatest energy in certain lines or axes, thereby determining an arrangement of the particles according to fixed laws, and causing the body to exhibit different degrees of tenacity, elasticity, permeability, refracting power, and conducting power for heat and electricity in different directions. It must not be assumed that a body is amorphous because it does not exhibit a regular shape in the mass: marble and loaf-sugar have no definite external form; but they consist of aggregates of minute crystals, and when broken, exhibit, not a conchoidal, but a granular fracture.

The amorphous state is by no means peculiar to certain substances, a great number of bodies being capable of existing both in the amorphous and in the crystalline state. Sulphur, when it solidifies slowly from fusion or solution, forms regular crystals, but when poured in the melted state into cold water, it solidifies in a soft, plastic, viscid mass, capable of being drawn out into threads, and exhibiting no trace whatever of crystalline structure. Phosphorus also assumes a regular crystalline form when slowly cooled from solution in bisulphide of carbon or from fusion, but when cast into moulds and quickly cooled, it forms a waxy solid, having a conchoidal fracture; and by other modes of treatment to be described hereafter, it may be reduced to a perfectly amorphous red powder. Carbon is crystalline in the diamond and in graphite; amorphous in charcoal, lamp-black, and the various other forms which it assumes when

---

* The term *amorphous* is generally used in contradistinction to *crystalline* alone; but its proper use is in opposition to *regular*, whether crystalline or organised: for organic structures exhibit many properties of which amorphous bodies, properly so called, are destitute; thus wood, according to the researches of Dr. Tyndall, exhibits three distinct axes of cleavage, permeability, elasticity, and conducting power for heat.

separated from organic bodies by imperfect combustion. Boron and silicon exhibit similar varieties. Arsenious acid, as it collects in the chimneys of furnaces in which arsenical ores are roasted, is a glassy amorphous mass; but by dissolving it in hot water or hydrochloric acid, and leaving the solution to cool, it is obtained in the crystalline form (see ARSENIC). Native sulphide of antimony, which is crystalline, may be rendered amorphous by melting it in a glass tube and plunging the tube into ice-cold water: and by melting it again and cooling slowly, the crystalline structure may be restored. Similar transformations may be effected with native sulphide of mercury, also with the minerals Vesuvian and Axinite, and certain varieties of garnet. Glass, which is perhaps the most characteristic of amorphous bodies, may be devitrified by keeping it for some time in the soft state at a high temperature: it then acquires a crystalline structure and becomes nearly opaque, forming the substance called Reaumur's porcelain. Generally speaking, rapid cooling from fusion is favourable to the assumption of the amorphous structure, while crystallisation is promoted by slow cooling, the particles then having time to arrange themselves in a definite manner. It is also true to a great extent that bodies which pass at once from the perfectly fluid to the solid state, — water, for instance, — crystallise on solidifying, whereas those which pass through the viscous form, like glass, solidify in the amorphous state; to this, however there are some striking exceptions: thus sugar, the solution of which is extremely viscid when concentrated, solidifies by slow evaporation in crystals of great size and regularity.

The passage from the amorphous to the crystalline state sometimes takes place spontaneously, the body all the while remaining solid. Vitreous arsenious acid, which, when recently prepared, is perfectly transparent, becomes turbid when left to itself for a few months, and subsequently white and opaque. Sugar which has been melted in the form of barley-sugar is in the vitreous state, but after a while acquires a crystalline structure and becomes opaque. These phenomena show that the molecules of bodies, even in the solid state, possess a certain freedom of motion.

The change from the amorphous to the crystalline condition, or the contrary, is generally accompanied by an alteration of other physical properties. Bodies are for the most part denser and less soluble in the crystalline than in the amorphous state, and have less specific heat. Vesuvian, which crystallises in square prisms of specific gravity about 3·4, and garnet, which occurs in rhombic dodecahedrons of specific gravity 3·63, both form by fusion and subsequent cooling, transparent glasses whose specific gravity is about 2·95, so that, in passing from the crystalline to the amorphous state, garnet suffers an expansion of about $\frac{1}{5}$ and vesuvian of $\frac{1}{8}$. The glass also dissolves readily in hydrochloric acid, whereas the crystallised minerals are quite insoluble. Many other crystalline siliceous minerals not soluble in acids become so by fusion, probably from the same causes. Quartz, which is crystallised silica, is much harder and denser than opal, which is the same chemical compound in the amorphous state. Quartz-powder dissolves but very slowly in boiling potash-ley and is quite insoluble in that liquid when cold, whereas pulverised opal is gradually dissolved at ordinary temperatures and in a few minutes at the boiling heat. A remarkable exception to the general rule is, however, presented by arsenious acid, which is both less dense and more soluble in the crystalline than in the vitreous state.

Another difference first observed by Graham is, that bodies have greater specific heat in the amorphous than in the crystalline state. Ordinary phosphate of sodium (PO^4Na^2H) solidifies from fusion in the vitreous state; the corresponding arsenate in the crystalline form: now the former in solidifying gives out perceptibly less heat in a given time than the latter, a greater portion of the latent heat of fusion appearing to be retained by it. Connected with this law is the remarkable phenomenon of incandescence which many bodies exhibit when their temperature is gradually raised. Hydrated oxide of chromium if heated merely to the point at which it parts with its water, remains nearly as soluble in acids as before, but if the heat be raised nearly to redness, the oxide suddenly becomes incandescent, and is afterwards found to be much denser and nearly insoluble in acids. Similar phenomena are exhibited by alumina and zirconia. Gadolinite (silicate of yttrium) which in its natural state exhibits a conchoidal fracture and obsidian-like appearance, becomes vividly incandescent when moderately heated, and is afterwards found to dissolve but very imperfectly in hydrochloric acid, although before ignition it is very easily soluble; its density increases at the same time, though its absolute weight remains unaltered. Vitreous arsenious acid also sometimes exhibits incandescence in passing from the amorphous to the crystalline state. When a solution of the vitreous acid in hot hydrochloric acid is left to cool in the dark, the formation of every crystal is accompanied by a flash of light; but a solution of the crystalline acid, under the same circumstances, exhibits no light whatever.

AMPELIC ACID. An acid isomeric with salicylic acid, $C^7H^6O^3$, obtained in small quantity by the action of strong nitric acid upon those schist-oils which boil between 80° and 150° C. Picric acid and a flocculent matter are formed at the same time. Ampelic acid is a white substance, without odour, nearly insoluble in cold water, but little soluble in boiling water. Its solution reddens litmus. Boiling alcohol and ether dissolve it readily, and on cooling deposit it in the form of a powder, having a scarcely perceptible crystalline character. Saturated with ammonia, it exhibits the following reactions. With chloride of calcium, a white precipitate, which does not form when hot; the mixture deposits crystals on cooling. No precipitate with the chlorides of barium, strontium, manganese, or mercury. A green precipitate with acetate of nickel; blue with acetate of copper; and white with acetate and nitrate of lead. (Laurent, Ann. Ch. Phys. [2] lxiv. 325.)

AMPELIN. A substance resembling creosote, obtained from that portion of schist-oil which boils between 200° and 280° C. The oil is shaken up several times with strong sulphuric acid, then mixed with $\frac{1}{15}$ or $\frac{1}{20}$ of its bulk of aqueous potash, and the liquid is left at rest for a day. The lower watery layer of liquid is then separated from the upper oily layer, and shaken up with dilute sulphuric acid, and the oil which rises to the surface is removed with a pipette, and gently heated with 10 or 20 times its bulk of water, which dissolves the ampelin, leaving a small quantity of oil. On separating this oil, and adding a few drops of sulphuric acid to the aqueous solution, the ampelin rises to the surface in the form of an oil, having a slight brownish tint.

Ampelin dissolves in 40 or 50 times its volume of water, and is separated from the solution by a few drops of sulphuric or nitric acid, even when very dilute. Potash, soda, and their carbonates render the solution slightly turbid at the first instant, but it recovers its transparency when heated. Carbonate of ammonium renders it permanently turbid. Chloride of sodium or chloride of ammonium added to a solution of ampelin in caustic potash or carbonate of potassium separates the ampelin, which is then not redissolved on heating the liquid. Ampelin dissolves in alcohol, and in all proportions in ether. It does not solidify at —20° C. It is decomposed by distillation, yielding water, a light oil, and charcoal. Boiling nitric acid attacks it strongly, producing oxalic acid, and an insoluble viscous substance. (Laurent, Ann. Ch. Phys. [2] lxiv. 321.)

AMPHIBOLE and **AMPHIBOLITE.** (See HORNBLENDE.)

AMPHID SALTS. A name applied by Berzelius to salts which, according to his views, are compounds of two *oxides*, *sulphides*, *selenides*, or *tellurides*, *e. g.* sulphate of copper, $Cu^2O.SO^3$; sulpharsenate of potassium, $3K^2S.As^2S^5$; sulphantimonate of sodium, $3Na^2S.Sb^2S^5$, &c.,—such salts containing three ultimate elements—in contradistinction to the haloid-salts, namely, the chlorides, bromides, iodides, &c., which are binary compounds of the first order, containing only two elements, such as chloride of sodium, NaCl, iodide of silver, AgI, &c. It is evident that the so-called amphid salts are those which belong to the *water-type*, *e. g.* nitrate of copper, $Cu^2O.N^2O^5 = O\left\{\begin{matrix}NO^2\\Cu\end{matrix}\right.$ Sulpharsenate of potassium, $3K^2S.As^2S^5 = S^3\left\{\begin{matrix}(AsS)'''\\K^3\end{matrix}\right.$, whereas the haloid-compounds belong to the type HH or HCl.

AMPHIGENE. See LEUCITE.

AMPHILOGITE. See DIDRIMITE.— **AMPHODELITE.** See ANORTHITE.

AMYGDALIC ACID, $C^{20}H^{28}O^{13}$.—Produced by the metamorphosis of amygdalin under the influence of alkalis. Amygdalin dissolves in cold baryta-water without decomposition, but on boiling the mixture, ammonia is disengaged. The ebullition is continued until the liberation of ammonia ceases altogether; a current of carbonic acid is then passed through the liquid, to precipitate the excess of baryta; and the acid is finally liberated from the barium-salt by cautious precipitation with sulphuric acid. It is a slightly acid liquid, which dries up to a gummy mass,—insoluble in absolute alcohol, cold or boiling, and insoluble in ether. Boiled with a mixture of peroxide of manganese and sulphuric acid, it yields formic and carbonic acids and hydride of benzoyl. Its salts are not well defined; they are more or less soluble in water. (Liebig and Wöhler, Ann. Ch. Pharm., lxiv. 185.)

Amygdalate of ethyl is obtained, according to Wöhler, by dropping a mixture of alcohol and amygdalin into hydrochloric acid gas. (Wöhler, Ann. Ch. Pharm. lxvi. 240.)

AMYGDALIN, $C^{20}H^{27}NO^{11} + 3H^2O$.—A crystalline principle existing in bitter-almonds, the leaves of the *Cerasus lauro-cerasus*, and many other plants, which by distillation yield hydrocyanic acid. The bitter-almond oil and hydrocyanic acid do not exist ready formed in these plants, but are the result of the decomposition of amygdalin under the influence of emulsin, a nitrogenised fermentable principle existing with it in the plant.

To prepare amygdalin,—the oil is expressed from the paste of bitter-almonds, and the residual mass extracted with boiling alcohol. This alcoholic solution is rendered turbid by the presence of globules of oil, which are allowed to collect and separated by decantation; it is then evaporated to half its original volume, and the amygdalin separated by the addition of ether, in which it is insoluble. The precipitated amygdalin is pressed between folds of bibulous paper, washed with ether, and finally crystallised from concentrated boiling alcohol. (Liebig and Wöhler.)

Amygdalin crystallises in white scales having a pearly lustre, insoluble in ether, but very soluble in water, from which it crystallises in thin transparent prisms containing 3 atoms of water of crystallisation. Its aqueous solution has a slightly bitter taste. It deflects the plane of polarisation of a ray of light to the left: $[a] = 35{\cdot}51$. The change which amygdalin undergoes by the action of emulsin (and other albuminous vegetable principles), is expressed by the following equation:

$$\underset{\text{Amygdalin.}}{C^{20}H^{27}NO^{11}} + 2H^2O = \underset{\substack{\text{Hydride}\\\text{of benzoyl.}}}{C^7H^6O} + \underset{\substack{\text{Hydro-}\\\text{cyanic}\\\text{acid.}}}{CNH} + \underset{\text{Glucose.}}{2C^6H^{12}O^6}$$

By distillation with nitric acid, or other oxidising agents, it is resolved into ammonia, hydride of benzoyl, benzoic, formic, and carbonic acids. Caustic alkalis convert it into amygdalic acid.

It is a neutral body, forming compounds neither with acids nor with alkalis.

AMYL, C^5H^{11}, or $C^{10}H^{22}$. (Gm. xi. pp. 1—83; Gerh. ii. pp. 675—708).—The fifth term of the series of alcohol-radicles, C^nH^{2n+1}. The alcohol in an impure state (potato-fusel oil), appears to have been first noticed by Scheele; and has been investigated, together with its derivatives, by Pelletan (J. Chim. med. i. 76, also Ann. Ch. Phys. [2] xxx. 200), Dumas (Ann. Ch. Phys. [2] lvi. 314; Dumas and Stas, Ann. Ch. Phys. [2] lxxiii. 128); Cahours (Ann. Ch. Phys. [2] lxx. 81, lxv. 193); and Balard, Ann. Ch. Phys. [3] xii. 294). The radicle itself was isolated by Frankland in 1849. (Chem. Soc. Qu. J. iii. 307; Ann. Ch. Pharm. lxxiv. 41.)

Amyl in the free state, $C^{10}H^{22} = C^5H^{11}.C^5H^{11}$, is prepared by the action of zinc-amalgam upon iodide of amyl, the reaction being completed by the addition of potassium (Frankland).—2. By the action of sodium upon iodide of amyl (Wurtz).—3. By the electrolysis of caproate of potassium (Brazier and Gossleth).—4. By the destructive distillation of certain kinds of coal (Greville Williams).

(1.) Pasty zinc-amalgam is brought into the copper cylinder used in the preparation of zinc-ethyl (see ETHYL): the cylinder is then half filled with granulated zinc and iodide of amyl is added. After gently warming to expel the air, the cylinder is closed and heated for several hours at about 170° C. After cooling, it is opened and potassium is added (about $\frac{1}{20}$th by weight of the iodide of amyl employed). The cylinder is again closed and heated for an hour at the same temperature. To obtain the amyl, the cylinder is heated in a water-bath at 80° C., whereupon amylene and hydride of amyl pass over. On applying the heat of a naked flame, amyl distils over, and may be purified by one rectification. (Frankland.)

(2.) Iodide of amyl is warmed with sodium, and distilled; the product again distilled from sodium and rectified, the portion which passes over at 158° C. being collected apart. (Wurtz, Ann. Ch. Phys. [3] xliv, 275.)

(3.) A concentrated solution of caproate of potassium is submitted to the electrolytic action of six zinc-carbon elements, the platinum poles being separated by a porous diaphragm. Amyl collects upon the surface of the liquid surrounding the negative pole: it is distilled from alcoholic caustic potash and washed with water. (Brazier and Gossleth, Chem. Soc. Qu. J. iii. 221.)

(4.) Bog-head naphtha is submitted to fractional rectification, the portion boiling between 154°—169° C. being collected apart, and the product thus obtained is submitted to the action of fuming nitric acid, the action of the acid being checked by cold. The mixture on standing separates into two layers, the upper of which is again shaken with nitric acid. The product which has remained unacted upon is washed with caustic soda and water successively, dried with solid caustic potash, and distilled over sodium. The resulting liquid is again rectified at 157°—160° C. (C. Greville Williams, Phil. Trans. 1857, 447.)

Amyl is a transparent colourless liquid, of agreeable smell and burning taste. Specific gravity, 0·77 at 11° C.—Boiling-point 155°—159° C. Vapour-density 4·90. It is miscible with alcohol, immiscible with water. Amyl is not acted upon by fuming sulphuric acid; it is slowly attacked by nitric and nitro-sulphuric acids, and decomposed after long digestion with pentachloride of phosphorus.

BROMIDE OF AMYL.—Prepared by the action of bromine and phosphorus upon amylic alcohol (Cahours, Ann. Ch. Phys. [2] lxx. 98). In three flasks are placed respectively 15 pts. of amylic alcohol, $2\frac{1}{2}$ pts. of bromine, and 1 pt. of phosphorus. A little of the bromine is added to the amylic alcohol, and the latter is poured upon and digested with the phosphorus to decoloration. It is then poured into its own flask, and a little more bromine is added. The process is repeated, and the final product is washed with water, dried, and rectified.

Bromide of amyl is a transparent colourless liquid, heavier than water. It has an alliaceous odour and sharp taste. It is soluble in alcohol, insoluble in water. Decomposes by boiling with alcoholic caustic potash.

CHLORIDE OF AMYL, $C^5H^{11}Cl$.—Obtained by the action of strong hydrochloric acid upon amylic alcohol (Balard, Ann. Ch. Phys. [3] xii. 294); also by the action of pentachloride of phosphorus upon amylic alcohol. (Cahours.)

Preparation.—1. Amylic alcohol is heated in a retort to 110° C., a rapid current of hydrochloric acid being passed through the tubulus into the amylic alcohol; the chloride of amyl as it is formed distils over. When the retort is nearly empty the distillate is poured back, and the same process repeated (Guthrie). The product is then shaken with strong hydrochloric acid, in which amylic alcohol is soluble, chloride of amyl insoluble,—then with water.

2. Amylic alcohol is distilled with its own weight of pentachloride of phosphorus, washed, dried, and rectified.

Chloride of amyl is a colourless, transparent, neutral liquid, of agreeable odour. It boils at 101° C. Vapour-density, 3·8. Burns with a luminous flame bordered with green.

Chlorine acts upon chloride of amyl, giving rise to substitution-products, which go as far as $C^5H^3Cl^8Cl$.

CYANIDE OF AMYL. See CYANIDES.

HYDRATE OF AMYL, or AMYL-ALCOHOL, $C^5H^{12}O = \left.\begin{matrix}C^5H^{11}\\ H\end{matrix}\right\}O$ [or $C^{10}H^{11}O^2 = C^{10}H^{11}O.HO$].—*Amylate of Hydrogen. Hydrate of Amyl. Hydrate of Pentyl. Hydrated Oxide of Amyl. Fusel-oil.*—This alcohol seems invariably to accompany ethylic alcohol (see ALCOHOLS, p. 97) when the latter is formed by fermentation. The conditions of its formation are unknown; it seems, however, to occur in largest quantity in those liquids which remain most alkaline during fermentation. In the distillation of vegetable juices which have been fermented, the latter portions of the distillate contain water, ethylic, propylic (?) butylic and amylic alcohols, besides the acids and aldehydes of these alcohols and probably higher fatty acids and aldehydes. To obtain the pure amylic alcohol from the crude product, it is shaken several times with hot milk of lime, decanted, dried over chloride of calcium, and rectified at 132° C.

Amylic alcohol is a transparent colourless liquid having a peculiar odour (the peaty smell of whisky is due to its presence in small quantities), which causes coughing, and burning taste. It burns with a white smoky flame. Solidifies at about − 22° C. Specific gravity 0·811 at 19° C. Boiling-point 132° C. Vapour-density 3·147. Soluble in common alcohol and ether, nearly insoluble in water. It dissolves small quantities of sulphur and phosphorus.

According to Pasteur (Compt. rend. xli. 296), ordinary amylic alcohol is a mixture of two amylic alcohols identical in chemical composition and vapour-density, but differing in their optical properties, one of them turning the plane of polarisation of a ray of light to the left, while the other is opticially inactive. A difference of solubility in some of the salts obtained from the mixed alcohols, furnishes the means of their separation; the active amyl-sulphate of barium is $2\frac{1}{2}$ times more soluble in water than the corresponding inactive salt. The optical rotatory power of amylic alcohol varies, on account of its being a variable mixture of these two modifications. This difference in the two amylic alcohols is said to be traceable in some other of their derivatives, *e. g.* caproic acid prepared from active cyanide of amyl, rotates the plane of polarisation. (Wurtz.)

Decompositions of Amyl-alcohol.—1. By *heat.* The vapour of amyl-alcohol passed through a glass tube heated to dull redness, is resolved into tritylene (propylene) marsh-gas and other hydrocarbons. (Reynolds.)

2. By *oxidation.*—Amyl-alcohol is difficult to set on fire, and burns with a white smoky flame. In contact with the air at ordinary temperatures, it is very slowly oxidised and acquires a slight acid reaction. The oxidation is greatly accelerated by the presence of platinum-black, the amyl-alcohol being then converted into valeric acid:

$$C^5H^{12}O + O^2 = C^5H^{10}O^2 + H^2O.$$

Amyl-alcohol distilled with a mixture of sulphuric acid and peroxide of manganese or bichromate of potassium, yields valeric aldehyde, valeric acid, and valerate of amyl. The same products, together with nitrite of amyl and hydrocyanic acid, are formed by the action of nitric acid. Amyl-alcohol is also converted into valeric acid by heating it to 220° C. with a mixture of lime and hydrate of potassium, hydrogen gas being evolved:

$$\underset{\text{Amyl-alcohol.}}{C^5H^{12}O} + KHO = \underset{\text{Valerate of potassium.}}{C^5H^9KO^2} + 4H.$$

3. By *sulphuric acid.*—Amyl-alcohol mixes readily with strong sulphuric acid, forming a red liquid, which contains amylsulphuric acid, $SO^4.C^5H^{11}.H$, as well as free sulphuric acid. On distilling the mixture, the amyl-alcohol is dehydrated, and amylene, C^5H^{10} passes over, together with the polymeric compounds, $C^{10}H^{20}$ and $C^{20}H^{40}$, and perhaps also amylic ether, $(C^5H^{11})^2O$; at the same time, however, a portion of the alcohol is oxidised and converted into valeric aldehyde and valeric acid, sulphurous acid being evolved and a black pitchy mass remaining in the retort.

4. With *phosphoric acid*, amyl-alcohol yields amyl-phosphoric acid, $PO^4.C^5H^{11}.H^2$.—Distilled with phosphoric anhydride, it is converted into amylene and its multiples.

5. *Trichloride of phosphorus* converts amyl-alcohol into phosphite of amyl, amylphosphorous acid, chloride of amyl, and hydrochloric acid:

$$3(C^5H^{11}.H.O) + PCl^3 = \underset{\text{Phosphite of amyl.}}{PO^3.(C^5H^{11})^2.H} + C^5H^{11}Cl + 2HCl.$$

$$\text{and} \quad 3(C^5H^{11}.H.O) + PCl^3 = \underset{\text{Amylphosphorous acid.}}{PO^3.C^5H^{11}.H^2} + 2C^5H^{11}Cl + HCl.$$

6. With *pentachloride of phosphorus*, amyl-alcohol forms chloride of amyl, hydrochloric acid, and chlorophosphoric acid, or, when the amyl-alcohol is in excess, diamylphosphoric acid:

$$C^5H^{11}.H.O + PCl^5 = C^5H^{11}Cl + HCl + \underset{\text{Chlorophosphoric acid.}}{POCl^3}$$

$$\text{and } 9(C^5H^{11}.H.O) + 2PCl^5 = 5C^5H^{11}Cl + 5HCl + 2\underset{\text{Diamylphosphoric acid.}}{[PO^4.(C^5H^{11})^2.H]} + H^2O.$$

7. *Chlorine-gas* is absorbed in large quantity by amyl-alcohol and forms chloramylal, a compound homologous with chloral.—8. Amyl-alcohol absorbs *hydrochloric acid gas* and mixes with the concentrated aqueous acid; on heating the mixture chloride of amyl is formed.—9. It dissolves, with the aid of heat, in a concentrated aqueous solution of *chloride of zinc*, forming a liquid which boils at 130°C., and yields a distillate of amylene and its multiples.—10. Distilled with *phosphorus* and *bromine* or *iodine*, it yields bromide or iodide of amyl.—11. Distilled with *fluoride of boron*, or *fluoride of silicon*. it yields amylene and its multiples, but little or no oxide of amyl.—11. *Phosgene gas* is abundantly absorbed by amyl-alcohol, forming chloroformate of amyl, and the liquid when distilled yields carbonate of amyl (**Medlock**) [*with evolution of phosgene* (?)]

$$C^5H^{11}.H.O + \underset{\text{Phosgene.}}{COCl^2} = \underset{\text{Chloroformate of amyl.}}{CClO^2.C^5H^{11}} + HCl.$$

$$\text{and} \quad 2(CClO^2.C^5H^{11}) = \underset{\text{Carbonate of amyl.}}{CO^3.(C^5H^{11})^2} + COCl^2 \quad [?]$$

Carbonate of amyl is also obtained by adding water to the solution of phosgene in amyl-alcohol (**Medlock**):

$$2(CClO^2.C^5H^{11}) + H^2O = CO^3.(C^5H^{11})^2 + 2HCl + CO^2.$$

21. *Disulphide of carbon*, in presence of *potash*, converts amyl-alcohol into amylsulphocarbonic or amylxanthic acid (p. 206).—13. *Chloride of cyanogen* is rapidly absorbed by amyl-alcohol, and forms products similar to those which it yields with ethyl-alcohol.

$$\underset{\text{Amyl-alcohol.}}{C^5H^{12}O} + CNCl + H^2O = \underset{\text{Amyl-urethane.}}{C^6H^{13}NO^2} + HCl.$$

14. Potassium (and sodium) decomposes amyl-alcohol in the same manner as ethyl alcohol, forming amylate of potassium, $C^5H^{11}KO$ with evolution of hydrogen.

Amyl-alcohol combines with a few metallic chlorides in the same manner as ethyl-alcohol. With *chloride of calcium* and *dichloride of tin*, it forms crystalline compounds which are decomposed by water. It dissolves in caustic potash and soda.

HYDRIDE OF AMYL, $C^5H^{11}.H$.—Iodide of amyl is heated with zinc and its own volume of water for a few hours to 142° C. in a copper cylinder (see zinc-ethyl), and the contents are distilled from a water bath at 60°. The distillate consists principally of amylene and hydride of amyl. The mixture is left for 24 hours in contact with caustic potash, and again rectified from a water-bath at 35°. The distillate is immersed in a freezing mixture and treated with a mixture of anhydrous and fuming sulphuric acid, which retains the amylene. Lastly, the hydride of amyl is distilled from a water-bath (Frankland, Ann. Ch. Pharm. lxxiv. 41). Colourless transparent liquid, having a pleasant odour. Specific gravity 0·638, at 14° C. Boiling-point 30° C. Vapour-density 2·382.

Iodide of Amyl, $C^5H^{11}I$.—Prepared by the action of iodine and phosphorus upon amylic alcohol (Cahours, Ann. Ch. Phys. [2] lxx. 81). Four parts of iodine are placed in one flask, and excess of phosphorus in another. Seven parts of moist amylic alcohol are poured upon the iodine, the liquid shaken till opacity is produced, then poured upon the phosphorus and digested till the colour is removed—again poured upon the iodine, and so on, till all the iodine is exhausted. The nearly colourless product so obtained, is washed with slightly alkaline water, dried over chloride of calcium and rectified. The latter portions are the purest.

Iodide of amyl is a colourless transparent liquid of faint odour and pungent taste. Specific gravity 1·511 at 11° C. Boiling-point 146°. Vapour-density 6·675. It turns brown on exposure to light.

Oxide of Amyl, $C^{10}H^{22}O = (C^5H^{11})^2O$ [or *$C^{10}H^{11}O$*]. — *Amylic ether. Amylate of Amyl.* — Prepared by the action of sulphuric acid on amyl-alcohol. Strong sulphuric acid is heated to 150° C. in a retort. and amyl-alcohol allowed to enter slowly through the tubulus; the distillate is then shaken with carbonate of sodium, washed and rectified.—2. By the action of amylate of potassium on iodide of amyl. Amylate of potassium is digested in a retort connected with an inverted condenser, with an equivalent quantity of iodide of amyl, and the product is distilled and rectified.—3. By the dry distillation of amylsulphate of calcium (Kekulé). Oxide of amyl boils at about 180° C. It is colourless and of agreeable odour.

Oxide of Amyl and Ethyl, $C^7H^{16}O = C^2H^5.C^5H^{11}.O$. *Amylate of Ethyl, Ethylate of Amyl, Ethylamylic Ether.* Prepared by the action of amylate of potassium upon iodide of ethyl, or of iodide of amyl upon ethylate of potassium. (Williamson, Chem. Soc. Qu. J. iv. 103, 234.)—(1.) A known weight of potassium is dissolved in absolute alcohol in a tubulated retort; iodide of amyl is added in sufficient quantity for there to be rather less than 1 at. of iodine for every at. of potassium in the ethylate of potassium; the retort is connected with an inverted condenser; and the contents are digested for some time. After distillation, water is added, and the liquid which separates out is dried and rectified.—(2.) Iodide of ethyl is added to a hot solution of potash in amylic alcohol, digested &c., as in 1 (Guthrie). Amylate of ethyl is a colourless transparent liquid of agreeable odour, similar to that of sage. It is lighter than water. Boiling-point 112° C. Vapour-density 4·04.

Amylate of Methyl, or *Methylate of Amyl*, $C^6H^{14}O = CH^3.C^5H^{11}.O$, is prepared in the same manner as (1) amylate of ethyl (Williamson). Boils at 92° C. Vapour-density 3·74.

Amylate of Potassium, $C^5H^{11}KO$. — On bringing freshly cut potassium into dry amylic alcohol, the potassium is dissolved and hydrogen is evolved. To obtain this body in a state of purity, the action is aided by heat until the mass becomes viscid. Any globules of metal which have remained unacted upon are removed, and the product is poured upon a cold slab, and allowed to solidify. It is then strongly pressed between many folds of bibulous paper to remove the unaltered amylic alcohol.

Amylate of potassium is a crystalline white body, soapy to the touch, and alkaline to the taste. It is soluble in the alcohols. By water it is instantly converted into amylic alcohol and hydrate of potassium.

Amylate of sodium, $C^5H^{11}NaO$. Closely resembles amylate of potassium.

Sulphides of Amyl. *Protosulphide of Amyl.* $(C^5H^{11})^2S$ or $C^{10}H^{22}S$.—Equivalent quantities of amylsulphate and monosulphide of potassium are intimately mixed in a retort (by solution and evaporation) and distilled (Balard, Ann. Ch. Phys. [3] xii. 248). Colourless liquid of offensive odour. Boiling-point 216° C. Vapour-density 6·3.

Disulphide of Amyl, $C^5H^{11}S$.—Obtained by distilling together amylsulphate and disulphide of potassium (O. Henry, Ann. Ch. Phys. [3] xxv. 246). Amber-coloured liquid. Boiling at about 250°. Specific gravity ·918 at 18° C.

Sulphide of Amyl and Hydrogen: Amyl-mercaptan, $C^5H^{11}.H.S$ [or *$C^{10}H^{11}S.HS.$*] Prepared by saturating caustic potash with sulphuretted hydrogen, adding the product to crude amylsulphate of potassium (prepared by mixing equal weights of amylic alcohol and sulphuric acid, neutralising with carbonate of potassium and filtering) and distilling from a capacious retort in a chloride of calcium bath. The oily drops in the distillate are washed, dried, and rectified (Kreutzsch, J. pr. Chem. xxxi. 1). Colourless liquid of intolerable odour. It is soluble in alcohol and ether, but insoluble in water. Specific gravity 0·845 at 0° C. Boiling-point about 120° C. Vapour-density 3·631. It combines with metallic oxides.

Amylmercaptide of mercury is obtained as a colourless liquid on bringing amylmercaptan in contact with mercuric oxide. The mixture solidifies to a solid mass on cooling. The compound is insoluble in water, but soluble in boiling alcohol. The other amylmercaptides are not distinctly known.

Sulphide of Carbonyl, Amyl, and Hydrogen. Amylsulphocarbonic acid. Amylxanthic acid. $C^6H^{12}S^2O = \left.\begin{array}{c}(CO)''\\ C^5H^{11}.H\end{array}\right\} S$.—The free acid is prepared from the potassium-salt by treating the aqueous solution of the latter with dilute hydrochloric acid (Balard, Ann. Ch. Phys. [3] xii. 307). Light yellow oily liquid, of penetrating odour, heavier than water, acid to test paper. It is quickly decomposed by water.

Amylxanthate of potassium, $C^6H^{11}.K.S^2O$.—A cold saturated solution of hydrate of potassium in amylic alcohol, is treated with bisulphide of carbon until the alkaline reaction has disappeared, and the yellow crystals of the potassium-salt which separate out on cooling, are washed with ether, and dried between blotting paper.

The ethyl and methyl salts of amylxanthic acid, are formed by digesting equivalent quantities of ethylsulphate or methylsulphate of potassium, with amylsulphocarbonate of potassium. They are oily liquids lighter than water. (Johnson, Chem. Soc. Qu. J. v. 142.)

Dioxysulphocarbonate of Amyl, $C^6H^{11}S^2O$.—The compound so-called, which contains 1 at. hydrogen less than amylxanthic acid, is produced by the action of iodine on amylxanthate of potassium. It is an oily liquid which boils at 187° C, undergoing decomposition at the same time, and yielding among other products amylxanthate of amyl, $CS^2O.(C^5H^{11})^2$. Digested with aqueous ammonia, it yields *amylxanthate of ammonium*, and *xanthamylamide* or *sulphocarbamate of amyl*, $\left.\begin{array}{r}(CS)''H^2\\ C^5H^{11}\end{array}\right\}\begin{array}{l}N\\ O\end{array}$

$$\underbrace{2C^6H^{11}S^2O}_{\text{Dioxysulpho-carbonate of amyl.}} + 2NH^3 = \underbrace{CS^2O.C^5H^{11}.NH^4}_{\text{Amylxanthate of ammonium.}} + \underbrace{C^6H^{13}NSO}_{\text{Xanthamylamide.}} + S.$$

The last mentioned compound, *xanthamylamide*, is a yellow neutral oil, which boils at 184° C. but not without decomposition, being resolved by distillation into amylmercaptan and cyanuric acid:

$$3C^6H^{13}NSO = 3C^5H^{12}S + C^3N^3H^3O^3.$$

Heated on platinum foil, it burns with a yellow luminous flame, giving off white vapours. Boiled with hydrate of barium, it is resolved into amyl-alcohol and sulphocyanide of barium:

$$C^6H^{13}NSO + BaHO = C^5H^{12}O + CNSBa + H^2O;$$

similarly with potash. It is decomposed by chlorine and by nitric acid.

Xanthamylamide is insoluble in water, but dissolves readily in alcohol and ether. It unites with chloride of mercury, forming the compound $C^6H^{13}NSO.4HgCl$, which crystallises in white feathery crystals. With dichloride of platinum dissolved in water, it forms a yellow precipitate. (M. W. Johnson, Chem Soc. Qu. J. v. 142.)

Amysulphocarbamic acid, $C^6H^{13}NS^2$ (see next page).

TELLURIDE OF AMYL, or TELLURAMYL, $(C^5H^{11})^2.Te$. has been obtained in an impure state by distilling telluride of potassium with amylsulphate of calcium. It is a liquid having a strong disagreeable odour, and boiling at about 198° C. but decomposing at the same time, and depositing tellurium in small shining prisms. By exposure to the air it is converted into a white mass. The nitrate of telluramyl is a colourless heavy oil, obtained by heating telluramyl with moderately strong nitric acid. Treated with the bromide, chloride, or iodide of hydrogen or sodium, it yields the corresponding compounds of telluramyl in the form of viscid heavy oils. The chloride treated with oxide of silver, yields *oxide of telluramyl* in the form of an oily liquid soluble in water, and so strongly alkaline that it separates ammonia from salammoniac. It forms a crystalline salt with sulphuric acid. (Wöhler and Dean, Ann. Ch. Pharm. xcvii. 1.)—F. G.

AMYLAMINES:

AMYLAMINE, $C^5H^{13}N = C^5H^{11}.H^2.N$. *Amylammonia, Amylia.*—This organic base is formed: (1.) By heating cyanate or cyanurate of amyl with caustic potash (Wurtz, Ann. Ch. Phys. [3] xxx. 447):

$$\underbrace{CNO.C^5H^{11}}_{\text{Cyanate of amyl.}} + \underbrace{2KHO}_{\text{Hydrate of potassium.}} = \underbrace{C^5H^{13}N}_{\text{Amylamine.}} + \underbrace{CO^3K^2}_{\text{Carbonate of potassium.}}.$$

(2.) In the destructive distillation of animal substances (Anderson).—(3.) By heating amylsulphate of potassium with alcoholic ammonia to 250° C. (Berthelot).—(4.) By the dry distillation of leucine, carbonic anhydride being at the same time evolved (Schwanert, Ann. Ch. Pharm. cii. 221):

$$\underbrace{C^6H^{13}NO^2}_{\text{Leucine.}} = \underbrace{C^5H^{13}N}_{\text{Amylamine.}} + CO^2$$

Also by carefully distilling a solution of horn in strong caustic potash, leucine being then formed and afterwards decomposed as above (Schwanert).—(5.) By the action of caustic potash on flannel, tetrylamine being also found among the products. (Gr. Williams, Chem. Gaz. 1858, 310.)

Preparation.—Cyanate or cyanurate of amyl (obtained by distilling cyanate of potassium with amylsulphate of potassium) is distilled with strong caustic potash; the distillate is neutralised with hydrochloric acid, evaporated and recrystallised; and the hydrochlorate of amylamine decomposed by distillation from lime and rectified over hydrate of barium. Colourless liquid. Specific gravity 0·75 at 18° C. Boiling-point 94° C. Amylamine precipitates most metallic oxides which are precipitable by ammonia; it redissolves alumina.

Carbonate of amylamine is formed as a crystalline solid, when its base is exposed to the carbonic acid of the air.—*Hydrobromate of amylamine*, $C^5H^{13}N.HBr$, or *bromide of amylium*, $C^5H^{14}NBr$, is formed by adding hydrobromic acid to the base.—*Hydrochlorate of amylamine*, $C^5H^{13}N.HCl$ or *chloride of amylium*, $C^5H^{14}NCl$, forms with dichloride of platinum a double salt, $C^5H^{14}NCl.PtCl^2$, which is soluble in boiling water.

Amylsulphocarbamate of Amylium, $C^{11}H^{26}N^2S^2 = \left.\begin{matrix}(CS)''.H.C^5H^{11}\\ N(H^3.C^5H^{11})\end{matrix}\right\}\begin{matrix}N\\ S\end{matrix}$, is produced by the union of 2 molecules of amylamine with 1 molecule of bisulphide of carbon: ($C^{11}H^{26}N^2S^2 = 2C^5H^{13}N + CS^2$). The mixture of the two substances becomes warm, and on cooling deposits the compound in white shining scales, insoluble in water and in ether, but easily soluble in alcohol. At 100° C. it decomposes after a while, giving off sulphuretted hydrogen. Treated with hydrochloric acid, it yields chloride of amylium, and *amylsulphocarbamic acid* $\left.\begin{matrix}(CS)''.H.C^5H^{11}\\ H\end{matrix}\right\}\begin{matrix}N\\ S\end{matrix}$, which is an oily body, soluble in ether, ammonia and potash; mixed with amylamine, it reproduces the original salt. (A. W. Hofmann, Chem. Soc. Qu. J. xiii. 60.)

DIAMYLAMINE, $(C^5H^{11})^2HN$.—When amylamine is heated to 100° C. with bromide of amyl, direct combination occurs, and the solid hydrobromate of diamylamine is formed. The base is obtained by distillation of the bromide with caustic potash (Hofmann, Phil. Trans. 1851, p. 357). Slightly soluble in water. Boiling-point about 170°. The salts of diamylamine are difficultly soluble in cold water, more readily in hot water.

TRIAMYLAMINE, $(C^5H^{11})^3N$, is obtained by heating diamylamine with bromide of amyl, and distilling the so-formed bromide of triamylium with caustic potash (Hofmann). Its properties and those of its salts are similar to those of diamylamine. It boils at about 257° C.

TETRAMYLIUM, $N(C^5H^{11})^4$. *Tetramylammonium.*—Ammonium in which the whole of the hydrogen is replaced by amyl. Not known in the separate state, but obtained as an iodide by the action of iodide of amyl on triamylamine, the mixture solidifying, after three or four days' boiling, into an unctuous crystalline mass. The iodide of tetramylium is also produced, but very slowly, by heating iodide of amyl in a sealed tube with strong aqueous ammonia. This salt, $N(C^5H^{11})^4I$, dissolves sparingly in water, forming an extremely bitter liquid, from which it is precipitated in the crystalline form by alkalis. Boiled with oxide of silver, it yields a very bitter alkaline solution of the *hydrate of tetramylium*:

$$N(C^5H^{11})^4.I + AgHO = AgI + \left.\begin{matrix}N(C^5H^{11})^4\\ H\end{matrix}\right\}O.$$

On mixing the liquid with potash, or concentrating it strongly by evaporation, the hydrate of tetramylium rises to the surface in the form of an oily layer, which gradually solidifies. A moderately concentrated solution of the base left to evaporate in an atmosphere free from carbonic acid, deposits the hydrate in definite crystals sometimes an inch long, and containing several atoms of water of crystallisation. These crystals when heated, melt in their water of crystallisation, and ultimately leave the pure hydrate in the form of a semi-solid transparent mass. At higher temperatures, the hydrate is completely decomposed, giving off water, triamylamine, and a hydrocarbon, which is probably amylene:

$$\underbrace{N(C^5H^{11})^4H.O}_{\text{Hydrate of tetramylium.}} = H^2O + \underbrace{N(C^5H^{11})^3}_{\text{Triamylamine.}} + \underbrace{C^5H^{10}}_{\text{Amylene.}}$$

Hydrate of tetramylium dissolves readily in acids, forming solutions which yield crystalline salts by evaporation. The sulphate crystallises in long, capillary threads: the nitrate in needles, the oxalate in large deliquescent plates, the chloride in laminæ with palm-like ramifications; the chloroplatinate, $(C^5H^{11})^4NCl.PtCl^2$, in beautiful orange-yellow needles. (Hofmann, Chem. Soc. Qu. J. iv. 316.)—F. G.

(For the *Amyl-phosphines*, *Arsines*, and *Stibines*, see PHOSPHORUS, ARSENIC, and ANTIMONY.)

AMYLENE. C^5H^{10}, or $C^{10}H^{10}$.—This hydrocarbon, a homologue of ethylene or olefiant gas, and the fifth term of the series, C^nH^{2n}, is produced by the dehydration of amylic alcohol by sulphuric acid, phosphoric anhydride, or chloride of zinc, also by the dry distillation of amyl-sulphate of calcium (Kekulé). To prepare it, a concentrated aqueous solution of chloride of zinc is heated to 130° C., with an equal volume of amylic alcohol: and the product is distilled from a water-bath over caustic potash, and repeatedly rectified (Balard, Ann. Ch. Phys. [3] xii. 320). It is a transparent colourless, very thin liquid, having a faint but offensive odour. Boils at 39° C. (Balard); at 35° (Frankland); at 42° (Kékulé). Vapour-density, 2·68 (Balard), 2·386 (Frankland), 2·43 (Kékulé); (by calculation, for 2 vol. = 2·4265). The vapour is rapidly and completely absorbed by sulphuric anhydride and pentachloride of antimony (Frankland). It possesses anæsthetic properties, and has been tried as a substitute for chloroform, but has been found to be very dangerous, having in more than one instance led to fatal results.

Amylene is diatomic, like ethylene, uniting with 2 at. Br, NO^2, HO, &c., and with 1 at. O, S, &c.

ACETATE OF AMYLENE, $C^9H^{16}O^4 = \left.\begin{matrix}(C^5H^{10})''\\(C^2H^3O)^2\end{matrix}\right\}O^2$, is produced by heating the bromide $C^5H^{10}Br^2$, with a mixture of acetate of silver mixed with glacial acetic acid:

$$C^5H^{10}Br^2 + 2(C^2H^3O.Ag.O) = 2AgBr + \left.\begin{matrix}C^5H^{10}\\(C^2H^3O)^2\end{matrix}\right\}O^2.$$

It is a colourless neutral liquid, insoluble in water, boiling above 200° C. and easily decomposed by alkalis into acetic acid and amylene-glycol. (Wurtz, Ann. Ch. Phys. [3] lv. 458.)

BROMIDE OF AMYLENE, $C^5H^{10}Br^2$, is produced by passing bromine-vapour into amylene. Heated in a sealed tube with alcoholic ammonia, it forms bromide of ammonium, and *bromamylene*, C^5H^9Br. — By treating amylene with a larger quantity of bromine, another compound is formed, containing $C^5H^9Br^3$, probably *dibromide of bromamylene*, $C^5H^9Br.Br^2$. This compound, treated with alcoholic potash, yields *dibromamylene*, $C^5H^8Br^2$. (Cahours, Ann. Ch. Phys. [3] xxxviii. 90.)

HYDRATE OF AMYLENE, OR AMYLENE-GLYCOL, $C^5H^{12}O^2 = \left.\begin{matrix}(C^5H^{10})''\\H^2\end{matrix}\right\}O^2$.—Prepared by distilling acetate of amylene with dry pulverised hydrate of potassium, and purified by a second distillation in the same manner, and subsequent rectification *per se*:

$$\left.\begin{matrix}C^5H^{10}\\(C^2H^3O)^2\end{matrix}\right\}O^2 + 2KHO = 2(C^2H^3KO^2) + \left.\begin{matrix}C^5H^{10}\\H^2\end{matrix}\right\}O^2.$$

It is a colourless, very syrupy liquid, having a bitter taste with aromatic after-taste. When cooled with a mixture of solid carbonic acid and ether, it solidifies into a hard transparent mass. It does not affect polarised light. Its specific gravity is 0·987 at 0° C. It boils at 177°, and distils without alteration. When pure it dissolves in water in all proportions. The aqueous solution turns acid when exposed to the air in contact with platinum-black, yielding chiefly carbonic acid, with only a small quantity of a fixed acid, apparently butylactic acid. When gently heated with nitric acid, it is rapidly oxidised, the chief product of the action being butylactic acid, $C^4H^8O^3$. (Wurtz, *loc. cit.*)

Amylene-glycol, treated with hydrochloric acid, either gaseous or aqueous, is converted, slowly at ordinary, more quickly at higher temperatures, into the *chlorhydrin of amylene-glycol*, $C^5H^{10}.HO.Cl$. This compound cannot be isolated, but remains dissolved in the excess of acid and is decomposed by distillation. The acid solution treated with potash yields oxide of amylene.

NITRYLIDE OF AMYLENE, $C^5H^{10}(NO^2)^2$. *Nitroxide of Amylene.*—Obtained by passing peroxide of nitrogen (nitryl, NO^2, prepared by heating anhydrous nitrate of lead) into a flask containing amylene, and surrounded by a freezing mixture. The gas is instantly absorbed, and the amylene is gradually converted into a pasty mass of minute crystals, which may be purified by washing with cold alcohol, recrystallisation from boiling ether and drying in vacuo over sulphuric acid. It gave by analysis, 37·26 per cent. C, 6·51 H, and 17·66 N; the formula requiring 37·09 C, 6·18 H, and 17·28 N.

The compound may also be obtained, though less advantageously, by passing vapour of amylene mixed with air into fuming nitric acid. It is remarkable as affording the first example of the direct combination of nitryl, (NO^2), with an organic radicle.

Heated by itself in a dry tube, it decomposes at about 95° C., giving off nitrous anhydride, N^2O^3, and nitrous acid, HNO^2, and leaving a heavy liquid apparently containing nitrate of amyl. Heated with quick lime, it gives off an aromatic body, probably consisting of oxide of amylene. (Guthrie, Chem. Soc. Qu. J. xiii. 45, 129.)

OXIDE OF AMYLENE, $(C^5H^{10})''.O$, a volatile liqnid, isomeric with valeric aldehyde, It boils at 95° C. Has a pleasant ethereal odour, and a rough taste. Specific gravity in the liquid state, 0·8244 at 0° C. Vapour-density by experiment 2·982, by calculation (2 vol.) = 2·805. It burns easily, with a yellow flame. It is insoluble in *water*, and is not converted into amylene-glycol when heated with water in a sealed tube. It dissolves in *alcohol*, in *ether*, and in a mixture of the two. It mixes with *acids*. It unites with *anhydrous* or *crystallisable nitric acid* at a higher temperature, but the combination is attended with partial decomposition. (A. Bauer, Compt. rend. li. 500.)

AMYLENE WITH SULPHUR AND CHLORINE:

1. *Dichlorosulphide of Amylene*, $C^5H^{10}SCl^2$, or $C^{10}H^{10}S^2Cl^2$.—Protochloride of sulphur (SCl^2) is brought into a flask surrounded with ice and an excess of amylene added very gradually. The excess of amylene is evaporated off,—the residue digested and washed with water, dissolved in ether, filtered, and evaporated. It is a non-volatile liquid, having a pungent odour, insoluble in water, soluble in ether and alcohol. Specific gravity, 1·149 at 12° C. Distilled with excess of alcoholic caustic potash, it yields amylene, *disulphide of fusyl* (C^5H^9S), and other products.

2. *Disulphochloride of Amylene*, $C^5H^{10}SCl$, or $C^{10}H^{10}S^2Cl$.—On treating disulphide of chlorine (SCl), with excess of amylene, and evaporating the latter, a transparent yellow, non-volatile liquid, of faint and nauseous odour is obtained, having the above composition. It is obtained pure by digestion with water, solution in ether, filtration, and evaporation. Specific gravity, 1·149 at 12° C. Soluble in ether, absolute alcohol, and sulphide of carbon. (Guthrie, Chem. Soc. Qu. J. xii. 112.)

Disulphochloride of amylene treated with chlorine, gives off hydrochloric acid, and is converted into a non-volatile liquid, of specific gravity 1·406 at 16° C., miscible with ether, insoluble in water, but soluble in hot alcohol. This liquid gave by analysis numbers agreeing approximately with the formula, $C^{10}H^7Cl^4S$, which may be that of *chlorosulphide of trichloramylene*, $C^{10}(H^7Cl^3).SCl$, or that of *sulphide of tetrachloramyl*, $C^{10}(H^7Cl^4)S$. (Guthrie, Chem. Soc. Qu. J. xiii. 43.)

AMYLENE WITH SULPHUR AND OXYGEN:

Disulphoxide of Amylene, $C^{10}H^{10}S^2O$.—Prepared by digesting the disulphochloride in alcoholic solution with protoxide of lead, till all the chlorine is combined, dissolving in ether, filtering and evaporating. Specific gravity, 1·054 at 13° C. Non-volatile, yellow, or almost colourless. Soluble in ether and alcohol, insoluble in water.

Hydrate of Disulphoxide of Amylene, $C^{10}H^{10}S^2O.HO$.—Disulphochloride of amylene is heated in alcoholic solution for some hours, in a current of ammonia; the liquid is then poured off from the chloride of ammonium formed, and heated for some hours in a sealed tube to 100° C. with alcoholic ammonia; the excess of alcohol is driven off in a water-bath; the residue treated with water; and the oil which is thereby precipitated is washed with water. Yellow liquid of meaty odour. Somewhat soluble in hot water, soluble in alcohol and ether. Non-volatile. Specific gravity 1·049 at 8°. (Guthrie, Chem. Soc. Qu J. x. 120.)—F. G. and H. W.

ANACARDIC ACID, $C^{44}H^{64}O^7$. or $C^{44}H^{32}O^7$.—This acid is contained, together with cardol, in the pericarps of the cashew nut (*Anacardium occidentale*). The pericarps are extracted with ether, which dissolves out both the anacardic acid and the cardol; the ether is distilled off, and the residue, after being washed with water to free it from tannin, is dissolved in 15 or 20 times its weight of alcohol. This alcoholic solution is digested with recently precipitated oxide of lead, which removes the anacardic acid in the form of an insoluble lead-salt. The lead-salt is suspended in water, and decomposed by sulphide of ammonium, and from the solution of anacardate of ammonium, obtained after the removal of the sulphide of lead by filtration, the anacardic acid is liberated by the addition of sulphuric acid. After repeated purification by solution in alcohol, conversion into a lead-salt, and decomposition of this salt by hydrosulphuric acid, the acid is obtained as a white crystalline mass, which melts at 26° C. It has no smell, but its flavour is aromatic and burning. When heated to 200° C. it is decomposed, producing a colourless very fluid oil. It burns with a smoky flame, stains paper, and liquefies by prolonged contact with air, emitting an odour similar to that of rancid fat. Alcohol and ether dissolve it readily, and these solutions redden litmus.

Some of its salts are crystalline, others amorphous. The silver-salt is a pulverulent white precipitate, soluble in alcohol, in presence of a free acid. It contains two atoms of metal, $C^{44}H^{62}Ag^2O^7$. The lead-salt, obtained by mixing a boiling alcoholic solution of anacardic acid with an alcoholic solution of acetate of lead, is said to contain $C^{44}H^{60}Pb^4O^7$ or $\mathit{C^{44}H^{60}Pb^2O^7}$; if this formula be correct, the acid is tetrabasic [or dibasic, if the smaller atomic weights of carbon and oxygen are used]. The salts of ammonium, potassium, barium, calcium and iron, have been described, but they are not very definite, and their formulæ have not been fixed. (Städeler, Ann. Ch. Pharm. lxiii. 137.)

ANALCIME, $\left.\begin{matrix}Na^2\\Al^4\end{matrix}\right\}4SiO^3 + H^2O = Na^2O.SiO^2 + Al^4O^3.3SiO^2 + H^2O$ or $3\mathit{NaO.2SiO^3} + 3(\mathit{Al^2O^3.2SiO^3}) + 2\,\mathit{HO}$.—A mineral belonging to the zeolite family containing, according to H. Rose's analysis, 55·7 per cent. of silica, 13·5 soda, 23·0 alumina, and 8·3 water, which agrees very nearly with the preceding formula. It belongs to the regular system. Primary form a cube; it occurs also in leucite-octahedrons, and in cubes with the faces of the leucite-octahedron replacing the solid angles. Cleavage indistinct, parallel to the faces of the cube. Specific gravity from 2·1 to 2·2. Softer than felspar. In its purest form, it is colourless and transparent, but sometimes white inclining to grey or flesh-colour. According to Brewster, it polarises light in a peculiar manner, indicating a grouping of the molecules very different from that which is usually found in the regular system. Before the blowpipe, it loses water and becomes milk-white; but when the heat is increased, it becomes clear again, and then melts quickly to a transparent glass. It is readily decomposed by hydrochloric acid, with separation of viscid silica; after ignition, however, the decomposition is less easy. Analcime occurs frequently in clefts and geodes in granite, trap-rocks and lava. It is found on the Calton Hill, Edinburgh, at Talisker in the Isle of Sky, in Dumbartonshire, in the Ferroe Islands, in the Harz, and in Bohemia.

ANALYSIS—INORGANIC.

The object of chemical analysis is to ascertain the composition of any substance whatever. The distinction usually made between organic and inorganic compounds, has led to a corresponding division into organic and inorganic analysis: the latter being confined to the investigation of inorganic or mineral compounds. The methods employed in this branch of analysis, are far more numerous and varied than those hitherto devised for the analysis of organic compounds. Inorganic analysis is divided into qualitative and quantitative analysis. The former teaches us how to ascertain the elements of a substance with regard to their quality only, and how to separate them one from another: the latter establishes the methods of proceeding, by which we determine the relations of weight or volume, which these elements bear to one another. It is obvious that, before we can proceed to estimate the quantities of each element contained in a compound, we must know what are the elements that it contains: hence qualitative must always precede quantitative analysis.

Analysis is one of the most recent of the various branches of chemical science. Considerable progress had already been made in synthetical chemistry, in the preparation of chemical compounds, &c. at a time when the foundations of analytical chemistry (in the sense at present attached to the term) had not even been laid. Less than a century ago, when the properties and compounds of many elements were either entirely unknown or but imperfectly established, few problems were more difficult than that of inorganic analysis: the analyst had need of both penetration and caution in the highest degree, in order to discriminate between known and unknown substances. It is only within a comparatively recent period, that the discovery of many new elements, and the more complete investigation of the reactions of those already known, have enabled us to construct a systematic course of analysis, circumscribed within definite and well established rules.

Analytical chemistry, as we have already observed, aims at two objects, each closely connected with the other:—1. To ascertain what are the elements contained in substances whose composition is unknown:—2. To determine the relative proportions of those elements whose existence has previously been qualitatively ascertained. In the earliest analytical researches, both these objects were pursued simultaneously. Hence, in the very brief sketch of the history of analytical chemistry, which it is now our purpose to give, it is not possible to trace the progress of each of these branches of analysis independently of the other. For this purpose it is more convenient to adopt the distinction of analysis *in the wet* and *in the dry way* (*vide infra*): for these two branches of analysis aimed originally at different objects, and the progress of each was in great measure independent of that of the other.

The earliest analytical methods of which we have any information were in the dry way. They were directed exclusively to the separation of noble from ignoble metals; and they were generally conducted quantitatively, the object being to determine the commercial value of alloys, &c., by extracting the amount of the most precious metal contained in them. As early as the second century B.C., Agatharchides of Cnidos (quoted by Diodorus Siculus) gives an account of a method employed by the Egyptians for the extraction and purification of gold, which closely resembles the process of cupellation, at present so extensively employed for the separation of silver from lead. Strabo (about the Christian era) describes the extraction of silver from its ores by fusion with lead; and all the analytical methods which we meet with in the course of several successive centuries are but modifications of the same process. We find a description of the process given by Geber in the latter half of the eighth century, which corresponds very closely with that at present employed.

Strictly speaking, the employment of analysis in the dry way for qualitative purposes, is of much later date, commencing from the observation of the behaviour of different metallic compounds when exposed to a high temperature in contact with certain reagents, commonly called fluxes. It is to Pott, Professor of Chemistry at Berlin, circ. 1750, that we owe the first distinct record of these observations; he pointed out that it was possible, by the addition of certain fluxes, to fuse many substances which were infusible alone; and that the colour of the fused mass afforded information as to the nature of the original substance. This method of experimenting, which was conducted by him in crucibles and furnaces, on a comparatively large scale, received an immense extension by the introduction of the blowpipe, by means of which far more accurate indications were obtained with a much smaller quantity of the original substance. The first mention of this implement occurs about 1660, in the Memoirs of the Academia del Cimento, at Florence, when it is noticed as being employed by glass-blowers; and the first indication of its use for chemical purposes, is found in Kunkel's *Ars vitraria experimentalis*, 1679. Cramer, a German chemist, in his *Elementa Artis docimastica* (1739), gives the earliest instructions for its use as an implement of analysis. The further investigation of the results to be attained by means of this invaluable instrument, was effected mainly by a succession of Swedish chemists, of whom Cronstedt and Bergman were perhaps the most remarkable; and it is to Berzelius that the establishment of the existing system of blowpipe analysis was finally owing.

According to the present course of analysis, the method by the dry way is usually employed only in the preliminary examination: the cases are very rare in which its results can be relied upon for complete information as to all the constituents of a substance. For this purpose, recourse is now invariably had to analysis *in the wet way*. The early history of this method of analysis is very obscure, amounting in fact to nothing but the enumeration of a few random reactions, in the employment of which no system was observed. It was originally employed solely for the qualitative detection of adulterations in drugs, &c. It was next directed to the examination of mineral waters, to which purpose it was mainly confined until the latter half of the seventeenth century, at which period the first true perception of the problem involved in analytical chemistry was obtained by Boyle, who gave to this branch of the science the name by which it is at present designated. He was the first to establish clearly the idea of a chemical element, and to seek for methods of ascertaining what elements or known compounds are contained in any substance of unknown composition. Although these methods comprise many reactions which were known before his time, still he has the credit of being the first to generalise these scattered facts, and to collect them into a coherent system. Among the new reactions introduced in his time, we may mention the precipitation of calcium-salts by sulphuric acid, as serving for the detection of either calcium or sulphuric acid; of silver-salts by hydrochloric acid, as a test for both silver and chorine; that of iron with tincture of galls; the blue colour of copper-salts with excess of ammonia, &c. Since the time of Boyle, analytical chemistry, in the hands of Marggraf, Scheele, Bergman, Klaproth, H. Rose, &c. has made continual advances, the enumeration of which cannot be attempted in a brief historical summary like the present; until by degrees it has assumed the systematic form of which we shall presently proceed to give an outline.

The establishment of quantitative analysis, as a distinct branch of chemical science, is of comparatively recent date. For a long time it was almost entirely neglected, little if any importance being attached to the relative proportions in which elements exist in a compound. Until the latter half of the last century, it was confined to the purpose of assaying, or of determining approximately the value of ores; and it was not until Lavoisier, with such triumphant success, employed the balance as a means of refuting old errors and of establishing new truths, that inquiries into the quantitative composition of bodies came to be regarded as the only sure test and foundation for chemical theory. Almost all the quantitative analyses by which any reliable knowledge of the constitution of substances has been obtained, are included in this period, and date within the last 60 or 70 years. The empirical results thus obtained, have led to the discovery of the most important theoretical truths, *e.g.* the theory of atoms and equivalents, the law of multiple proportions, &c., which in turn have been of inestimable value in controlling the results of analysis, and ensuring to them a degree of accuracy which could never have been attained by merely empirical determinations.

Until a comparatively recent period, the only method of quantitative analysis was that *by weight*. By this method, the substance to be estimated is either weighed directly, or in the form of some compound of known composition, from whose weight that of the substance to be estimated is readily calculated, the reagent by which the substance is separated being always employed *in excess*. More recently, another method has been introduced, which depends upon the employment of only the exact quantity of the reagent which is necessary to produce the reaction desired; and upon the determination of this quantity, not by weight, but by measure. This method, known as the *Volumetric method of analysis* (see ANALYSIS VOLUMETRIC), is only applicable in cases where the point at which the reaction is complete can be determined accurately by means of some distinctly visible phenomenon occurring in the solution to be analysed. The first introduction of this method is due to Descroizilles, who, at the close of the last century, applied it to the valuation of bleaching powder by means of indigo-solution: since which time it has been gradually extended until it has grown into a distinct and most important branch of analysis, which, in most cases, is at least equal in accuracy to the method by weight, while it is greatly superior in speed and facility of execution.

The methods of qualitative analysis consist in bringing the substance under examination into contact with other bodies of known properties, and observing the phenomena which ensue. These phenomena consist in alterations, either in state of aggregation, form, or colour, depending upon some chemical change. All bodies which we employ for this purpose, we call by the general name of *reagents*, the ensuing phenomena are called *reactions*. Acids, bases, salts, and simple bodies (elements) are alike used as reagents.

By means of reagents, the chemist puts questions to the substance under examination, enquiring whether it contains this or that group of chemically similar elements, or only this or that member of such group. If the question be put correctly—*i.e.* if all the conditions under which the reaction expected can be produced by the reagent employed be carefully observed, the answer is decisive as to the presence or absence of the element, or group of elements, sought: if, on the other hand, these conditions—*i.e.* the properties and chemical relations of the bodies formed by the chemical changes which constitute the reaction, have been wholly or partially neglected, the answer, if not certainly erroneous, is at least of doubtful accuracy.

Reagents may be employed either in *the wet way* or in *the dry way*. In the wet way, the reagent in solution, *i.e.* in the liquid form, is brought into contact with the substance to be examined, which is also in the liquid form. In the dry way, the two bodies are brought together in the solid state, and subjected to a high temperature. Of the utmost importance in analysis by the latter method, is the knowledge of the use of the blowpipe, and of the behaviour of bodies in the different flames which can be produced by it. (See BLOWPIPE.)

Many reagents exhibit the same, or a similar behaviour, with a certain fixed number, *i.e.* with a *group*, of elements, and with most of the compounds of these elements; and can therefore, be employed for the division of the elements into groups. Such reagents are termed *general reagents*. Others serve for the further distinction of the several members of such groups: their selection depends upon the knowledge of the special characteristic behaviour to such reagents of each single element, or of each of its several compounds. Such reagents are called *special* or *characteristic reagents*. Their number is much greater than that of the general reagents, their nature being as various as that of the substances which can come under examination: their selection depends upon the solubility or insolubility, colour, or other physical or chemical properties of the new compounds to which they give rise. They may frequently be employed reciprocally: thus, starch is a characteristic test for iodine, and reciprocally, iodine is a characteristic test for starch.

The analyst has not only to establish that this or that body is present in a compound, but he has also to prove that no other body is present besides those which he has actually found. Hence it is evident that he must not treat the substance under examination with any reagent indiscriminately. He must follow a certain fixed order, a methodical system, in the application of reagents, which will be the same for all inorganic substances whatever, let their elements be what they may. This systematic method, which cannot be departed from or abbreviated without danger, except in certain cases by the experienced chemist, consists in the employment of general reagents for the successive elimination of groups of elements possessing certain common chemical properties; and finally, in the recognition of each member of such groups by the employment of characterisric reagents. If the object be not a complete and accurate analysis, but merely to establish the presence or absence of some particular body, the characteristic reagent may in many cases be employed at once, without previous recourse to general reagents.

The first thing to be done in the qualitative analysis of a solid body, is to subject it to a preliminary examination in the dry way, by which means important information as to its composition may frequently be obtained: after which it is dissolved, and its constituents ascertained by examination in the wet way. The course of qualitative analysis, therefore, consists of 3 parts:

I. Preliminary examination in the dry way.
II. Solution, or conversion into the liquid form.
III. Analysis of the solution in the wet way.

We shall now proceed to treat successively of each of these operations.

I. *Preliminary Examination.*

This consists partly in an accurate observation of the physical properties of the substance (its form, colour, hardness, specific gravity, &c.): but chiefly in observing its behaviour *at a high temperature*, either alone, in contact with air, or with some chemical compound which produces either decomposition or simple solution.

1. *The substance is heated alone in a dry test-tube, on charcoal, or on platinum-foil.* — Water, sulphur and its acids, ammonium-, arsenic-, and mercury-compounds are completely volatilised. Carbon burns when heated in the air. If water is evolved, observe whether it is acid or alkaline to litmus. If gases are evolved, observe whether they are combustible: and if so, whether their combustion is sustained or intermittent. Organic compounds are decomposed by heat, generally with evolution of inflammable gas and separation of carbon: when heated with strong sulphuric acid and bichromate of potassium, they evolve carbonic anhydride, which gives a white precipitate with lime- or baryta-water. Bodies which are very rich in oxygen, nitrates, chlorates, perchlorates, bromates, iodates, deflagrate when heated on charcoal. Most alkaline, and some alkaline-earthy salts, melt without volatilising or changing colour; after strong ignition, the residue is alkaline to test-paper. Many silicates (especially zeolites) melt when a thin fragment of them is exposed in platinum-tongs to the blowpipe flame. Borates and alum swell up: other salts, *e. g.* chloride of sodium, decrepitate. Of metals: antimony, lead, tin, bismuth, cadmium, zinc, tellurium, fuse readily before the blowpipe, giving an incrustation of oxide; gold, silver, and copper, fuse with difficulty, and give no incrustation; iron, nickel, cobalt, molybdenum, wolfram, and platinum metals are infusible. The oxides and salts of the earthy and alkaline-earthy metals are infusible, or difficultly fusible; they become vividly incandescent, with a white light, but do not change colour; the earths, after ignition, are not alkaline to test-paper. The oxides and salts of some metals assume a darker colour when heated: those of zinc, tin, titanium, columbium (niobium), and antimony, become yellow: those of lead, bismuth, mercury (and chromates), become dark-brown.

2. *The substance, after ignition on charcoal, is moistened with a drop of a solution of nitrate of cobalt, and again strongly heated before the blowpipe.*—Alkaline phosphates borates, and silicates, give a *blue glass:* the earths, earthy phosphates, silica and many silicates give a *blue infusible mass:* zinc-oxide and titanic anhydride become *yellowish-green:* binoxide of tin, *bluish-green:* antimonic and columbic anhydrides, *dirty-green:* magnesia and tantalic anhydrides, *flesh-red:* baryta, *brown* or *brick-red:* glucina, lime, and strontia, *grey.*

3. *The substance is heated on platinum-wire (if a metallic salt, on charcoal) in the inner blowpipe flame, and the colour of the outer flame observed.*—A *yellow* colour indicates sodium: a *violet*, potassium: a *carmine-red*, lithium or strontium. The yellow colour imparted by sodium, completely overpowers those of the other alkaline metals: but, if the flame be observed through dark blue glass, the yellow rays are cut off, and the colours of potassium and lithium are plainly visible, even in presence of a large excess of sodium. A *reddish-yellow* colour indicates *calcium;* a *yellow-green*, barium or molybdenum; a *green*, cupric oxide, phosphoric, boric, or tellurous acid; a *blue*, arsenic, antimony, lead, selenium, or cupric chloride. In many cases, the colour is rendered more apparent if the substance be previously moistened with hydrochloric acid, or a

little chloride of silver added: phosphates and borates should be moistened with sulphuric acid.

The delicacy and sharpness of these chromatic indications are greatly increased by a method of observation lately introduced by Bunsen and Kirchhoff. It consists mainly in igniting a metallic salt on platinum wire, in a feebly luminous and nearly monochromatic flame, such as that of a Bunsen's gas-burner, and observing the flame through a prism. Very characteristic spectra are then produced, containing luminous coloured bands coincident in position with certain of Fraunhofer's lines. *Sodium* gives a spectrum reduced to a single bright narrow band; *lithium*, a bright red and a fainter yellow band; *potassium*, a spectrum nearly resembling the ordinary solar spectrum in the middle, but characterised by a bright line near the red extremity, and a fainter line near the violet end of the spectrum. The *strontium* spectrum consists of a broad bright orange band, with some fainter red bands; the *calcium* spectrum, of a broad bright green band, a somewhat narrower bright orange band, and some fainter yellow bands; and that of *barium*, of several bright green, yellow and orange with two faint red bands. The sodium reaction is extremely delicate, sufficing for the detection of a quantity of sodium as small as $\frac{1}{3000000}$ of a milligramme; distinct indications are likewise obtained with $\frac{9}{100000000}$ of a milligramme of lithium, $\frac{1}{1000}$ milligramme of potassium and barium, $\frac{6}{100000}$ milligramme of strontium, $\frac{6}{100000000}$ milligramme of calcium. (For details see the article LIGHT; also Pogg. Ann. cx. 161; Chem. Soc. Qu. J. xiii. 270.)

4. *The substance is heated on charcoal in the reducing flame with carbonate of sodium, or with carbonate of sodium and cyanide of potassium.*—Most arsenic compounds give a smell of garlic. All sulphur-, selenium-, and tellurium-compounds, give an alkaline sulphide, selenide, or telluride, which, when moistened, leaves a black stain on a clean silver plate. Tin-, silver-, copper-, and gold-compounds give malleable shining scales: compounds of nickel, cobalt, iron, molybdenum, wolfram, and the platinum-metals are reduced to a grey infusible powder: no incrustation is formed in any of these cases. Antimony-compounds give a *brittle* metallic globule, and a white incrustation: bismuth, a *brittle* globule and a brown-yellow incrustation: lead, a *malleable* globule, and a yellow incrustation. Zinc and cadmium are not reduced to the metallic state, but give, the former a white incrustation, not volatile in the outer flame, the latter, a brown-red incrustation.

5. *The substance is heated in a glass tube, open at both ends, held obliquely.*—The following substances yield gases having a peculiar smell: sulphides, of burning sulphur; selenides, of horseradish; arsenides, of garlic; many ammonium-salts, of ammonia; fluorides (especially on addition of microcosmic salt), of hydrofluoric acid. A metallic sublimate indicates arsenic- or mercury-compounds: a white sublimate is given by arsenides (crystalline), by antimonides and tellurides, (fusible), and by many ammonium-salts. A fused sublimate is given by the higher sulphides (brown-yellow), by selenides and selenium (blackish-red), and by sulphide of arsenic (yellow). All hydrated salts or substances containing hygroscopic water yield drops of water, the acid or alkaline reaction of which should be ascertained.

6. *The substance is heated in contact with metallic zinc and dilute hydrochloric or sulphuric acid.*—Many metallic acids are reduced to lower oxides by this treatment, a change of colour being produced. Titanic acid gives a *violet* colour: tungstic acid, and the chlorides of tantalum and columbium, a *blue*: molybdic acid, *blue*, changing to *green* and dark-brown: columbous acid, *blue*, changing to *dark brown*: chromic acid, *green*, iodic acid, *brown*, or if starch be added, *blue*.

II. *Solution of Solid Bodies.*

After having ascertained by the preliminary examination in the dry way, to what class of bodies the substance under examination belongs, the next step is to bring it into the liquid form, in other words, to *dissolve* it. In order to effect this, it is generally necessary, when the nature of the substance allows it, to reduce it to a fine powder by pounding in a mortar, and, if necessary, by subsequent levigation with water. This is indispensable in the case of minerals, especially of silicates, and of all other difficultly soluble, insoluble, or difficultly decomposible compounds. If the substance contains organic matter, this should be removed before proceeding further, as its presence materially interferes with the reactions of many mineral compounds. This may generally be effected by heating the substance strongly for some time in contact with air (more speedily with oxygen), until the whole of the carbon is converted into carbonic anhydride. In many cases, the oxidation of the carbon is facilitated by dropping nitric acid on the heated substance.

The solvents which are usually employed in the analysis of inorganic bodies are water, hydrochloric and nitric acids, and aqua-regia. The finely-powdered substance is first boiled with from 12 to 20 times its weight of *distilled water*, in order to ascertain its complete or partial solubility or insolubility therein. If it be not completely dissolved, the solution is filtered off from the residue, and a drop or two of it evaporated to dryness on platinum-foil, when, if the substance is partially soluble in water, a distinct residue is left; if the substance is completely insoluble, there is no residue after evaporation. In the former case, the solution is tested with litmus paper to see whether it has a neutral, acid, or alkaline reaction, and set aside for further examination. The portion insoluble in water is then treated successively with *dilute* and *concentrated hydrochloric acid*, particular attention being paid to the nature of the gases, if any, thereby evolved, and to the separation of solid products of decomposition. Carbonates evolve carbonic anhydride, with effervescence; peroxides, chromates, and chlorates evolve chlorine; cyanides, hydrocyanic acid; many sulphides, hydrosulphuric acid; sulphites and hyposulphites, sulphurous anhydride, with separation of sulphur in the latter case. Most metals (iron, zinc, tin, &c.) evolve hydrogen; or, if arsenic or antimony be present, arsenide or antimonide of hydrogen. If hydrochloric acid does not completely dissolve the substance, it generally effects the complete separation of one or more elements; for which reason the solution should be separated from the residue, and examined apart. The residue may consist of compounds undecomposible by hydrochloric acid, which existed in the original substance; or of insoluble compounds formed by the decomposition of the original substance by hydrochloric acid. Thus sulphur is separated from polysulphides, pulverulent or gelatinous silica from many silicates, tungstic acid from tungstates, &c.; or if lead, silver, or subsalts of mercury be present, insoluble chlorides of these metals will be formed.

If the substance is not completely soluble in hydrochloric acid, the insoluble residue is treated successively with *nitric acid* and *aqua regia*. In many cases (*e. g.* with phosphates, arsenates, silicates, tungstates, &c.), these compounds act merely as solvents; on many other bodies they exert an oxidising action. Thus, most sulphides, when treated with nitric acid, separate sulphur, which, by prolonged digestion with the acid, collects into yellow globules which swim on the surface of the liquid, or disappears altogether, being oxidised into sulphuric acid, which may be detected in the solution, unless it forms an insoluble salt with the dissolved metal. Sulphide of lead is converted by nitric acid into sulphate of lead: sulphides of antimony and tin into white oxides: protosulphide of mercury is insoluble in nitric acid, readily soluble in aqua regia. Most metals are completely soluble in nitric acid: the only metals not attacked by it are gold, platinum, and the rarer metals found in platinum-ores (with the exception of palladium, which is slowly soluble in nitric acid). Gold and platinum are soluble in aqua regia. Tin and antimony are not dissolved by nitric acid, but are converted into white oxides, insoluble in the acid; they are readily soluble in aqua regia (or hydrochloric acid and chlorate of potassium), if excess of nitric acid be avoided.

When a finely powdered substance is neither dissolved by successive treatment with the above solvents, nor so decomposed or attacked by them as to give an idea of its nature, it must be *rendered soluble*, in order that its constituents may be determined in the wet way. The method of doing this frequently depends upon the results of the preliminary examination. The following are the principal insoluble (or difficultly soluble) substances.

1. *Sulphates* (of barium, strontium, calcium, and lead). When heated on charcoal with carbonate of sodium, they give an alkaline sulphide: sulphate of lead gives also a malleable metallic globule; it is blackened by sulphide of ammonium, and soluble in basic tartrate of ammonium. They are rendered soluble by fusion with 3—4 pts. alkaline carbonate: after treating the fused mass with water, the solution contains the acid as alkaline sulphate, and the residue the base, as carbonate, which is now soluble in hydrochloric acid. In this and in all the following cases, the substance must be powdered as finely as possible before fusion. The sulphates of strontium, calcium, and lead are decomposed (the first not completely), by digestion with a solution of sodic carbonate: sulphate of calcium is somewhat soluble in water.

2. *Silica and silicates.*—When heated before the blowpipe with microcosmic salt, they swim undissolved in the fused bead. They are rendered soluble by fusion with 3—4 pts. alkaline carbonate (or hydrate of barium), treatment with hydrochloric acid, and evaporation with free acid, when the silica remains insoluble; or by treatment with hydrofluoric and sulphuric acids.

3. *Fluorides* (fluorspar, &c.)—When gently heated with concentrated sulphuric acid, they evolve hydrofluoric acid, which corrodes glass: if silica be present, fluoride of silicium is evolved, which gives a precipitate on contact with water. They are decomposed by fusion with 4 pts. alkaline carbonate, with addition of silica if necessary.

4. *Alumina* or *Aluminates.*—They give a blue infusible mass when heated with cobalt-solution. They are rendered soluble by fusion with 3—4 pts. acid sulphate of potassium.

5. *Chromic oxide* (chrome-iron-ore).—It gives a green bead in both flames with borax or microcosmic salt. Chrome-iron-ore is decomposed by successive fusion with acid sulphate of potassium, and with alkaline carbonate and nitre.

6. *Binoxide of tin*, and *Antimonic anhydride*.—They are coloured yellow by sulphide of ammonium, and dissolved by digestion in excess of the reagent: when heated on charcoal with sodic carbonate, they yield, the first a malleable, the second a brittle, metallic globule. They are rendered soluble in acids by fusion with 3—4 pts. alkaline carbonate.

7. *Tantalic*, *tungstic*, *titanic*, and *columbous anhydrides*.—They give with microcosmic salt a blue, violet, or (in presence of iron) a blood-red, bead: with zinc and hydrochloric acid, a coloured solution. They are rendered soluble by fusion with 6 pts. acid sulphate of potassium.

8. *Chloride, bromide, iodide, of silver; Sulphides of molybdenum, lead, &c.*—Chloride, bromide, and iodide of silver, are soluble in cyanide of potassium: when heated on charcoal with sodic carbonate, they yield metallic silver. Insoluble sulphides give off sulphurous anhydride when heated: sulphide of molybdenum gives a yellowish-green bead with microsmic salt, and is converted by roasting into molybdic anhydride, which gives a blue colour with zinc and hydrochloric acid.

9. *Metals* (osmide of iridium, or residues of platinum-ores).—The insoluble substance has metallic lustre, or is a black powder, not affected by ignition. It is rendered soluble by mixture with chloride of calcium and ignition in a stream of chlorine; or by fusion with potash and chlorate of potassium.

10. *Carbon*.—The insoluble substance is black (as diamond, colourless): it disappears when strongly ignited in an open platinum crucible, or before the blowpipe. It detonates when fused with nitre, forming carbonate of potassium; and yields carbonic anhydride when ignited with oxide of copper.

If the preliminary examination furnishes no distinct idea as to the nature of the insoluble substance, it must be fused with four times its weight of carbonates of potassium and sodium, the fused mass exhausted with water, and the residue treated with hydrochloric acid. If the substance contains any easily reducible metal (arsenic, antimony, tin, lead, bismuth, &c.) it must not be fused in a platinum crucible.

III. *Qualitative Analysis of Solutions.*

The first steps to be taken in the qualitative analysis of solutions are to ascertain whether the solution is neutral, acid, or alkaline to test paper; and whether it contains any non-volatile constituents. For the latter purpose, a small portion of it is carefully evaporated on platinum-foil: when, if non-volatile compounds are present, a residue is left which does not disappear when strongly heated, and should be submitted to the preliminary examination above described.

These precautions are of course unnecessary when the solution has been made by the analyst himself, as described in Section II.: but they should never be neglected when the substance to be examined is already in the liquid form, since, if carefully performed, they may enable him to conclude at once as to the presence or absence of whole groups of bodies. Thus it is evident that a solution which, after *careful* evaporation, leaves no fixed residue, cannot contain any non-volatile metallic salts. A solution *neutral* to test-paper can generally contain only salts of the alkaline or alkaline-earthy metals, since the salts of most other metals have an acid reaction. An *alkaline* solution (in which no non-volatile organic compounds are present), cannot contain any metals whose salts are insoluble in alkaline liquids: if the alkaline reaction be caused by the presence of an alkaline carbonate, the presence of the alkaline-earthy metals is impossible. If, however, non-volatile organic compounds are present, an alkaline solution may contain salts of copper or sesquisalts of iron, as well as such oxides, cyanides, sulphides, &c., as are soluble in cyanide of potassium or alkaline sulphides. The presence of certain acids implies the absence of certain metals, and *vice versâ*: thus the same acid solution cannot contain sulphuric acid and barium, hydrochloric acid and silver, &c. Silver need not be looked for in an alloy soluble in hydrochloric acid, nor gold, antimony, tin, &c. in one soluble in nitric acid.

It is advisable, when possible, to examine for acids and metals in separate portions of the solution.

a. Examination for Metals.

The systematic course of examination for metals which is now almost exclusively employed, depends upon the behaviour of metallic salts in solution towards the following general reagents: *hydrochloric acid*, *hydrosulphuric acid*, *sulphide of ammonium*, and *carbonate of ammonium*. It will be observed that all these reagents are volatile; so that in their application no substance is introduced into a solution which cannot be removed by simple elevation of temperature. Their application depends upon the different solubility of metallic chlorides and sulphides, and of the carbonates of the alkaline-earthy and alkaline metals. By means of these general reagents, as we have already observed, the metals are divided into certain groups, which are successively eliminated from the solution under examination; by which proceeding the detection of each individual member of each group is considerably facilitated. The following are the groups into which the metallic elements are thus divided:

α. Metals whose *chlorides* are insoluble, or difficultly soluble in water or dilute acids. These are lead, silver, and mercury (the last as sub-salts). These metals are not generally classed in a group by themselves, but are included in the group next following, to which they also belong.

β. Group 1.—Metals whose *sulphides* are insoluble in water or in dilute acids. They are all precipitated from their slightly acid solution by hydrosulphuric acid. They are further divided into two subdivisions according to the behaviour of their sulphides to sulphide of ammonium.

Subdivision A.—Metals whose sulphides possess acid properties. Their sulphides are soluble in alkaline sulphides (sulphides of ammonium, potassium, or sodium), forming therewith soluble sulpho-salts, which are generally analogous to the oxygen salts of the same metals, oxygen being replaced by sulphur. They are arsenic, antimony, tin, gold, platinum, iridium, selenium, tellurium, molybdenum, wolfram, vanadium.

Subdivision B.—Metals whose sulphides do *not* possess acid properties, not combining with alkaline sulphides, and so being insoluble therein. They are lead, silver, mercury, bismuth, copper, cadmium, palladium, rhodium, osmium, ruthenium. (Sulphide of mercury is soluble in sulphide of potassium or sodium: sulphide of copper is somewhat soluble in sulphide of ammonium.)

γ. Group 2.—Metals which are not precipitated by hydrosulphuric acid, but which are precipitated by sulphide of ammonium, from acid solutions. This group also is further subdivided.

Subdivision A.—Metals which are precipitated as *sulphides*. They are nickel, cobalt, manganese, iron, uranium, zinc. Their sulphides are insoluble in water, but soluble in dilute acids, with evolution of hydrosulphuric acid: hence they are not precipitated *at all* by hydrosulphuric acid from acid solutions, and not completely from neutral solutions. They are however completely precipitated from an acid solution by sulphide of ammonium, the acid being neutralised by the ammonia contained in it.

Subdivision B.—Metals which are precipitated as *hydrates*. They are aluminium, glucinum or beryllium, zirconium, thorium, yttrium, erbium, terbium, cerium, lanthanum, didymium: titanium, tantalum, columbium, chromium. (The first ten metals in this subdivision are known as *metals of the earths*, or *earthy metals*). They do not combine with sulphur in the wet way, and so are not precipitated by hydrosulphuric acid under any circumstances. Their hydrates, however, being insoluble in water, are precipitated from their neutral or acid solutions by sulphide of ammonium, the acid by which they were held in solution being neutralised by the ammonia of the reagent, while hydrosulphuric acid escapes.

Certain compounds of the earthy and alkaline-earthy metals with non-volatile acids (phosphates, oxalates, borates, &c.), being soluble in dilute acids and insoluble in water, are similarly precipitated by sulphide of ammonium.

δ. Group 3.—Metals whose *sulphides* and *hydrates* are soluble in water; which, therefore, are not precipitated by hydrosulpuhric acid or sulphide of ammonium from any solution. This group includes the *alkaline-earthy* and *alkaline* metals. They are further subdivided according to their behaviour to carbonate of ammonium in presence of chloride of ammonium.

Subdivision A.—Metals which are precipitated by carbonate of ammonium. They are barium, strontium, calcium. Their normal carbonates are insoluble in water or in chloride of ammonium.

Subdivision B.—Metals which are *not* precipitated by carbonate of ammonium. They are magnesium, potassium, sodium, lithium, ammonium. Carbonate of magnesium is insoluble in water, soluble in chloride of ammonium: the carbonates of the other four metals (alkaline metals), are soluble in water. The different solubility of their phosphates affords a means for the further detection of the metals of this subdivision.

In the usual classification, the alkaline-earthy metals (barium, strontium, calcium, magnesium) constitute Group 3: and Group 4 comprises the alkaline metals.

The following table exhibits in a compendious form the behaviour of all the metals to the general reagents above enumerated.

Behaviour of Metallic Solutions with Hydrochloric Acid, Ammonium,

Hydrochloric Acid.	Hydrosulphuric Acid.		
Metals which are precipitated as *chlorides* from their neutral or acid solutions by *hydrochloric acid.*[*]	Metals which are precipitated as sulphides from their hydrochloric acid solution by *hydrosulphuric acid.*		Metals whose salts are partly *reduced* in an acid solution by *hydrosulph. acid,* with separation of sulphur.[*]
	Soluble in sulphide of ammonium.	*Insoluble in sulphide of ammonium.*	
Lead (partially), white, crystalline, soluble in hot water, precipitated thence by sulphuric acid. **Silver**, white, curdy, soluble in ammonia, precipitated thence by nitric acid. **Mercury as subsalt**, white, finely-divided, blackened by ammonia.	**Arsenic** (yellow). **Antimony** (orange). **Tin**[*] (brown or yellow). **Gold** **Platinum** **[Iridium]** } (black-brown). **Molybdenum**[†] (brown). **[Selenium]** (red-yellow). **[Tellurium]** (black).	**Mercury**[*] **Silver** **Lead**[†] **Copper** } (black). **Cadmium** (yellow). **Bismuth** (brown). **[Palladium]**[‡] **[Osmium]** **[Rhodium]** **[Ruthenium]** } (black-brown).	**Iron as ferric salt.** The solution becomes colourless, and contains a ferrous salt. **Chromium as chromate.** The solution becomes green, and contains a chromic salt.
[*] In a saturated solution of a barium-salt, hydrochl. acid gives a white precip. readily soluble in water. In an *alkaline* solution, hydrochloric (or nitric) acid gives a precipitate in presence of *Silicic* *Boric* *Antimonic* *Tungstic* *Molybdic* *Benzoic* } acids; or of those metals whose oxides are soluble in alkalis (aluminium, &c., soluble in excess of acid); or of *cyanides* and *ferrocyanides*; or of those *sulphides* which are soluble in sulphide of ammonium. In presence of soluble *polysulphides* or *hyposulphites*, sulphur is separated.	[*] SnS is brown, SnS^2 yellow. From the solution of SnS in sulphide of ammonium, hydrochl. acid precipitates yellow SnS^2. [†] The sulphides of *tungsten* and [*vanadium*] are not precip. by hydrosulph. acid from an acid solution: but they are when their solution in sulphide of ammonium is decomposed by an acid.	[*] Mercury as protosalt is precip. white by a little hydrosulph. acid; black by excess. [†] Lead is only precip. completely from dilute, not too acid, solutions. [‡] The sulphides of all the platinum-metals are precipitated very slowly.	[*] Sulphur is also separated in presence of free *chlorine*, *bromine*, and *iodine*, of *sulphurous*, *nitrous*, *hypochlorous*, *chloric*, *iodic*, *bromic acids*, &c.: and generally in presence of easily reducible salts of metals which are not precip. as sulphides from an acid solution.

The metals enclosed thus [ ] are very rare, and

Hydrosulphuric Acid, Sulphide of Ammonium, and Carbonate of successively applied.

Sulphide of Ammonium.			**Carbonate of Ammonium.**	
Metals which are precipitated by *sulphide of ammonium*, in presence of chloride of ammonium. (The solution should be neutralised with ammonia before adding sulphide of ammonium.)			Metals which are precipitated neither by *hydrosulphuric acid* nor by *sulphide of ammonium*. *Carbonate of ammonium*, in presence of chloride of ammonium,	
As Sulphides:	*As Oxides:* also precip. by ammonia.	*As Salts:* also prec. by amm.	*precipitates* [*]	*does not precip.*
Nickel [*] **Cobalt** (black). **Iron** **Uranium** (black-brown). **Manganese** (flesh-red). **Zinc** [†] (white).	a. soluble in potash. **Aluminium** [*] (colour- **[Glucinum]** less). **Chromium** (green). **[Tantalum]** [†]. **[Columbium or Niobium.]** b. insol. in potash. **[Cerium]** **[Lanthanum]** **[Didymium]** generally colourless. **[Yttrium]** **[Erbium]** **[Terbium]** **[Zirconium]** **[Thorium]** **Titanium**	a. in presence of phosphoric acid. **Magnesium** (crystalline). b. in presence of phosphoric, oxalic, boric or hydrofluoric acid. **Calcium** [*] **Strontium** (white). **Barium** as phosphates, oxalates, borates, or fluorides.	**Barium** **Strontium** (white). **Calcium** as carbonates.	a. precipitable by phosphate of ammonium (and ammonia) **Magnesium** (crystalline). b. not precip. by phosphate of ammonium. **Potassium.** **Sodium.** **Lithium.** [*] **Ammonium.**
[*] Sulphides of nickel and cobalt are difficultly soluble in acetic and dilute hydrochl. acids. Sulphide of nickel is slightly sol. in yellow sulphide of ammonium, forming a brown solution. [†] Sulphide of zinc is insoluble in acetic acid.	[*] In presence of phosphoric acid aluminium is also precip. as phosphate, sol. in potash. [†] Soluble after fusion with potash.	[*] The alkaline-earthy phosphates are insol. in potash, sol. in acetic acid. Oxalate of calcium is insol. in acetic acid.	[*] The precipitation is not complete unless ammonia is added, and the whole heated to boiling.	[*] A concentrated solution of a lithium-salt is precip. by phosph. sod. on heating.

need not be sought for except in special cases.

If we suppose the case of a solution containing all the metals, it is obvious that, by the successive application of each of these general reagents, we shall separate, first, by hydrochloric acid, those metals whose chlorides are insoluble; secondly, by hydrosulphuric acid, those metals whose sulphides are insoluble in dilute acids; thirdly, by sulphide of ammonium, those remaining metals whose sulphides or hydrates are insoluble in neutral or alkaline liquids; and lastly, by carbonate of ammonium, those metals whose carbonates are insoluble: so that at last we have only the alkaline metals left in solution. In order, however, to effect the complete separation of each group, the general reagents must be employed *in the order* above stated: for sulphide of ammonium would precipitate those metals whose sulphides are insoluble in dilute acids, as well as those whose sulphides are only insoluble in neutral or alkaline liquids; and carbonate of ammonium, if employed before the other reagents, would precipitate most of the metals of Groups 1 and 2, their carbonates being also insoluble.

The following rules, the importance of which will be obvious on the least reflection, must also be strictly observed.

1. The mineral acid employed to acidify the original solution (when it is not already sufficiently acid), is either hydrochloric or nitric acid. Both are employed dilute, and not in sufficient quantity to interfere with the formation of the sulphides of Group 1. Hydrochloric is generally preferable to nitric acid: for it serves as a general reagent, separating at once those metals which form insoluble chlorides. If nitric acid be employed, these metals will be found in the precipitate by hydrosulphuric acid.

2. The precipitation by each general reagent must be complete. To ensure this, the reagent must be added gradually, allowing the precipitate to subside between each addition, until no further precipitate is produced. In the case of hydrosulphuric acid, the precipitation is complete when the solution, after agitation, still smells strongly of the gas. Gentle heat facilitates the separation of precipitates in almost every case. Arsenic (as arsenic acid), gold, platinum, iridium, rhodium, and molybdenum, are precipitated very slowly by hydrosulphuric acid. Tungsten and vanadium are not precipitated by hydrosulphuric acid from an acid solution: they are, however, included in Group 1, because their sulphides (obtained by adding sulphide of ammonium and then hydrochloric acid), are insoluble in acids, but soluble in sulphide of ammonium.

3. Each group, when precipitated, must be thoroughly freed by washing with water from all members of the subsequent groups, which may be contained in the solution. This washing is effected, according to circumstances, either on a filter, or by decantation. If the precipitate contains any easily oxidable sulphides, a little hydrosulphuric acid must be added to the wash-water (if the sulphide is insoluble in dilute acids, *e.g.* sulphide of copper), or a little sulphide of ammonium (if the sulphide is soluble in dilute acids, *e.g.* sulphides of iron and manganese), in order to prevent the partial oxidation of the sulphide by exposure to the air during the washing of the precipitate. After the precipitation of each group, it is advisable to ascertain the presence or absence of any members of the succeeding groups, by carefully evaporating on platinum-foil a moderate quantity of the filtrate; if, after ignition, there is no distinctly visible residue, non-volatile substances need not be looked for further. It is obvious that, if these two precautions (complete precipitation and thorough washing) be neglected, metals belonging to one group are liable to be found among those of another group; and consequently, as the analysis proceeds, reactions will be obtained which will be the source of great perplexity to the unpractised analyst.

Each group of metals having been separated by the application of general reagents, the presence or absence of each member of each group is ascertained by means of special or characteristic reagents. It seldom happens that the number of elements contained in any inorganic compound exceeds ten or twelve: and in most cases some distinct idea of the nature of its principal constituents is afforded by the results of the preliminary examination. In metallic minerals and alloys, the heavy metals are chiefly to be looked for: in silicates, the earthy, alkaline-earthy, and alkaline metals, iron, and manganese. It frequently happens that important information may be derived from the colour of a precipitate or of a solution. Thus solutions of cupric, chromic, molybdic, and vanadic salts, are blue or green; those of nickel-salts, green; those of ferrous-salts, light bluish-green; those of chromates, gold-salts, ferric- and platinic-salts, yellow, with a red or brown tinge; those of cobalt-salts, red, &c. These colours are not perceptible when the amount of metal present is very small, or when they are masked by the presence of other metals, the colour of whose solutions is complementary to them.

In order to show the systematic method by which the members of each group are detected in presence of each other, we will now briefly go through the most important groups mentioned in the table.

1. *Precipitate produced by hydrochloric acid.*—Chloride of lead is soluble in a large quantity of water, especially on boiling; chloride of silver, in ammonia; subchloride

of mercury is blackened by ammonia. (The addition of either hydrochloric or nitric acid may produce a precipitate in presence of such acids, hydrates, cyanides, sulphides &c., as are soluble in alkaline liquids, but insoluble in water; or a precipitate of sulphur, in presence of a polysulphide or hyposulphite, or a white precipitate, readily soluble in more water, in a saturated solution of a barium-salt.)

2. *Precipitate produced by hydrosulphuric acid.*

a. Portion soluble in alkaline sulphides. — Sulphide of arsenic is soluble in acid sulphite of potassium or in sesquicarbonate of ammonium, the sulphides of antimony and tin are not. When the three sulphides are dissolved in aqua-regia, and the solution is introduced into a Marsh's apparatus, antimony and arsenic are detected by the behaviour of their gaseous hydrogen-compounds; tin, after its separation by zinc, by its solubility in hydrochloric acid, and by the reaction of its solution with chloride of mercury.

b. Portion insoluble in alkaline sulphides. — The precipitate is treated with nitric acid: sulphide of mercury and sulphate of lead may remain undissolved. In the solution, lead is detected by sulphuric acid; silver, by hydrochloric acid; bismuth by its precipitation by ammonia, or by water if no excess of acid is present; copper, by the blue colour of its ammoniacal solution, or by ferrocyanide of potassium; cadmium, by the precipitation of its ammoniacal solution by hydrosulphuric acid, after the addition of cyanide of potassium.

3. *Precipitate produced by sulphide of ammonium.*—The precipitate is digested with excess of caustic potash in the cold: chromium, zinc, aluminium, and glucinum are found in the solution. Of the metals contained in the residue: cobalt, nickel, and manganese form soluble double salts with ammonia, and so are not precipitated by it: iron, uranium, the rarer earthy metals, and alkaline-earthy phosphates, oxalates, &c., are precipitated by ammonia, even in presence of chloride of ammonium. The hydrates of uranium and the rarer earthy metals are readily soluble in carbonate of ammonium: ferric hydrate is less soluble, and the alkaline-earthy salts are insoluble. Ferric salts are detected by sulphocyanate or ferrocyanide of potassium; the alkaline-earthy salts by appropriate characteristic reagents.

4. *Precipitate produced by carbonate of ammonium.* — The metals which compose this group (barium, strontium, calcium) are distinguished by the different solubility of their sulphates, oxalates, chromates, &c.: and by the colours which they communicate to the blowpipe flame, or to that of burning alcohol.

5. The solution, after the successive application of the above general reagents, can only contain magnesium and the alkaline metals. Magnesium is detected by its precipitation by phosphate of ammonium; the alkaline metals by the colour which they impart to the blowpipe or alcohol flame, and by the different solubility of their tartrates or chloroplatinates. Ammonium is always sought for in a separate portion of the original solution: it is detected by the evolution of ammonia when any of its salts are heated with a fixed alkali or alkaline earth.

Since *hyposulphite of sodium* is decomposed by the salts of most of those metals which are precipitated by hydrosulphuric acid from an acid solution, a metallic sulphide being precipitated, it has been proposed to employ this compound as a general reagent instead of hydrosulphuric acid, and so to avoid the unpleasant smell of the latter. This substitution, however, has not as yet been generally adopted.

Carbonate of barium may also be employed as a general reagent. When a solution containing metallic salts is shaken up with excess of this salt, in the cold:

Are precipitated.

Tin.
Gold.
Iridium.
Rhodium.
Palladium.
Platinum.
Mercury.
Copper.
Bismuth.
Cadmium.
Aluminium.
Manganese }
Iron } as sesquisalts.
Uranium }
Chromium, as sesquisalt, or as chromic acid.
Titanium, as titanic acid.

Are not precipitated.

Silver.
Lead.
Iron }
Nickel }
Cobalt } as protosalts.
Manganese }
Zinc.
Cerium.
Yttrium.
Glucinum.
Magnesium.
Calcium.
Barium.
Strontium.
Ammonium.
Lithium.
Sodium.
Potassium.

Mercury, platinum, palladium, rhodium, iridium, and gold are precipitated by carbonate of barium only when they are present as oxygen-salts, not when present as chlorides, &c. Arsenic, antimonic, phosphoric, selenic, and sulphuric acids are not precipitated by carbonate of barium until the solutions of their salts have been acidulated with nitric or hydrochloric acid. Carbonate of barium is not much used as a general reagent; it is however employed with advantage for the separation of the metals which are precipitated by sulphide of ammonium, since it precipitates completely those which are present as sesquisalts, while the protosalts remain in solution.

When, in the course of a systematic qualitative analysis, one or more members of the different groups have been recognised as constituents of the substance under examination, by means of the reactions above enumerated, the results must be confirmed by certain special reactions, which will be detailed at length in the articles devoted to the several elements.

b. *Examination for Acids.*

The qualitative detection of acids, is, on the whole, more difficult than that of metals; still, with due care, it may be accomplished with great precision. In most cases, the preliminary examination, as well as the nature of the metals already found, give information as to what acids should especially be looked for. The knowledge of the solubility of different salts, and of the reactions of their aqueous solutions with vegetable colours, is of the greatest importance in this examination. By heating the substance either alone or with concentrated sulphuric acid, the presence or absence of *organic* and *volatile inorganic* acids is at once ascertained, these acids either volatilising undecomposed, or yielding volatile products of decomposition. For this purpose, a small portion of the dry substance is heated in a test-tube (not to boiling) with 3 to 4 times its volume of concentrated sulphuric acid; when, in the case of all acids which are either volatile without decomposition, or are decomposed by sulphuric acid at a high temperature, gases or vapours are evolved, the properties of which, in most cases, indicate the nature of the acids present.

1. *Non-volatile acids:* whose compounds evolve no vapours when heated with sulphuric acid, the mixture not being blackened—Silicic, Boric, Phosphoric, Sulphuric, Iodic, Arsenic, Selenic, Tungstic, Molybdic, Titanic acids.

2. *Acids which evolve a coloured gas*, the mixture not being blackened—Hydriodic, Hydrobromic, Bromic, Chloric, Hypochlorous, Nitrous acids.

3. *Acids which evolve a colourless gas, generally possesses an irritating smell and an acid reaction*, the mixture not being blackened—*a.* Volatile without decomposition: Hydrosulphuric, Hydrochloric, Nitric, Acetic, Benzoic, Succinic, Hydrofloric acids. The gas evolved is not inflammable, except in the case of hydrosulphuric acid — *b.* Decomposed — Cyanic, Chromic (evolves oxygen), Carbonic, Sulphurous, Hyposulphurous, Polythionic, Oxalic, Formic, Hydrocyanic, Sulphocyanic, acids, Ferro- and Ferri-cyanides. In most of these cases, the gas evolved is inflammable.

4. *Non-volatile organic acids:* Tartaric, Racemic, Citric, Malic, Tannic, Gallic, Uric acids. The mixture is blackened, and carbonic and sulphurous anhydrides and carbonic oxide are evolved.

The behaviour of a mixture of salts, when heated alone or with sulphuric acid, is often different from that of each individual salt under the same circumstances. Thus a mixture of a nitrate or chlorate with a salt of an organic acid, does not blacken when ignited, but commonly detonates: a chloride, in presence of a nitrate, when heated with sulphuric acid, evolves chlorine and red nitrous fumes; in presence of a chromate, red fumes of chlorochromic acid; in a mixture of a sulphite and a nitrate, chlorate, chromate, &c., the sulphurous acid is converted into sulphuric acid; in a mixture of a sulphide and a sulphite, the two acids decompose each other, sulphur being separated, and the characteristic smell of each destroyed. Chloride and subchloride of mercury, and chloride of tin are decomposed with difficulty, if at all, by sulphuric acid.

From a solution containing volatile and non-volatile acids, the former may be separated by distillation with dilute sulphuric acid.

The general reagents usually employed in the examination for acids in the wet way, are chloride or nitrate of barium; chloride of calcium; a mixture of sulphate of magnesium, ammonia, and chloride of ammonium; sesquichloride of iron; nitrate of silver; and indigo-solution. By these reagents, the most important acids are divided into the following groups.

1. Acids which are precipitated by *chloride of barium:* —

a. from a solution acidulated with nitric or hydrochloric acid—Sulphuric, Selenic, Fluosilicic acids.

b. From a neutral solution (the precipitate being soluble in acids) — Sulphurous, Phosphoric, Carbonic, Silicic, Hydrofluoric, Oxalic, Chromic, Boric, Tartaric, Citric, Arsenious, Arsenic acids. The last five acids are not precipitated in presence of ammoniacal-salts.

2. Acids which are precipitated by *chloride of calcium:* —

a. From a neutral solution only (the precipitate being soluble in acetic acid)—Phosphoric, Arsenic, Boric, Carbonic, Sulphurous, Tartaric, Citric acids, and Ferrocyanides.

b. From a neutral or acetic acid solution—Sulphuric, Hydrofluoric, Oxalic, Racemic acids.

3. Acids which are precipitated by *sulphate of magnesium, in presence of ammonia and chloride of ammonium*—Phosphoric, Arsenic, Tartaric acids.

4. Acids which are detected by *sesquichloride of iron:* —

a. Are precipitated — Ferrocyanides (from a solution containing free hydrochloric acid): Phosphoric, Arsenic, Tannic acids (from a neutral or acetic acid solution): Boric, Benzoic, Succinic acids (from neutral solutions only).

b. Are coloured — In presence of free hydrochloric acid; Ferricyanides (brown), Sulphocyanic acid (red). In neutral solutions only: Acetic, Formic, Sulphurous, Meconic acids (red): Gallic acid (black).

5. Acids which are precipitated by *nitrate of silver:* —

a. From neutral solutions only (precipitate being soluble in dilute nitric acid) — Phosphoric, Pyro- and Meta-phosphoric, Arsenic, Arsenious, Chromic, Oxalic, Boric, Tartaric, Citric, Sulphurous, Formic acids: Silicic and Acetic acids from concentrated solutions.

b. From acid solutions also (the precipitate being insoluble in dilute nitric acid). Hydrochloric, Hydrobromic, Hydriodic, Hydrocyanic, Sulphocyanic, Iodic, Hydrosulphuric acids, and Ferro- and Ferri-cyanides.

6. *Indigo-solution* is decolorised, without the addition of an acid, by free chlorine and bromine; by all the oxygen-acids of chlorine, when free, and by metallic hypochlorites; by free nitric acid, if not too dilute, by alkaline sulphides, and by caustic alkalis. On addition of sulphuric acid, and heating, by chlorates, bromates, iodates, and nitrates. On addition of hydrochloric acid, and heating (chlorine being evolved), by all the foregoing compounds; also by chromates, selenates, tellurates, vanadates, manganates, permanganates, ferrates, and all peroxides.

In investigating the acids contained in a soluble compound, the first step is to ascertain the behaviour of the solution to vegetable colours. When, as is frequently the case, a neutral solution is required, the solution, if acid, is neutralised by ammonia: if alkaline, by nitric acid, or, if nitrate of silver be not employed as a reagent, by hydrochloric acid. But, as many of the heavy metals, as well as some alkaline-earthy salts, are precipitated when their solution is neutralised by ammonia, it is generally necessary to remove from the solution all metals except the alkaline metals, before proceeding to test for acids; in which process, the presence or absence of metallic acids, and of alkaline-earthy phosphates, oxalates, &c. will be ascertained. When this is not done, it is frequently necessary to substitute for the general reagents mentioned above, the nitrate of the same base, since nitric acid forms no insoluble salts: thus nitrate, instead of chloride, of barium, must be employed in solutions containing lead, silver, or subsalts of mercury. We have already mentioned cases in which the addition of nitric or hydrochloric acid to an alkaline solution will produce a precipitate. The following acids are also precipitated by the mere acidulation of their alkaline solutions: Tungstic, Molybdic, Antimonic, Benzoic, Uric acids; Boric and Silicic acids from concentrated solutions. Under the same circumstances, a precipitate of sulphur is produced in presence of hyposulphurous acid or polysulphides: of iodine, in a solution containing an iodide and an iodate: of acid tartrate of potassium or ammonium, in a solution containing the normal tartrates of these metals. The nature of the metals found in a solution will often imply the absence of one or more acids: generally speaking, a neutral or acid solution containing one of the metals whose salts are used as general reagents for acids, need not be examined for any of those acids which are precipitated by that metal. Thus, sulphuric or hydrochloric acid need not be sought for in soluble compounds containing barium or silver respectively. In order not to overlook the presence of uncombined volatile organic acids, the acid solution is neutralised with carbonate of sodium, evaporated to dryness, and ignited: when the organic acid, which, if free, would have been volatilised undecomposed, is decomposed, with separation of carbon.

Substances which are insoluble in water or acids are rendered soluble by one of the methods already described, and the solution is examined for acids in the wet way. Insoluble compounds of the heavy metals are mostly decomposed by digestion with sulphide of ammonium; sulphates of strontium and calcium by digestion with carbonate of sodium: in both cases, the filtrate contains the acid, together with an excess of the decomposing agent, while the metal is found in the residue. Insoluble salts of organic acids are decomposed by boiling with an alkaline carbonate; ferric salts of volatile organic acids by digestion with ammonia: in both cases, the filtrate contains an alkaline salt of the acid. Sulphides and all salts of the lower oxygen-acids of sulphur, yield sulphuric acid when digested with nitric acid, or any other oxidising agent.

The application of confirmatory tests is as necessary in the case of acids as in that of metals.—F. T. C.

The methods of *quantitative inorganic analysis* cannot be included in one article. The processes for the separation and quantitative estimation of each element are described in the article devoted to that element. The analysis of ashes, soils, mineral-waters, &c. and volumetric analysis, are also described in separate articles. We may here however describe a method, of general application, which is found useful in many cases, viz.:

The Indirect method of Quantitative Analysis.—The usual method of determining the quantities of the several constituents of a compound or mixture, is to separate each of them in the form of a definite compound, which can be collected and weighed, *e. g.* silver as chloride, barium as sulphate, &c., and calculate the weight of the required constituent from the known composition of this compound. It sometimes happens however, that the complete separation of certain substances is very difficult, or even impossible, and in that case, recourse is had to a method of determination, which depends on the general principle that any number of unknown quantities may be determined simultaneously, if we can find between them a number of relations equal to that of the quantities themselves; in other words, n unknown quantities may be determined by means of n equations.

Suppose for example, we have a mixture, either solid or liquid, containing potassium and sodium, in the form of hydrates or carbonates. Take two equal portions of the mixture (it is not necessary to know the weight of these portions), convert one portion into chlorides, the other into sulphates, and weigh the two products. Let the sum of the weights of the chlorides be a, and that of the sulphates b: the unknown weight of potassium x, and that of sodium y; then from the known atomic weights of the metals, their chlorides and sulphates, we have:

$$\frac{74\cdot5}{39}x + \frac{58\cdot5}{23}y = a$$

$$\frac{87}{39}x + \frac{71}{23}y = b$$

whence the quantities x and y may be determined.

Another form in which the indirect method may be applied to the determination of two substances, is to bring them both together into a form in which they can be weighed, *e. g.* as chlorides or sulphates, and determine the quantity of chlorine or of sulphuric acid in the mixture; thus, suppose a mixture of potash and soda to be converted into chlorides: let the sum of the weights of these chlorides be s, and let the amount of chlorine in this mixture, determined as chloride of silver, be c; then if x be the quantity of potassium and y the quantity of sodium, we have the two equations:

$$\frac{\mathrm{KCl}}{\mathrm{K}}x + \frac{\mathrm{NaCl}}{\mathrm{Na}}y = s; \qquad \frac{\mathrm{Cl}}{\mathrm{K}}x + \frac{\mathrm{Cl}}{\mathrm{Na}}y = c$$

$$\text{or} \qquad \frac{74\cdot5}{39}x + \frac{38\cdot5}{23}y = s; \qquad \frac{35\cdot5}{39}x + \frac{35\cdot4}{23}y = s$$

whence x and y may be found.

If three substances are to be determined, *e. g.* barium, strontium, and calcium, we should of course require three equations, which, in the case supposed, might be obtained by weighing the three substances, first as carbonates, then as oxalates, then as sulphates. It is seldom, however, that the indirect method is applied to the determination of more than two substances.

A case in which this indirect method of analysis is often applied, is to the determination of a small quantity of bromine or iodine in presence of chlorine, as in the analysis of mineral waters. The chlorine and bromine are precipitated by a solution of silver, and the mixed chloride and bromide of silver is weighed. It is then ignited in a stream of chlorine till all the bromine is expelled, and the resulting chloride is again weighed: let the difference of the two weights be d: then, since chlorine and bromine replace one another in the proportion of their atomic weights, viz. as 35·5 to 80, we have:

$$\mathrm{Br} - \mathrm{Cl} = d; \qquad \frac{\mathrm{Br}}{\mathrm{Cl}} = \frac{80}{35 \cdot 5}$$

whence $\mathrm{Br} - \frac{35 \cdot 5}{80} \mathrm{Br} = d; \qquad \frac{44 \cdot 5}{80} \mathrm{Br} = d.$

and therefore $\mathrm{Br} = 1 \cdot 797\, d.$

The indirect method of analysis can only be employed with advantage to ascertain the relative quantities of substances whose atomic weights differ considerably: with a mixture of bodies of the same atomic weight, it cannot give any definite result; in fact the two equations which it involves become in that case identical.

ANALYSIS (ORGANIC).—The analysis of organic substances divides itself, like that of inorganic bodies, into qualitative and quantitative. A further division is also convenient, viz. into *Elementary* or *Ultimate Analysis* and *Proximate analysis*, according as the object of the inquiry is to determine the ultimate elements, carbon, hydrogen, &c., of which the body is composed, or the proximate principles, such as sugar, starch, fibrin, &c., in which those elements are grouped.

I. ELEMENTARY OR ULTIMATE ORGANIC ANALYSIS.

Organic bodies are composed of carbon, hydrogen, and oxygen, with or without nitrogen, sometimes also associated with sulphur and phosphorus: these are all the elements that occur in natural organic compounds; those which are artificially prepared may contain any elements whatever.

The detection and estimation of these elements depends essentially on the process of COMBUSTION. When an organic compound is heated to redness in contact with free oxygen, or with a substance which gives up that element with facility, it is completely decomposed, its elements being separated either in the free state or in new forms of combination.

Qualitative Analysis. *Carbon* and *Hydrogen* are detected by burning the compound in a glass tube in contact with oxide of copper or chromate of lead. The carbon is then converted into carbonic acid*, which if passed into baryta-water, forms a white precipitate of carbonate of barium, and the hydrogen into water, which collects in drops in a small cooled receiver attached to the combustion-tube, or, if in very small quantity, may be rendered visible by causing the vapour to pass through a narrow glass tube lined with phosphoric anhydride, which if water is present, will be converted into phosphoric acid and dissolved. Carbon may also, in nearly all cases, be detected by the black residue which remains when the organic substance is burned in the air, or ignited in a close vessel, or heated with strong sulphuric acid; very few organic bodies contain sufficient oxygen to burn away the carbon completely, even in contact with the air. The black residue of carbonaceous matter may be distinguished from black substances of inorganic origin, by burning slowly away when heated to redness, and by its property of deflagrating with nitre and chlorate of potassium.

Nitrogen in organic bodies is for the most part given off in the free state when the compound is burned with oxide of copper, but a surer mode of detecting it, especially when in small quantity, is to heat the substance in a test-tube with a considerable excess of hydrate of potassium or sodium. The carbon is then converted into carbonic acid by the oxygen of the alkaline hydrate, while the whole or the greater part of the hydrogen unites with the nitrogen to form ammonia, which may be detected by its odour, by its action on litmus paper, and by the white fumes which it produces when a glass rod dipped in dilute hydrochloric acid is held over the mouth of the tube (see AMMONIA). A still more delicate test for nitrogen is the following, given by Lassaigne. A portion of the organic compound is fused in a test-tube with a small piece of potassium; the mass is treated with water when cold; and the liquid boiled with protosulphate of iron partially oxidised by contact with the air. If it be then supersaturated with hydrochloric acid, the presence of nitrogen will be indicated by the formation of a precipitate of Prussian blue, or in case of very minute quantities, by a bluish green colour being communicated to the solution.

Chlorine in organic bodies is detected by igniting the compound with quick lime, whereby it is completely destroyed, the chlorine uniting with the calcium, in which state of combination it may be dissolved out by water, and the chlorine precipitated by nitrate of silver. In some organic compounds which contain hydrochloric acid ready formed, viz. the hydrochlorates of the organic bases, the chlorine may be immediately detected by nitrate of silver without this preliminary treatment.

---

* Throughout this article, the term *carbonic acid* is used for CO^2, in accordance with established usage, instead of the more correct appellation *carbonic anhydride*.

Bromine and *Iodine* may be detected by similar treatment; *Fluorine* in the same manner as in inorganic bodies.

Sulphur, *Phosphorus*, and *Arsenic*, are detected by igniting the organic compound with a mixture of hydrate of potassium, and nitre or chlorate of potassium, whereby those elements are converted into sulphuric, phosphoric, and arsenic acids, the presence of which may be demonstrated by reactions appropriate to each.

Metals occurring in organic compounds, remain for the most in the form of oxides, or in the metallic state when the organic matter is burnt. Mercury may be detected in the ordinary way, by distillation with lime.

Quantitative Analysis. The first quantitative analyses of organic bodies were made by Gay-Lussac and Thénard. The substance to be analysed was mixed with a known weight of *chlorate of potassium*, and made up into small pellets, which were dropped one by one through a stopcock of peculiar construction, into an upright glass tube heated to redness, the gas thereby produced escaping by a lateral tube and being collected over mercury. The volume of gas was exactly measured, and the carbonic acid absorbed by caustic potash. The remaining gas consisted either of pure oxygen, or (in the case of azotised bodies) of a mixture of oxygen and nitrogen, the proportions of which were determined eudiometrically (see ANALYSIS OF GASES). Knowing then the weight of the substance burned, the weight of the chlorate of potassium used, and consequently the quantity of oxygen evolved, also the quantity of carbonic acid produced, and of the oxygen remaining after its absorption, sufficient data were obtained for calculating the amount of carbon, hydrogen, and oxygen in the substance analysed: for, the difference between the total quantity of oxygen which had disappeared, and that which was consumed in burning the carbon (this latter quantity being equal in volume to the carbonic acid produced), gave the quantity which had united with the hydrogen to form water, and thence the amount of hydrogen was calculated.

This process was a great step in chemical science, and yielded many important results; but it was difficult of execution, requiring great skill on the part of the operator; it was also inexact in the case of nitrogenous bodies, and totally inapplicable to liquid or volatile compounds. Berzelius simplified it by mixing the chlorate of potassium with common salt, thereby causing the combustion to go on gradually, and rendering it possible to introduce the whole of the material at once. He also collected and weighed the water produced, and thus greatly simplified the calculation.

Saussure and Prout burned the organic substance in an atmosphere of oxygen. Prout's apparatus was so contrived that the substance was burnt in a measured volume of oxygen, and the volume of the gas remaining after combustion was compared with the original volume. Now, since the volume of carbonic acid produced by the combustion of carbon is equal to that of the oxygen consumed, while that which unites with the hydrogen to form water disappears altogether, it follows that if the organic substance contains oxygen and hydrogen exactly in the proportion to form water (as in acetic acid, sugar, &c.), the volume of gas remaining after combustion will be equal to that of the original oxygen: whereas if the proportion of hydrogen is greater (as in alcohol and ether), the volume of gas will be diminished by the combustion; and if the proportion of hydrogen is less (as in oxalic acid), the volume of gas will be increased. Hence, by absorbing the carbonic acid with potash and measuring the residual gas, sufficient data were obtained for calculating the quantities of carbon, hydrogen, and oxygen.

The method now universally adopted for the estimation of carbon and hydrogen in organic compounds, consists in burning the compound with a large excess of oxide of copper or chromate of lead, and determining the quantities of carbonic acid and water produced by the combustion, not by measure but by weight, the water being absorbed by chloride of calcium, and the carbonic acid by potash. The use of oxide of copper was first introduced by Gay-Lussac and afterwards adopted by Ure; but it is to Liebig that we are indebted for those modifications of the process which have brought it to its present state of simplicity and exactness.

The process, as now performed, requires the following materials and apparatus.

Oxide of Copper.—Prepared by dissolving copper in nitric acid, evaporating to dryness, and calcining the residual nitrate in a crucible at a low red heat. As thus prepared, it is a dense, soft black powder, which rapidly absorbs water from the air even before it is quite cold. If, however, it be very strongly heated, it aggregates into dense hard lumps, which, when broken into small pieces and sifted from the finer powder, yield an oxide well adapted for the combustion of volatile liquids. Oxide of copper may also be prepared by igniting copper turnings in a muffle. The oxide thus obtained is much harder and less hygroscopic than that prepared from the nitrate, but it is not so easily mixed with an organic substance in the state of fine powder. Oxide of copper must always be heated to low redness immediately before use.

Chromate of Lead.—Prepared by precipitating a solution of acetate of lead with bichromate of potassium, fusing the washed and dried precipitate in a crucible, and pulverising it in an iron mortar; it is then obtained in the form of a yellow-brown powder. It is but very slightly hygroscopic; but to ensure its complete dryness, it should be preserved in stoppered bottles and heated over a lamp just before it is used.

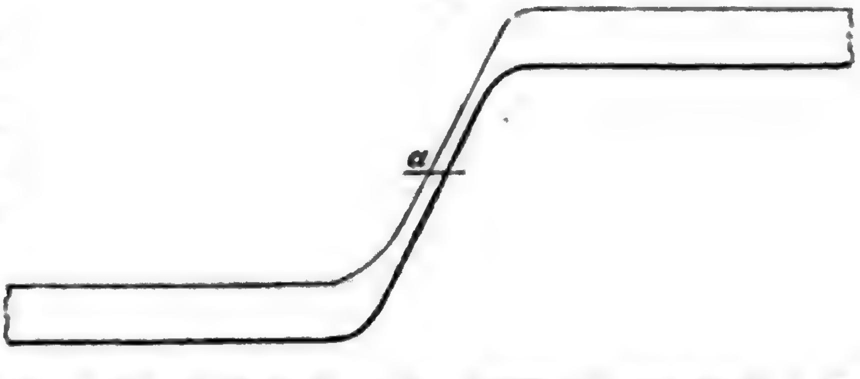
Metallic Copper.—Used in the analysis of bodies containing nitrogen. The most convenient form is that of fine copper turnings, or thin foil rolled up into a spiral. As the surface, especially of the turnings, is seldom clean, the metal should first be heated in a current of air, to destroy any organic matter adhering to it, then pressed into a combustion-tube, and heated in a current of dry hydrogen gas to reduce the oxide previously formed, the heat being continued as long as vapour of water continues to be given off, and the stream of hydrogen afterwards kept up till the metal is cold. By this treatment, the surface becomes covered with finely divided copper, which is very hygroscopic and must therefore be strongly heated over a lamp before use. Finely divided copper reduced by hydrogen from the oxide, is not applicable, being found to decompose carbonic acid at a red heat.

Combustion-tubes of hard glass.—They must be capable of sustaining a strong red heat without melting or even softening to such a degree as to be blown out by the pressure of the evolved gases. The best are made of the hard Bohemian glass (silicate of calcium and potassium), which may now be procured without difficulty. Glass containing lead is utterly unfit for the purpose. When the temperature required for a combustion is very high, the tube should be protected by wrapping it in copper foil or brass wire-gauze, to prevent it from bending if it becomes softened by the heat.

The length and diameter of tube required vary according to the substance to be burnt. For the combustion of ordinary solids, tubes of half an inch internal diameter, and 18 inches long, are well adapted: for solids containing very little carbon, a diameter of $\frac{4}{10}$ of an inch is sufficient: for liquids, it is necessary to use tubes $\frac{6}{10}$ of an inch wide and 20 or 30 inches long, the length being greater as the liquid is more volatile. The use of tubes of larger dimensions than the particular case requires, is not to be recommended, as it involves waste of oxide of copper and increases the unavoidable errors of the operation.

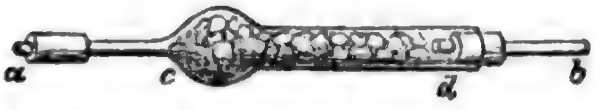
The tubes, after being thoroughly cleansed and dried, are drawn out into an inclined neck, and sealed at one end, while the other end is cut as evenly as possible with a file, and afterwards made smooth at the edges by careful heating in the blowpipe flame. The best mode of sealing is to take a tube of double the length required, soften it in the middle by means of a powerful blowpipe flame, then draw it out in the manner shown in *fig.* 8, and apply the point of the flame for an instant at the middle of the neck *a*, so as to divide and seal it. By this means, two tubes of the required shape are made at once.

Fig. 8.



Chloride of calcium tubes.—The chloride of calcium for absorbing the water generated in the combustion, is usually contained in a bulb-tube of the form shown in *fig.* 9. The end *a* passes through a perforated cork fitting into the combustion-tube, and the end *b* is fitted with a cork and narrow glass tube, which is connected with the potash-apparatus by means of a flexible tube of caoutchouc. Small plugs of cotton-wool are placed at *c*, *d*, to keep the chloride of calcium in its place. The cork *d* should be covered with sealing wax, so that it may not vary in weight by loss or absorption of atmospheric moisture.

Fig. 9.

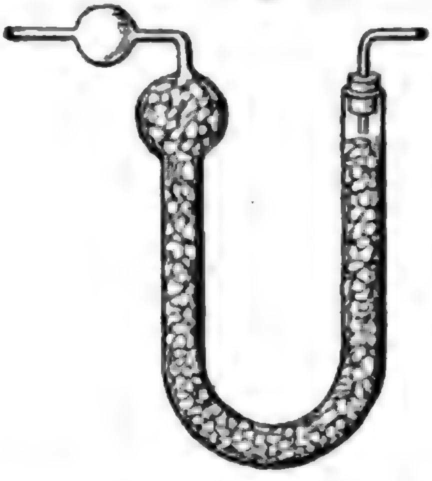


Another form of this apparatus presenting some advantages is the U-tube (*fig.* 10) having at the end nearest to the combustion-tube, a small test-tube, *t*, which serves to collect the greater part of the water, so that the chloride of calcium does not get so much wetted, and may be used several times without renewal. Chloride of calcium tubes are sometimes also made in the form of a U-tube (*fig.* 11), having two bulbs, the one at the extremity of the arm of the tube being filled with chloride of calcium, and the upper being empty to receive the greater part of the water. This form of tube is more expensive than that last described (*fig.* 10), and does not appear to possess any advantage over it.

The U-tube must always be used in preference to the straight tube (*fig.* 8), when the combustion is made in a stream of oxygen gas; because the current of gas being then rather strong, is apt to carry the vapour of water through the straight tube so quickly that a portion of it escapes uncondensed, whereas the U-tube detains it longer, and is more likely to ensure complete absorption.

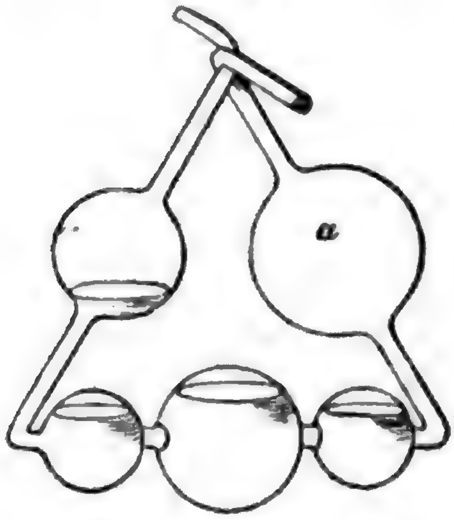
Fig. 10.

Fig. 11.



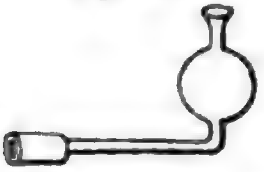
The chloride of calcium should be in the spongy state in which it is obtained by drying at about 200° C. The fused chloride is not so good for the purpose, because it often contains free lime, which absorbs carbonic acid as well as water.

Fig. 12.



Potash-bulbs. — The solution of caustic potash which absorbs the carbonic acid, is contained in a Liebig's bulb-apparatus (*fig.* 12), the form of which is so contrived as to keep the bubbles of gas in contact with the solution for a considerable time, without using a long column of liquid. The large bulb *a*, is connected with the chloride-of-calcium tube, the other extremity of the apparatus being left open. The solution of potash should have a density of about 1·27. If a weaker ley be used, the carbonic acid will not be completely absorbed, and stronger ley is apt to froth, and in that case a portion of it is sure to be forced out at the open end of the apparatus, thereby annihilating the result of the experiment. To fill the bulbs, the potash solution is poured into a small beaker or crucible, and drawn into the apparatus by means of a small suction-tube (*fig.* 13), attached to one end by means of a perforated cork. The quantity of liquid introduced should be sufficient to nearly fill the three lower bulbs, not more: the apparatus thus filled weighs from 40 to 50 grammes. Before weighing, it must be carefully wiped on the outside; and the inside of the tube, by which the liquid has entered, must be dried by means of a thin roll of filtering paper.

Fig. 13.



Corks.—The connection between the combustion-tube and the chloride of calcium tube, is made by a perforated cork. The greatest pains should be taken to select for the purpose good corks, smooth, and free from flaws. They should be softened by beating or by pressure. Immediately before the combustion, the cork must be thoroughly dried in an air-bath or sand-bath at a temperature a little above 100° C.: too great a heat must be avoided, as it renders the cork brittle.

Caoutchouc-tubes. — The chloride-of-calcium tube is connected with the potash-apparatus by a flexible tube of caoutchouc. These tubes are easily made by binding a piece of sheet-caoutchouc over a glass rod or tube of the proper size, and cutting it with a single stroke of a pair of scissors. If the edges be then pressed together, a perfectly tight tube will be made. The connections are made air-tight by tying with silk cord. Tubes of vulcanised caoutchouc, which may be purchased ready made, may also be used, and if of such a size as to require some force to fit them to the tubes, they make an air-tight joint without tying; they must however always be previously digested with a moderately strong solution of potash, in order to remove the sulphur, which is otherwise apt to get into the chloride of calcium tube and potash-apparatus.

Combustion-furnaces.—The combustion-tubes are heated either with charcoal or with coal gas: formerly charcoal was the only fuel employed; but gas-furnaces are now coming into general use. Furnaces have also been constructed for burning spirit; but the high price of that material in most countries renders its use very limited.

The charcoal-furnace is made of sheet iron, in the form of a trough (*fig.* 14), 22 to 24 inches long, and 3 inches high. The bottom is 3 inches wide, wth narrow apertures about $\frac{1}{2}$ an inch apart, which form a sort of grate; the sides of the furnace are inclined outwards, and $4\frac{1}{2}$ inches apart at top. To support the combustion-tube, pieces of strong sheet-iron of the form D (*fig.* 15), are riveted to the bottom of the furnace at intervals; they are of exactly equal height, with their edges ground flat, and correspond with the round aperture in front of the furnace A. The furnace is placed upon flat bricks, so that but little air can enter the grating unless the whole is purposely raised; the draught can thus be regulated at pleasure. The heat produced by the charcoal fire is very regular, and may be raised to any degree required, higher indeed than the best combustion-tubes can bear; on the other hand, the use of charcoal as fuel has many inconveniences; the operator is exposed to great heat and to the deleterious fumes of carbonic oxide, and the ash flies about to such an extent that it is always necessary to perform the combustions in a room apart from the general laboratory.

Fig. 14.

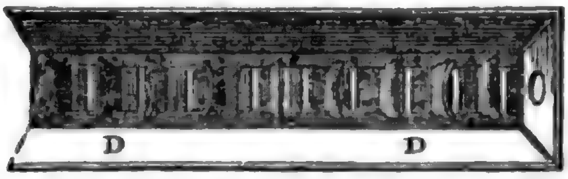


Fig. 15.

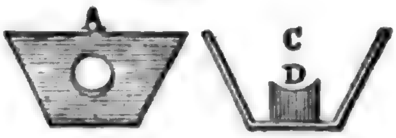

For these reasons, it has long been considered desirable to use coal-gas as the fuel for the combustion process, and several forms of furnace have been contrived for the purpose. It is only lately, however, that the problem has received a satisfactory solution, viz. in the gas furnace constructed by Dr. Hofmann, and described by him in the Journal of the Chemical Society, vol. xi. p. 30, whence the following details and illustrations are taken.

In using coal-gas as fuel, it is essential that the gas while burning be mixed with air in sufficient quantity to ensure complete combustion and prevent smoking. This is usually effected by interposing a sheet of wire gauze between the flame and the orifices from which the gas issues. This contrivance was indeed adopted in a form of furnace for organic analysis invented some years ago by Dr. Hofmann, and has also been adopted by others. But all furnaces thus constructed are very liable to get out of order, in consequence of the speedy destruction of the wire gauze; moreover, they do not afford sufficient heat for many combustions: hence they have not come into general use.

In the new form of gas furnace, the mixing of the gas with air is attained by causing it to issue through a number of small orifices placed very close together. For this purpose, a peculiar form of burner is used, called *atmopyre* (*fig.* 16). It consists of a hollow cylinder of burnt clay, closed at top, open at bottom, and having numerous perforations in the sides. Those which are used for the combustion-furnace, are 3 inches high, $\frac{7}{8}$ of an inch in external, and $\frac{3}{8}$ internal diameter. The perforations, of about the thickness of a pin, are made in rows, each cylinder having 10 rows of 15 holes each. From such a clay cylinder loosely fixed upon an ordinary bat's wing burner, the stopcock of which has been properly adjusted, the gas burns with a perfectly blue smokeless flame, which envelopes the cylinder and soon renders it incandescent.

Fig. 16.

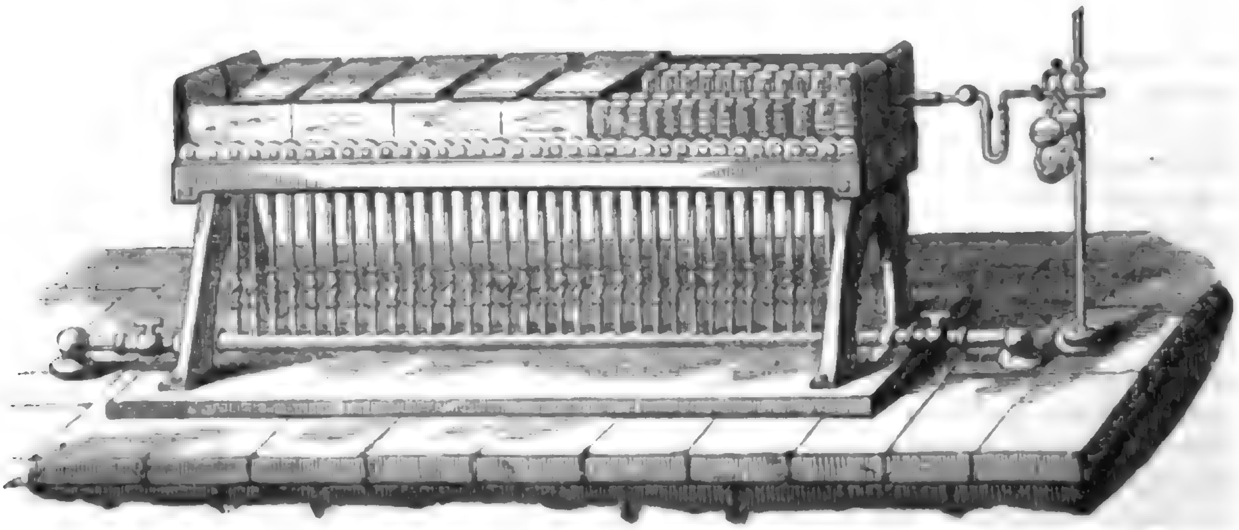
g g. Wrought iron frame.
h h. Cast iron supports.
i i. Cast iron footplate.
k k. Sides of fire-clay.
l l. Cover plates of fire-clay.

The disposition of the apparatus is shown in *fig.* 17. Into a brass tube *a*, from 3 feet to 3 feet 8 inches long, and 1 inch in diameter (shown in section in the figure), which communicates at both ends with the gas-main of the laboratory, there are screwed from 24 to 34 tubes *b*. These tubes, $\frac{1}{2}$ an inch wide and 7 inches high, are provided with stopcocks and carry brackets *c c*, $\frac{1}{2}$ an inch long, and $\frac{5}{8}$ of an inch in diameter, for the reception of five ordinary bat's wing burners (each consuming from 3 to 4 cubic feet of gas per hour, for a full luminous effect) upon which are fixed a corresponding number of clay burners. These clay burners *d d d d*, have the dimensions above stated, excepting the middle one, which is only $1\frac{7}{8}$ inches high and has 70 or 80 perforations. It serves as a support for the combustion-tube *f*, which is thus bedded in a channel of heated fire-clay. The system of brackets lying side by side, acquires sufficient stability by a strong iron frame *g g*, which rests upon two firm supports *h h*, of cast-iron, fastened down by screws upon the foot-plate, *i i*, likewise of cast-iron. The iron frame *g g*, has moreover a groove for the reception of moveable side plates of fire-clay *k k*. They are of the same height as the high burners, over which they project about $\frac{5}{8}$ of an inch, in consequence of their resting upon the frame *g*; lastly, *l l* are covering plates, likewise of fire-clay, which are supported by the side plates *k k*.

The whole disposition of this apparatus will be best understood by the perspective view given in *fig.* 18. In the front part, contiguous to the potash-apparatus, the side plates and the covering plates are omitted, in order to show the disposition of the burners. During the combustion, however, all the burners are inclosed, as exhibited in the posterior part of the apparatus.

Fig. 18.



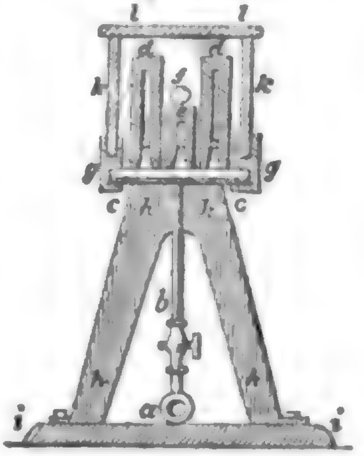
The efficiency of the furnace depends essentially upon the correct disposition of the gas jets. The most appropriate space between the several burners, is about $\frac{1}{8}$ inch. It is very important for the attainment of a perfectly uniform temperature that the several brackets bearing the burners should be equidistant. Their position is therefore specially secured by every bracket being fixed in an aperture formed in the iron frame *gg*, *fig.* 17.

According to the length of the combustion-tube, from 8 to 10 stopcocks (under all circumstances the largest possible number) are opened at once at the commencement of a combustion. If care has been taken to regulate the amount of gas, either by the stopcocks in the horizontal gas pipe, or by those in the separate supply-tubes, the lighted portion of the furnace will, in 10 or 12 minutes, be in a state of perfect incandescence. After this it is only necessary to open the remainder of the stopcocks, in appropriate succession, to insure a slow and regularly progressing combustion. The time required for the completion of an analysis varies from 40 minutes to an hour, rarely more.

The heat obtained by this furnace is very regular; and since it is conveyed to the combustion-tube chiefly by radiation from the incandescent mass of surrounding clay every part of the tube is equally heated. The temperature which it is capable of yielding *is entirely* at the command of the operator. When strained to its full power, it gives a heat equal to that of the strongest charcoal combustion-furnace; but by properly adjusting the stopcocks, it may be kept at any desired temperature, especially since it is only necessary to look into the channel, when, with a little practice, a correct idea of the temperature is rapidly obained from the colour of the glowing cylinders. It deserves, however, to be noticed that the apparatus furnishes rather more heat than is generally required; it is preferable, therefore, under all circumstances, to protect the combustion-tube by a metallic shield: for this purpose ordinary brass wire gauze may be conveniently employed; it is more easily manipulated, and may be used longer than the thin copper or brass plate generally employed.

One great advantage of this furnace is its durability. The clay plates and burners show but little tendency to split, and the mixture of gas and air is so perfect that the holes in the burners never become stopped up with carbon. Moreover, the cost of the gas consumed is very much less than that of the charcoal required to produce the same amount of heating effect. Dr. Hofmann has found that a combustion lasting 1 hour, and requiring the whole length of the furnace (34 rows of burners), consumes from 80 to 90 cubic feet of gas. For a carbon determination, with 24 rows of burners, which generally lasts about 40 minutes, from 50 to 60 cubic feet are required, and for a nitrogen determination, 25 to 30 cubic feet. In laboratories where many combustions are made, the saving of fuel soon covers the original cost of the furnace.

Fig. 19.



The expense of the apparatus and the consumption of gas, may be diminished by reducing the number of rows of burners from 5 to 3, as shown in *fig.* 19. The heat given by such a furnace is of course not so great as that afforded by the larger one, but it is sufficient for nearly all combustions.

Several other forms of gas furnace for organic analysis have also been proposed. One of these invented by Babo, which is much used in the German laboratories, is represented in *fig.* 26, page 235.

Preparation of the Substance for Analysis.

Before proceeding to determine the proportion of the elements in an organic compound, it is necessary to ensure that the substance is in a perfectly pure and definite state. It is but seldom that the processes of ultimate analysis can be advantageously applied to complex organic mixtures; only indeed when the proportion of a single element is to be determined for commercial purposes, as in the valuation of articles of food or of manures by the quantity of nitrogen which they contain.

In solids, uniformity and regularity of structure, whether crystalline or otherwise, is in many cases the best test of purity: in such cases, examination by the microscope is often of great service. Constancy of melting-point is also a test of the purity of many substances, especially of fatty bodies. The purification of solids is generally effected by recrystallisation from solution, or from the fused state, or in the case of volatile bodies, by sublimation. In liquids, the chief test of purity is constancy of boiling point, and purification is effected chiefly by fractional distillation. In all cases a small quantity of the substance must be burnt upon platinum foil, in order to ascertain whether it contains any inorganic matter; if the organic body is pure, it will burn without residue. If inorganic matter is present in considerable quantity, or if it forms an essential part of the compound, as in the salts of organic acids, its quantity must be exactly determined by burning a weighed portion of the compound.

Further, it is necessary before proceeding to the process of combustion, to free the compound from hygroscopic water. For this purpose, a weighed quantity of the substance is heated for some time in a water-bath at 100°, and then weighed again; if it has lost weight, it is again heated and again weighed: and these operations are repeated till two successive weighings, between which the substance has been heated, give the same result. The substance may then be considered dry.

Bodies which cannot bear a temperature of 100° C. without decomposition, may be dried by placing them over a large dish containing strong sulphuric acid, and covering the whole arrangement with a bell-jar; the desiccation is greatly accelerated by placing the whole apparatus on the plate of the air-pump, and exhausting the air.

The same methods may be applied to determine the amount of chemically combined water which exists in many compounds, the water of crystallisation of salts, for example. Many bodies, however, retain their water with too great force to be overcome by the means just mentioned. Such substances may be dehydrated by enclosing them in a test-tube immersed in a water or oil-bath, while a current of dry air is drawn through the tube by means of an aspirator. In some cases even this is not sufficient, and the desiccation can only be effected by heating the substance in a tube from which the air is exhausted by an air-pump, then introducing dry air, exhausting again, and so on, till the substance ceases to lose weight. (See Evaporation and Water.)

It is often, however, difficult to determine how much of the oxygen and hydrogen existing in a compound exists in the form of water: for many substances, before they give off all the water that can be eliminated by the methods above described, begin to decompose and form new compounds. In such cases, the process of organic analysis must be applied to the compound in the hydrated state, and the quantity of water estimated as nearly as possible by the phenomena which the substance exhibits when heated, or by its chemical reactions.

Volatile liquids are dehydrated by leaving them for some time in contact with lumps of fused chloride of calcium and then distilling, the chloride of calcium being however previously removed, as it might, when heated, give up some of the water which it has absorbed.

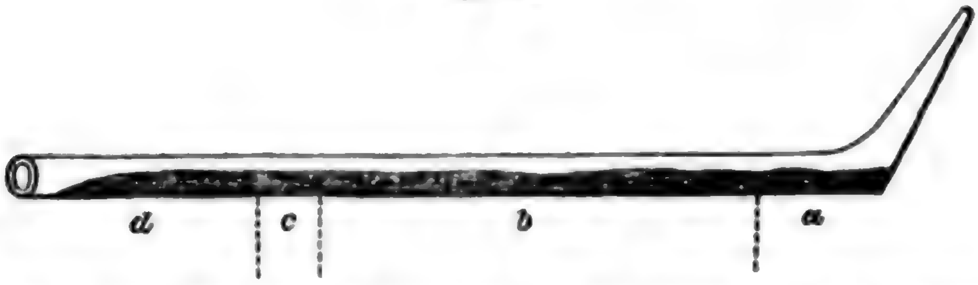
The substance having been brought to the proper state of purity and dryness, may now be subjected to the combustion process.

ESTIMATION OF CARBON AND HYDROGEN.

In Solids not containing Nitrogen.—The substance being thoroughly dry and in the state of fine powder, about 0·3 grm. (or 5 grains) is weighed out in a small test-tube, or between two watch-glasses, the weighing being made exact to the tenth of a milligramme (or ·001 of a grain). The vessel and its contents are weighed together, and after the substance has been removed, the vessel, with the small quantity of matter adhering to it is again weighed. This weight deducted from the former gives the quantity of substance used in the experiment. The combustion-tube after being cleansed, if necessary, is made very hot in the sand-bath, and a long glass tube being thrust into it, the air is sucked out so as to remove every trace of moisture.

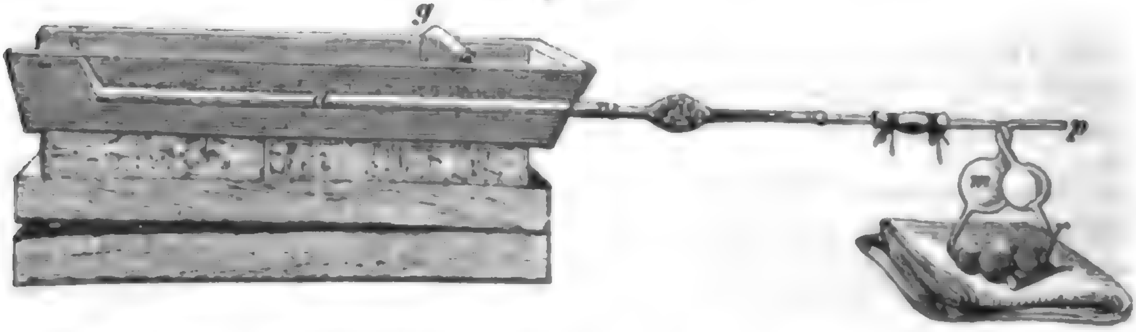
The combustion may be made either with oxide of copper or with chromate of lead; the latter being the more easily managed, on account of its possessing little or no hygroscopic tendencies, we shall describe its use in the first place:—A quantity of the chromate (previously fused and pulverised) sufficient to fill the tube, is heated over a gas lamp till its colour changes to brown-red. When it has cooled, a small quantity is poured into the tube, sufficient to fill about an inch of its length, and about two-thirds of the remainder is poured into a clean dry porcelain mortar. The substance to be analysed is then added to it, and the two are carefully mixed by gentle trituration. The combustion-tube being then taken in the right hand, and the mortar in the left, the mixture is transferred to the tube by a kind of screwing motion, the open end of the tube being slightly inclined upwards after each addition, and the tube lightly tapped against the side of the mortar to make the mixture descend. When nearly the whole of the mixture has been thus introduced, a small quantity of fresh chromate is poured into the mortar, triturated so as to rinse it, and then transferred to the tube in the same manner. The remainder of the tube up to within an inch of the end is filled with pure chromate. The contents of the tube are then shaken together by a few gentle taps on the table, so as to leave a free passage throughout for the evolved gas. The arrangement of the mixture in the tube is shown in *fig.* 20, where *a* represents the pure chromate, *b* the mixture, *c* the rinsings, and *d* the pure chromate near the open end.

Fig. 20.



The tube is now laid in the combustion furnace, and the chloride-of-calcium tube and potash-bulbs are attached to it in the manner already described, the potash-bulbs resting on a folded cloth, and the outer bulb being slightly raised by placing a cork under the apparatus at *r*. *Fig.* 21, represents the arrangement for burning with charcoal. The disposition of the gas-furnace is shown in *fig.* 16, page 225.

Fig. 21.



Before commencing the combustion, the apparatus must be carefully examined to ensure its tightness. For this purpose, a hot coal is held for a short time near the inner bulb (*m*) of the potash apparatus, so as to rarefy the air and cause a few bubbles to pass through the liquid. The coal is then withdrawn, and the apparatus left to itself for about ten minutes. If all the joints are air-tight, the liquid will now rise in the bulb *m* to a higher level than in the outer bulb, and will retain its position; but if any leak occurs, it will soon fall down to its original level. Should this be the case, the leakage is most probably in the cork which fits into the combustion-tube, or in the caoutchouc connector. To remedy this inconvenience without delay, it is well to be provided with two or three well dried perforated corks and a good stock of caoutchouc connectors.

The tightness of the apparatus having been established, the heat may now be applied. The anterior portion of the tube containing the pure chromate is first heated to redness, by laying red-hot charcoal round it (or turning on the gas jets immediately under it). The charcoal furnace is provided with a moveable screen *g*, (*fig.* 21), to prevent the heat from extending too quickly along the tube. When the anterior portion is thoroughly red-hot, the pure chromate of lead at the closed end of the tube must also be heated to redness, in order to burn any vapour that may diffuse into that part of the tube, and to prevent its deposition on the drawn out point, whence it would afterwards be difficult to remove (this precaution must be taken in every combustion, by whatever process). The fire is slowly extended towards the further extremity, each portion of the mixture being thoroughly burnt before the fire is extended further. The combustion should be so regulated that the carbonic acid may enter the potash-bulbs at a uniform rate, and in a succession of bubbles which may be easily counted. If no nitrogen is present, these bubbles are, after a certain time, completely absorbed by the potash; but when an azotised body is burnt, bubbles of nitrogen pass through the potash-solution during the whole process.

When the tube has been heated to redness throughout, the heat must be raised by fanning the fire on the top, and admitting air below by slightly raising the furnace from the bricks. As soon as the evolution of gas begins to slacken, the cork is removed from under the potash-bulbs, and the apparatus brought into the horizontal position. If the combustion has gone on well, the evolution of carbonic acid ceases all at once; if, on the contrary, the gas bubbles continue to pass slowly at intervals for a long time after the tube has been thoroughly ignited, we may be sure that the combustion is imperfect, most probably in consequence of the mixture not having been sufficiently intimate, and that the quantity of carbon will be found deficient.

As soon as the evolution of gas ceases, the liquid begins to rise in the bulb *m*. The coals must then be quickly removed from the end of the tube, and the point broken off with a pair of nippers. If the passage through the tube is clear, the potash-solution immediately falls to the same level in both bulbs: if it does not, there is a stoppage in the tube, and no time must be lost in clearing it, by thrusting in a stout iron wire from end to end; otherwise the potash-solution will be sucked up into the chloride of calcium tube, and the result will be entirely destroyed. To complete the experiment, it is now only necessary to draw a stream of air through the apparatus, by applying the suction-tube (*fig.* 13) to the extremity *p*, of the potash apparatus, so as to draw the small portions of carbonic acid and aqueous vapour remaining in the tube into the chloride of calcium tube and potash-bulbs. In doing this, however, a certain precaution is necessary: for the broken end of the tube being surrounded with an atmosphere of carbonic acid, a portion of this gas is likely to be drawn through the tube into the potash-solution, thereby making the proportion of carbon appear too great. To prevent this, a long glass tube open at both ends is placed over the end of

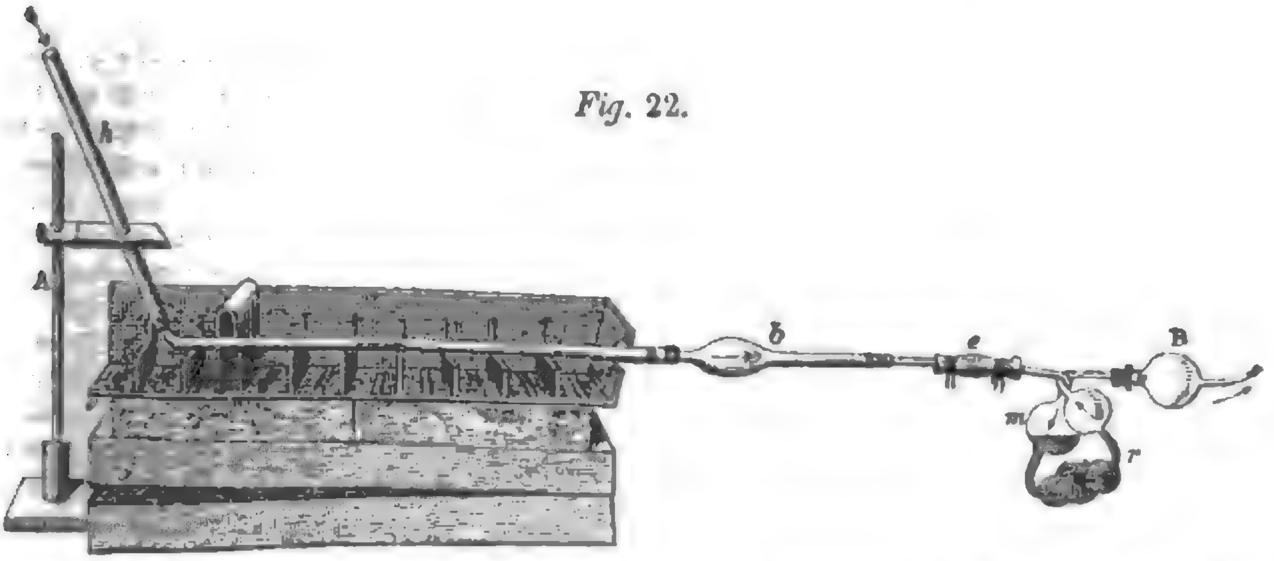


Fig. 22.

the combustion-tube, and supported in a slanting position, as in *fig.* 22, while the air is being drawn through the apparatus. By this means, the air is drawn from a height above the stratum of carbonic acid over the furnace. When the gas furnace is used, this precaution is of course superfluous, as the flame can be extinguished at once.

Lastly, the chloride-of-calcium tube and the potash-bulbs are detached, left to cool for about half an hour, and then weighed. The increase of weight of the potash-bulbs gives the quantity of carbonic acid produced, and $\frac{3}{11}$ of this is the quantity of carbon in the substance analysed. The increase of weight of the chloride-of-calcium tube gives the quantity of water produced, and $\frac{1}{9}$ of this is the amount of hydrogen. Knowing then the quantities of carbon and hydrogen in a given quantity of the substance analysed, it is easy to calculate the proportions of carbon and hydrogen in 100 parts. If the quantities thus determined make up 100, the substance is a hydrocarbon; if there is a deficiency, and it is known that no nitrogen, sulphur, chlorine &c. is present, the difference gives the percentage of oxygen. Examples of the calculation will be given further on.

Combustion with Oxide of Copper. — When the combustion is made with oxide of copper instead of chromate of lead, particular precautions are required to prevent the absorption of water during the mixing and filling of the tube. A quantity of the oxide is heated to redness in a covered earthen crucible, and left to cool till it will no longer burn a cloth in which the crucible is held. It is then mixed in a hot mortar with the substance to be analysed, and the mixture is arranged in the tube between two columns of pure oxide of copper, exactly as described for chromate of lead, the whole operation being conducted as quickly as possible. Some substances, however, will not bear mixing with hot oxide of copper; and even when this can be done, the oxide is sure to cool during the mixing sufficiently to cause an absorption of moisture from the air: hence an excess of hydrogen in the result of the analysis. To obviate this source of error, it is sometimes recommended to lay the tube, after filling, in a trough of hot sand, and connect it with an air-pump, then introduce air dried by passing over chloride of calcium, exhaust again, and so on. This, however, is a troublesome complication of the process. A simpler method of preventing the absorption of water, is to pour the oxide of copper, while still hot, into a long-necked flask (*fig.* 23), closed by a perforated cork in which a chloride-of-calcium tube is inserted, leave it to cool, and mix it with the organic substance in the combustion-tube itself. The neck of the flask must be a little wider than the combustion-tube, so that the latter will just pass into it (*fig.* 24): the oxide may then be transferred to the tube without coming in contact with the air. A small quantity of the cooled oxide is first introduced in this manner, then a portion of the organic substance is added, and upon this a column of oxide about three inches long is poured in the same manner as before. This portion of oxide is mixed with the organic substance by stirring it with a clean iron rod (*fig.* 25), the extremity of which is bent into two turns of a screw; and when it is thoroughly incorporated, the rest of the substance is introduced, then another column of oxide of the same length as before, and the stirring is repeated. Lastly, the rest of the tube is filled with pure oxide, and the combustion performed as above. This method of incorporation does not ensure so complete a mixture of the substance with the oxide as trituration in a mortar; but it answers this purpose sufficiently well in most cases.

Fig. 23.

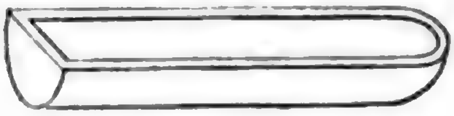
Fig. 24.

Fig. 25.

Oxide of copper is in many respects more convenient for use than chromate of lead, and indeed is more generally used for the combustion of substances which burn with facility. It is more easily prepared, and when partially reduced by the combustion process, may be restored to its original state by moistening it with nitric acid, and

air, and the other with oxygen gas. The communication is made by means of a T-tube provided with a cock, which renders it easy to connect either gas-holder with the combustion-tube and shut off the other at the same time. The air and oxygen before entering the combustion-tube, are made to pass through two U-tubes, one containing pumice-stone soaked in sulphuric acid, to dry the gas, the other lumps of caustic potash, to free it from carbonic acid. The combustion-tube may be heated either with gas or with charcoal (the figure represents a Babo's gas apparatus), and the mixture may be disposed in the tube in the ordinary way. But instead of mixing the substance with the oxide of copper, it is better in many cases to place it by itself in a small boat of platinum or porcelain *b* (*fig.* 27).

Fig. 27.



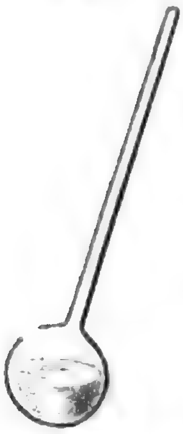
The combustion-tube is first filled to two-thirds of its length with oxide of copper, which need not be previously ignited, the remaining third, nearest to the gas-holder being left free to receive the boat. It is then laid in the furnace, and connected, in the manner just described, with the gas-holder containing atmospheric air; the oxide of copper is heated to redness; and a stream of dry air is passed through the tube so as to remove every trace of moisture. The tube is then left to cool; the boat containing the substance is put into its place, a plug of recently ignited asbestos having been previously introduced to prevent the oxide of copper from coming in contact with it; the chloride-of-calcium tube (U-shaped, see p. 228) and potash-bulbs are attached in the usual manner, and the apparatus is connected with the gas-holder containing oxygen. The oxide of copper is now once more heated to redness, and as soon as it is thoroughly ignited, heat is very cautiously applied to the part of the tube containing the boat, a slow stream of oxygen being passed through the apparatus, sufficient to prevent any backward passage of the evolved gases, but not to cause any free oxygen to pass through the solution of potash. If the oxide of copper exhibits a red colour, arising from reduction, the heating of the substance in the boat must be discontinued till the copper is reoxidised. When at length there is nothing left of the substance but black charcoal, the heat may be increased and the stream of oxygen accelerated. In this manner the combustion is soon completed; and when the bubbles of gas appear to pass through the potash without absorption, the process is continued in the same manner for a few minutes longer, and the potash-bulbs and chloride-of-calcium tube are then detached, after air has been passed through the apparatus for a little while to expel the oxygen. Lastly, the stream of air is continued for a sufficient time to effect the complete reoxidation of the copper, which is then ready for another experiment without further preparation.

After the tube has cooled, the boat is taken out and reweighed. If any inorganic matter remains in it, the quantity of this is at once ascertained if the weight of the boat itself is previously known.

This method, when carefully conducted, gives very exact results: it ensures the complete combustion of the carbon, and obviates all danger of an excess of hydrogen arising from moisture in the oxide of copper. It likewise saves the trouble of igniting the oxide of copper before the experiment, and afterwards treating it with nitric acid, But to ensure a good result, especial care must be taken not to heat the substance in the boat too suddenly; otherwise combustible gases will be given off more quickly than they can be burnt, and the analysis will be worthless.

Combustion of Liquids.—Volatile liquids are enclosed in small glass bulbs with narrow necks (*fig.* 28). The bulb is first weighed and then filled with the liquid, in the same manner as a thermometer tube, viz. by gently warming the bulb so as to rarefy the air, and dipping the neck into the liquid, so that as the air cools, a small quantity of the liquid may be forced up by external pressure. The bulb is then again heated till the liquid boils, the end of the neck immediately plunged again into the liquid, and the heat removed. The vapour now condenses and leaves a vacuum, into which the liquid is forced up so as to fill the bulb and the greater part of the neck. The neck is then sealed, and the bulb re-weighed. It is best to use two bulbs, each containing about 400 milligrammes of liquid.

Fig. 28.



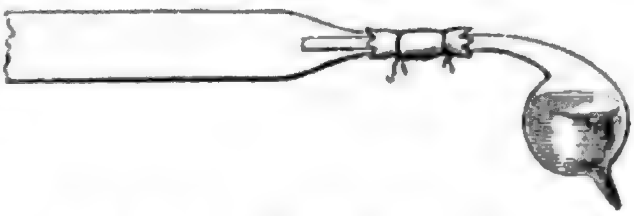
The analysis is made with oxide of copper: the coarse-grained variety obtained by oxidising copper turnings in a muffle, or by breaking oxide which has been hardened by strong ignition into small lumps, and sifting off the finer particles, is best adapted for the purpose, because it affords free space for the passage of the vapours, whereas the fine-grained oxide lies more compactly, and the greater part of the vapour passes over the surface instead of finding its way between the particles. For the same reason, chromate of lead, which fuses into a mass, is not so well adapted for the combustion of volatile liquids. The oxide of copper must be ignited in a crucible and left to cool completely in a corked flask (p. 234).

The combustion-tube should be at least 20 inches long, very volatile liquids requiring even a greater length. About an inch of the cold oxide is first poured in through a wide-necked funnel; one of the bulbs is then taken by the neck, a slight scratch having been previously made on it with a file; it is thrust into the tube, bulb downwards, the neck broken off at the scratch, and both bulb and neck dropt into the tube. About three inches more oxide is then added, the other bulb introduced in the same manner, and the tube filled up with oxide of copper. This oxide is first heated to redness, care being taken to proceed very gradually, and when the charcoal furnace is used, to protect the bulbs by a screen. As soon as the oxide is well ignited, a hot coal is approached to the nearest bulb, so as to volatilise a portion of the liquid, especial care being taken not to drive it over too fast. When the first bulb is empty, the heat is gradually extended; the liquid in the second bulb is then distilled in the same manner, and the combustion is finished in the ordinary way. As soon as the distillation of the liquid commences, a few pieces of hot charcoal must be placed under the point of the combustion-tube, to prevent the liquid from condensing there, as if this occurs, considerable heat will be required to dislodge the liquid, and a sudden burst of vapour is likely to take place.

The object of using two bulbs is to prevent too great a reduction of copper in the neighbourhood of either of them; when there is no longer any oxide close to the bulbs, a deposition of carbon is apt to take place, and then a stream of air or oxygen is required to burn it. Greville Williams, however, uses only one bulb, and drives all the liquid, at the very commencement of the analysis, into a column of cold oxide of copper about four inches long. This portion is not directly heated till the end of the analysis, the liquid being volatilised by the heat conducted by the oxide. Finally, a stream of oxygen is passed through the tube to burn the deposited charcoal. Volatile liquids cannot be burned in a continuous stream of oxygen, because an explosive mixture would be formed.

For extremely volatile liquids, like aldehyde, a different plan is adopted. Such liquids are enclosed in a bulb having the form of a small retort, the neck of which, previously sealed, is inserted into the hinder extremity of the combustion-tube, which is drawn out and left open for the purpose, the connection being made air-tight by means of a caoutchouc tube. As soon as the oxide of copper is ignited, the sealed end of the retort is broken off by pressing it against the combustion-tube, and the liquid is volatilised by cautiously applying the heat of the hand or of tepid water to the bulb. If the liquid is so volatile as to boil at the temperature of the room, the bulb must be immersed in ice, and the evaporation regulated by removing the ice from time to time, and replacing it as soon as the liquid begins to boil.

Fig. 29.



Fixed oils are weighed in a short test-tube, which is then dropped into the combustion-tube,—a small quantity of oxide of copper having been first introduced,—and by inclining the tube, the oil is made to spread itself over the sides for about half the length, after which the tube is filled up with oxide of copper or chromate of lead. Soft, easily fusible fats are treated in the same manner. Waxy bodies are weighed in small lumps, then dropped into the combustion-tube, and spread over its surface by fusion. Fatty and waxy bodies may also be placed in boats in the manner already described (p. 236), and burnt with chromate of lead, or with oxide of copper in a stream of oxygen.

Modification of the Combustion-process in particular Cases:

a. In bodies containing Nitrogen.—When an azotised organic body is burnt, the greater part of the nitrogen is given off in the free state, together with the water and carbonic acid; but a certain portion, varying according to the nature of the substance and the manner in which the combustion takes place, is converted into nitric oxide, or one of the higher oxides of nitrogen. Now, if either of these compounds is formed in the process of organic analysis, it will pass over with the carbonic acid, and if not decomposed before it reaches the potash-ley, it will be absorbed by that liquid and give rise to an error in the estimation of the carbon. Before, therefore, an organic compound is subjected to the combustion process, it must be carefully examined for nitrogen in the manner already described (p. 226), and if that element is found to be present, the combustion must be made in such a manner as to ensure that the whole of it shall be evolved in the free state.

For this purpose a long combustion-tube is taken, and after the mixture and the pure oxide of copper have been introduced in the ordinary way, about five inches of copper-turnings, prepared as described at p. 227, are placed at the open extremity. This metallic copper must be heated in a sand or air-bath just before it is wanted and introduced into the tube while still hot, as its surface is very hygroscopic. The combustion is made in the ordinary way, the metallic copper being however first heated to redness, and kept in a state of strong ignition during the whole process. The nitrogen is then evolved in the free state, and passes through the potash-ley in bubbles.

The combustion must be made with oxide of copper alone: if chromate of lead is used, or a continuous stream of oxygen passed through the tube, the quantity of nitric oxide formed is too large to be effectually decomposed, even by a very long column of red-hot copper. Oxygen may, however, be passed through the tube at the end of the combustion, being evolved for that purpose from chlorate of potassium (p. 235). The more slowly the combustion is conducted, the smaller will be the quantity of nitric oxide formed.

β. *In bodies containing Sulphur.*—When organic bodies containing sulphur are burned with oxide of copper, the sulphur is converted into sulphurous acid, which, if not intercepted, will pass into the potash-solution together with the carbonic acid. This may be prevented, by interposing between the chloride-of-calcium and potash-apparatus, a tube containing peroxide of lead: the sulphur will then be retained in the form of sulphate of lead. It is better however to make the combustion with chromate of lead, placing in the front part of the tube a rather long column of pure chromate, which is heated only to dull redness: the sulphur will then be retained in the combustion-tube.

γ. *In bodies containing Chlorine.*—When chlorinated organic compounds are burnt with oxide of copper, chloride of copper is formed, which being volatile, passes over into the chloride of calcium tube, and renders the determination of the hydrogen inexact. This source of error may be completely avoided by burning with chromate of lead, the chlorine then forming chloride of lead, which is not volatile even at a red heat.

Similarly with bodies containing *bromine* and *iodine.*

δ. *In bodies containing Inorganic Matter.*—If an organic body, when burnt in the air, leaves a residue which gives off carbonic acid on being treated with acids, its analysis by combustion with oxide of copper will not give exact results, because a part of the carbonic acid will be retained in the ash, instead of passing into the potash-bulbs. This is particularly the case with the organic salts of potassium, sodium, barium, strontium, and calcium. If the residue were in all cases a neutral carbonate, its quantity might be determined and the amount of carbonic acid contained in it added to that which is absorbed in the potash apparatus. But this is not the case, the composition of the residue being variable, and depending on a variety of circumstances.

In such cases, the complete evolution of carbonic acid may be ensured in two ways: either by burning with oxide of copper, and mixing the organic substances with ignited phosphate of copper, boric anhydride, or oxide of antimony; or better, by burning with chromate of lead, the alkaline carbonate being then completely decomposed by the chromic acid.—When these organic salts are burnt in a platinum boat, in a stream of oxygen (p. 231), the residue may be weighed, the quantity of carbonic acid in it determined in the ordinary way, and added to that absorbed by the potash.

Amount of Error in the Estimation of Carbon and Hydrogen.—By the methods above described, the carbon may be determined within 0·2 per cent. The error is generally in defect, in consequence of imperfect combustion; sometimes, however, it is in excess, especially in azotised bodies.

The hydrogen may be determined yet more nearly, viz. within 0·1 per cent. The error is usually in excess, arising from absorption of water from the air during the mixing of the substance with oxide of copper. But if this be avoided, by making the mixture in the tube itself, or if the combustion be made with chromate of lead, only a very slight excess of hydrogen need be apprehended. When the substance is burnt in the platinum boat (p. 231), the hydrogen sometimes comes out a little below the theoretical quantity.

ESTIMATION OF OXYGEN.

Oxygen is usually estimated by difference, after all the other elements of the compound have been determined directly. In compounds containing only carbon, hydrogen, and oxygen, this method is sufficiently accurate: for, the error of the carbon being generally in defect, and that of the hydrogen in excess, the two nearly compensate each other; but when chlorine, sulphur, and other elements are present, the errors upon all these being usually in the same direction, viz. in defect, the amount of oxygen determined by difference is likely to be much too great. A good method of determining oxygen directly is therefore a desideratum, more especially as it would afford a check on the estimation of the other elements.

A method of effecting this determination has been given by **Baumhauer** (Ann. Ch. Pharm. xc. 228), and applied in one or two cases. A combustion-tube open at both ends is fitted up in the ordinary way for the determination of carbon and hydrogen, and the two ends of the apparatus are placed in connection with graduated glass tubes, the one at the hinder extremity of the combustion-tube being filled with oxygen, so that, when the combustion is finished, a stream of oxygen may be passed through the tube and re-oxidise the reduced copper. The apparatus is then left to cool, the quantity of gas in the two tubes is read off, and compared with the quantity before the experiment, due regard being paid to corrections for temperature and pressure. The difference gives the quantity of oxygen taken up by the reduced copper. Now, the quantities of carbonic acid and water produced by the combustion having been determined, *the amount of oxygen in this carbonic acid and water, diminished by the quantity of oxygen which has disappeared, gives the quantity of oxygen contained in the substance analysed:* thus, if the amount of oxygen in the carbonic acid and water were 10, and the quantity of oxygen absorbed by the copper were 7, the amount of oxygen contained in the substance would be 3.

Baumhauer gives two analyses (of oxalic acid and oxalate of lead), in which the oxygen was determined by this method with great exactness. As, however, the total volume of gas in the apparatus (the combustion-tube, potash-bulbs, &c.) is not known, but only the difference of volume before and after the experiment, the corrections for pressure and temperature cannot be made with accuracy. For exact results, it is therefore necessary that the pressure and temperature at the beginning and end of the experiment should be nearly the same.

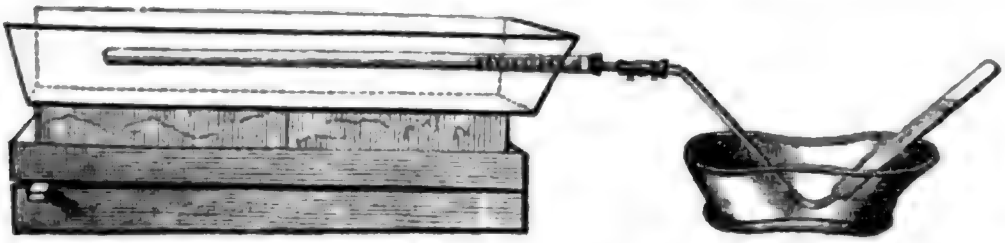
ESTIMATION OF NITROGEN.

The quantity of nitrogen in an organic compound is determined, either by burning the compound with oxide of copper and metallic copper in the manner already described, and measuring the quantity of nitrogen evolved,—or by igniting the compound with soda-lime, whereby the nitrogen is evolved in the form of ammonia, absorbing the ammonia by hydrochloric acid and precipitating by dichloride of platinum.

When the nitrogen is evolved in the free state, it may be estimated in two ways, viz. *comparatively*, that is, by comparison with the quantity of carbon in the compound, previously determined; or *absolutely*, that is, by direct measurement of the whole quantity evolved.

Liebig's Comparative method.—A mixture of the substance (which need not be weighed), with the usual proportion of oxide of copper, is introduced into a combustion-tube of such a length as to be half filled by it, the remainder of the tube being filled up, half with oxide of copper, half with copper turnings. To the mouth of the combustion-tube is fitted a gas-delivery tube, which passes into a trough of mercury and is made flexible by the insertion of a tube of caoutchouc.

Fig. 30.



A screen being placed between the mixture and the pure oxide of copper, the oxide and the metallic copper are first raised to a strong red heat; a second screen is then placed at the back part of the tube, about an inch from the sealed end, and the portion of mixture at that end is ignited, so that the products of the combustion may drive the atmospheric air out of the tube. The combustion of the rest of the mixture is then carried on in the ordinary way, the heat being gradually extended towards the hinder part of the tube, and the mixture of carbonic acid and nitrogen evolved is collected in a number of graduated jars, half an inch in diameter, and twelve or thirteen inches long. These jars must be accurately divided into equal parts of the same value in all; but the absolute value of the divisions may be any whatever.

As soon as one of the tubes is about three-fourths filled with gas, it should be lifted up and the rest of the mercury allowed to run out, so that its place may be supplied with atmospheric air. The object of this is to ascertain whether the gas is free from nitric oxide; if only $\frac{1}{1000}$ pt. of that gas is present, reddish fumes of peroxide of nitrogen will be produced, and if not seen immediately, will become visible on looking along the axis of the tube. If any red or yellow colour is perceptible, another jar must be examined in the same manner, and so on till perfectly colourless gas is obtained. When about six jars have been filled with the gaseous mixture, the process may be stopped, nothing being gained by carrying it to the end.

Fig. 31.

The jars filled with gas are now to be transferred one by one to a tall jar (*fig.* 31), containing mercury, and the proportion of carbonic acid and nitrogen in each of them determined, by first bringing the mercury to the same level inside and out, and reading off the volume of the gaseous mixture, then absorbing the carbonic acid by a strong solution of caustic potash, introduced by means of the curved pipette A, and reading off the volume of nitrogen left. If the combustion has been properly conducted, the proportion of carbonic acid and nitrogen should be the same in all the jars.

Now, a molecule of anhydrous carbonic acid CO^2, containing 1 atom of carbon [= 12], occupies the same volume as a molecule (or double atom) of nitrogen, NN [2 . 14 = 28]. If therefore, the volumes of carbonic acid and nitrogen in the gaseous mixture are to one another as $m : 1$, it follows that the number of carbon-atoms is to the number of nitrogen-atoms as $m : 2$, and consequently the weight of the carbon in the compound is to that of the nitrogen as $m \times 12 : 2 \times 14$, or as $3m : 7$; so that, if the percentage of carbon (c) be previously found, the percentage of nitrogen (n) will be given by the equation:

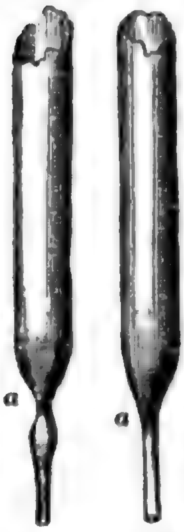
$$n = \frac{7}{3m} c.$$

For example, caffeine, which contains 49·48 per cent. of carbon, is found by the process just described to yield carbonic acid and nitrogen in the proportion by volume of 4 : 1; the percentage of nitrogen in caffeine is therefore $\frac{7}{3 \times 4} . 49·48 = 28·89$.

This comparative method of estimation yields perfectly satisfactory results for all compounds in which the proportion of nitrogen to carbon is not less than 1 : 8, provided the combustion is conducted in such a manner as to avoid the evolution of nitric oxide. The risk of error from this source is less, *the more intimately the organic substance is mixed with the oxide of copper, and the more slowly the combustion is performed.* This rule applies to all combustions of azotised bodies.

Liebig's comparative method has been variously modified by different chemists. Bunsen has contrived a form of apparatus by which it may be carried out with accuracy, even when the proportion of nitrogen is very small, and with not more than a few centigrammes of substance. This method consists in burning the substance with oxide of copper and metallic copper in a sealed tube filled with hydrogen, and analysing the resulting mixture of carbonic acid and nitrogen in a carefully graduated eudiometer.

Fig. 32.



A tube of thick Bohemian glass, about 15 inches long, and $\frac{3}{4}$ of an inch internal diameter, is drawn out at one end in the form of a cone, as shown at *a* (*fig.* 32), and the part *a* is then heated in the blowpipe flame till it is contracted and the glass very much thickened. A mixture of 3 to 5 centigrammes of the organic substance, with 5 grms. of oxide of copper, is now introduced into the tube, together with a few copper turnings, and the other end of the tube is drawn out and thickened in the same manner as the first. The tube is then connected at one end with a hydrogen-apparatus, *fig.* 33 (A being the generating vessel, and B a receiver containing sulphuric acid to dry the gas), and at the other with an exhausting syringe. The hydrogen, after passing through the tube, escapes by the cock *p*.

As soon as all the air is expelled, the cock *p* is closed, the cork of the generating vessel loosened, the caoutchouc tube *c* tightly tied, the tube partially exhausted by a stroke of the pump, and the cock *s* immediately closed. The tube is now sealed at *d* and *b* with the blowpipe flame, the sealing being much facilitated by the partial exhaustion. The next step of the process is to heat the tube to redness, having first enclosed it in a mould of gypsum, to prevent it from being blown out by the expansion of the enclosed gases. For this purpose, the two halves of a cylindrical mould of iron plate, shown in *fig.* 34, are filled with gypsum paste mixed

was carefully noted before the experiment, also the volume of air and gas when the combustion was finished and the apparatus had been left to cool, the observed volumes being in each case reduced to the standard pressure and temperature; the increase gave the volume of carbonic acid and nitrogen produced by the combustion. The volume of carbonic acid was then calculated from a previous determination of the carbon, and this, deducted from the volume of the mixed gases, gave the quantity of nitrogen by volume, from which the weight was calculated. For example, 0·1 grm. caffeine burnt in this manner yields 114·06 cub. cent. of gas at 0° C. and 28" bar. The same quantity burnt in the ordinary way yields 0·181 grm. carbonic acid, corresponding to 91·09 cub. cent. at 0° C. and 28 inches of the barometer: consequently 0·1 grm. caffeine yields 114·06 − 91·09 = 22·85 cub. cent. nitrogen gas = 28·86 per cent. by weight.

The process in this form is liable to numerous sources of error. In the first place, the necessary limits to the the size of gas jars standing over mercury, restricts the quantity of substance burnt to 1 or 2 decigrammes; and with this small quantity the errors of observation and manipulation bear too great a proportion to the whole to give even a good approximation to the truth, unless the proportion of nitrogen is rather large. Very considerable errors may arise from the alteration in the dimensions of the tube, likely to result from softening by heat, and from the consumption of a portion of the oxygen of the air in the tube during the combustion. (*For the details of the process*, see *Handwörterbuch d. Chemie*, 2^te^ Aufl. i. 873.)

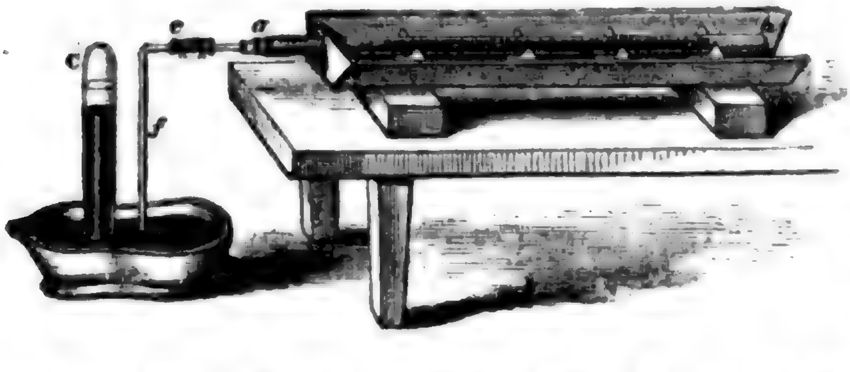
To remove these sources of error, the process has been modified by Dumas and others, so as to make the result independent of the volume of air in the apparatus. This is effected by replacing the air by another gas, which can afterwards be removed by absorption, and sometimes also by exhausting with the air-pump.

In Dumas's process, the air is removed from the combustion-tube, partly by exhaustion with the air-pump, and partly by a stream of carbonic acid gas evolved from carbonate of copper placed at the sealed end of the tube. The combustion is then performed; the carbonic acid and nitrogen evolved by it are collected in a graduated jar standing over mercury, and containing also solution of potash, which absorbs the carbonic acid; and, when the combustion is finished, the carbonate of copper is again heated, so as to evolve carbonic acid, and sweep all the remaining nitrogen into the jar. The volume of nitrogen is then observed, with due regard to pressure and temperature.

This process gives accurate results; but it is troublesome, and requires rather complicated apparatus. A simpler form of it is now generally used, in which the exhaustion with the air-pump is dispensed with by the use of a substance which evolves carbonic acid more abundantly than carbonate of copper. This simplification is due to Melsens. (Ann. Ch. Pharm. lx. 115.)

Fig. 35.

Fig. 36.



At the sealed end of a combustion-tube 30 inches long, is placed a layer, 6 inches long, of acid carbonate of sodium, *a b* (*fig.* 35); then oxide of copper, *b c;* then the mixture of the organic substance with oxide of copper, *c d;* then strongly ignited oxide of copper, *d e;* and, lastly, copper turnings, *e f*. The tube is enveloped in copper foil or brass wire gauze, and connected by a gas delivery-tube with a graduated jar, standing over mercury (*fig.* 36), and partly filled with strong solution of potash. The tube is laid in the combustion furnace, and the acid carbonate of sodium gradually heated, the other part of the tube being protected by a screen. Carbonic acid gas is then evolved, and drives the air out of the tube. It is tested from time to time by collecting it in small tubes filled with mercury, and passing caustic potash into it. As soon as the gas is completely absorbed by the potash-ley, showing that all the air is expelled from the tube, the heat is removed from the acid carbonate of sodium; the graduated jar, filled partly with mercury, and partly with potash-ley, is adjusted in its place over the extremity of the delivery-tube, and the combustion is commenced. The nitrogen and carbonic acid then pass over together; the carbonic acid is absorbed by the potash; and the nitrogen collects in the jar. When the combustion is finished, heat is again applied to the acid carbonate of sodium, so as to evolve more carbonic acid, and sweep all the residual nitrogen into the gas jar.

The gas is left standing over the caustic potash till the absorption of the carbonic acid appears to be quite complete: it may be accelerated by a gentle agitation. A ground glass plate is then placed under the jar, pressed against it, to prevent the mercury from running out, and the jar is transferred from the mercury-trough to a large vessel of water. On removing the glass plate, the mercury and potash-ley run out, their place being supplied by water. The volume of the gas is then read off, and reduced to the standard pressure and temperature, allowance being also made for the tension of the aqueous vapour. From the corrected volume of nitrogen thus obtained, the weight is easily deduced by calculation.

If commercial bicarbonate of soda is used in this process, it must be tested beforehand, in order to ascertain whether it gives off any gas not absorbable by potash. Indeed, it is advisable to subject all the materials used in the process to a trial by ignition without the organic substance. They ought not to yield more than ½ to 1½ c. c. of gas not absorbed by potash-ley.

It is also of the greatest importance, in all nitrogen estimations in which the nitrogen is determined by volume, to test carefully the accuracy of the weights with which the substance to be analysed is weighed out. In other analyses, the absolute value of the weights used is unimportant, provided they agree amongst themselves; but if the gramme weight and its subdivisions, with which the substance is weighed out, are not true to their standard values, the weight of the nitrogen, determined by calculation from its observed volume, according to fixed data, will not give the true weight of nitrogen contained in the compound.

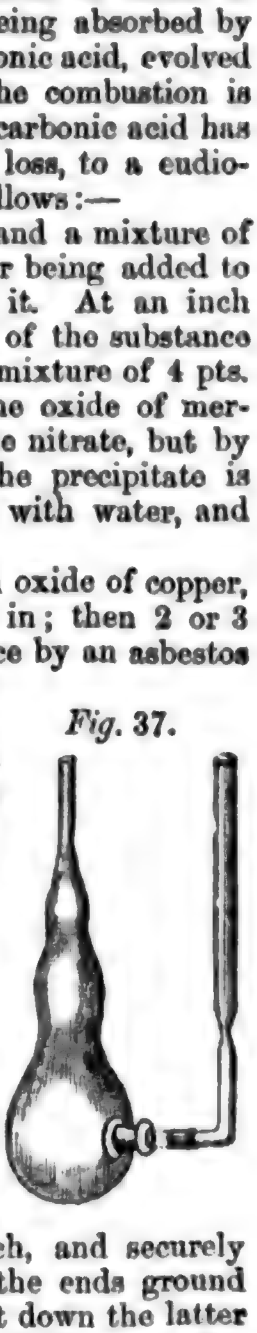
Another modification of Dumas's process is given by Dr. **Maxwell Simpson** (Chem. Soc. Qu. J. vi. 299). The combustion is made with a mixture of oxide of copper and mercuric oxide, the free oxygen evolved by the latter being absorbed by red-hot copper, and the atmospheric air expelled by a stream of carbonic acid, evolved from carbonate of manganese. The gaseous mixture evolved by the combustion is collected in a receiver of peculiar construction, from which, after the carbonic acid has been absorbed by potash, the nitrogen can be transferred, without loss, to a eudiometer, and accurately measured over mercury. The details are as follows:—

A combustion-tube, from 2½ to 3 feet long, is sealed at one end, and a mixture of 12 grm. carbonate of manganese and 2 grm. mercuric oxide (the latter being added to prevent the possible formation of carbonic oxide) is introduced into it. At an inch from this mixture is placed a plug of asbestos, and then the mixture of the substance to be analysed (5 or 6 decigm.) with about 45 times its weight of a mixture of 4 pts. oxide of copper and 5 pts. oxide of mercury. To ensure that the oxide of mercury is free from nitrogen, it must be prepared, not by ignition of the nitrate, but by precipitating corrosive sublimate with excess of caustic potash; the precipitate is washed with aqueous phosphoric acid, to remove free potash, then with water, and dried at a rather strong heat.

The mixture having been introduced, the mortar is rinsed out with oxide of copper, and the rinsings added as usual; then a plug of asbestos is thrust in; then 2 or 3 inches of pure oxide of copper added, this also being kept in its place by an asbestos plug; and the tube is filled up with metallic copper, prepared by reducing the coarse-grained oxide (p. 226) with hydrogen. The open end of the tube is then drawn out, and the neck joined by a caoutchouc connector with a gas delivery-tube, bent at right angles and dipping into the mercury-trough.

The combustion-tube is now laid in the furnace, and heat is applied to the metallic copper and oxide of copper, and at the same time to the carbonate of manganese, the heated portions being shut off by screens from the middle of the tube; and as soon as the air is completely expelled from the tube by the stream of carbonic acid, the mixture of the organic substance with the oxides is heated in the usual way, from the front backwards, the tube being first connected with the vessel intended to receive the nitrogen. This vessel has the form shown in *fig.* 37, and a capacity of about 200 cub. cent.: the external diameter of the upper part should not exceed 7 or 8 mm. A tube of thick vulcanised caoutchouc, 1½ inch long, is slipped over the top, which it must accurately fit, to the extent of half an inch, and securely bound round with silk cord. A glass rod, half an inch long, with the ends ground flat, and having the same diameter as the caoutchouc tube, is thrust down the latter till it touches the gas vessel. A piece of thermometer tubing, also of the same diameter, and having a fine hair-bore, is bent into the form shown in *fig.* 38, and also

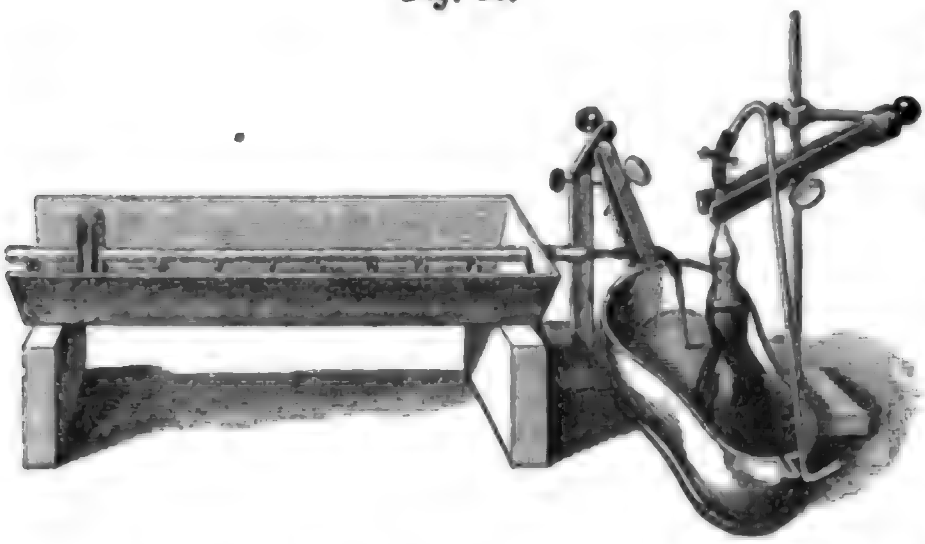
Fig. 37.



inserted. The caoutchouc is next slightly stretched over it, and firmly secured with silk cord, so that there may be no interval between the glass rod, bent tube, and gas vessel. A silk cord is, lastly, tied round the part of the caoutchouc tube where the solid rod lies, so as to make it perfectly air-tight. Before using the apparatus, the joints must be tested by partially filling it with mercury, plunging the mouth beneath the surface of the liquid, and observing if the level remains constant.

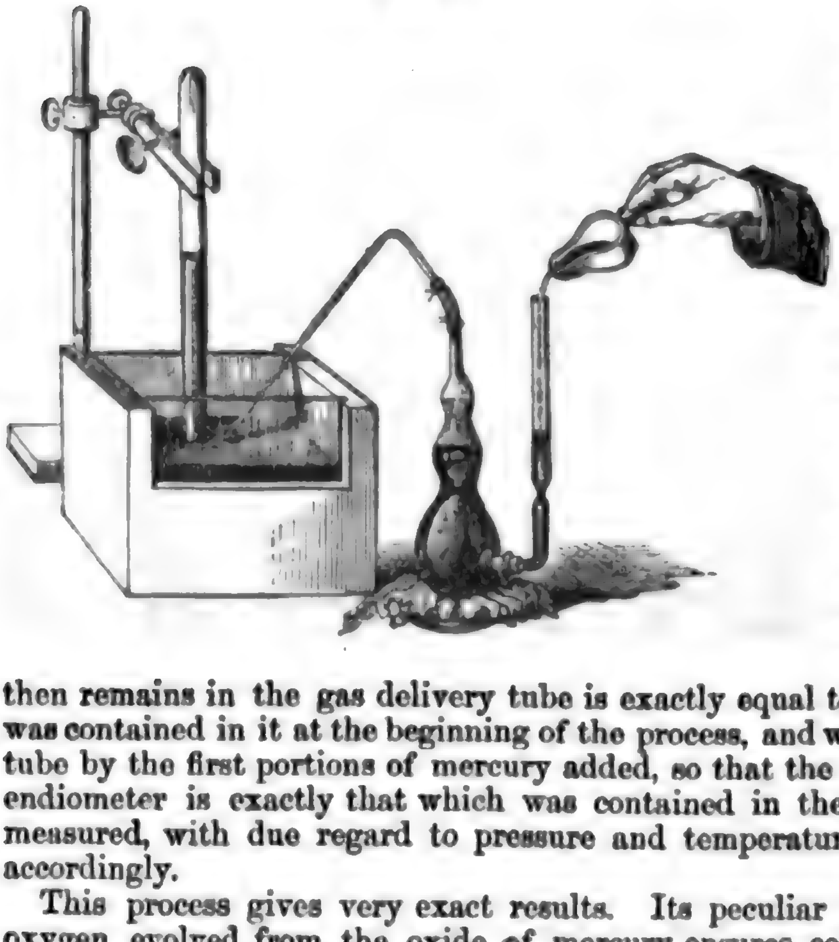
The apparatus is completely filled with mercury and caustic potash solution, and placed in the mercurial trough as shown in *fig*. 38. The gas delivery-tube, proceeding from the combustion-tube, being then inserted into its lateral opening, the products of combustion pass into it, the carbonic acid being absorbed by the potash-ley, while the nitrogen remains. At the termination of the combustion, the nitrogen still remaining in the tube is swept out into the receiver by a stream of carbonic acid, evolved by heating the portion of carbonate of manganese still remaining undecomposed.

Fig. 38.



The next thing to be done is to transfer the nitrogen to a eudiometric tube. For this purpose a bent tube, narrowed towards the lower part of the upright arm is fitted air tight to the lateral opening of the receiver by means of a cork, care being taken that no air is introduced in fitting it, to ensure which it is best to moisten the cork with a solution of corrosive sublimate. Mercury is now poured into the bent tube, and the receiver is lifted out of the mercury, carried to a mercurial trough with glass sides (*fig*. 39), and allowed to stand for an hour or two, so that the absorption of the carbonic acid may be complete. A eudiometer, previously moistened with a drop of water, so that the gas may be saturated with moisture, is then carefully filled with mercury, and inverted in the trough; the end of the gas delivery-tube from the receiver is brought under it; the cord which tied the caoutchouc tube to the glass rod is removed; and the nitrogen is driven into the eudiometer by slowly pouring mercury into the bent tube, as shown in the figure. As soon as the potash-ley makes its appearance in the gas delivery-tube, the addition of mercury is stopped. The volume of nitrogen which then remains in the gas delivery tube is exactly equal to the volume of the air which was contained in it at the beginning of the process, and was driven into the eudiometer tube by the first portions of mercury added, so that the volume of gas driven into the endiometer is exactly that which was contained in the receiver. Lastly, the gas is measured, with due regard to pressure and temperature, and the weight calculated accordingly.

Fig. 39.



This process gives very exact results. Its peculiar advantages are, that the free oxygen evolved from the oxide of mercury ensures complete combustion, while the vapour of mercury prevents the formation of any oxides of nitrogen: moreover, it enables the gas to be measured over mercury, which is much more exact than the ordinary mode of measuring over water.

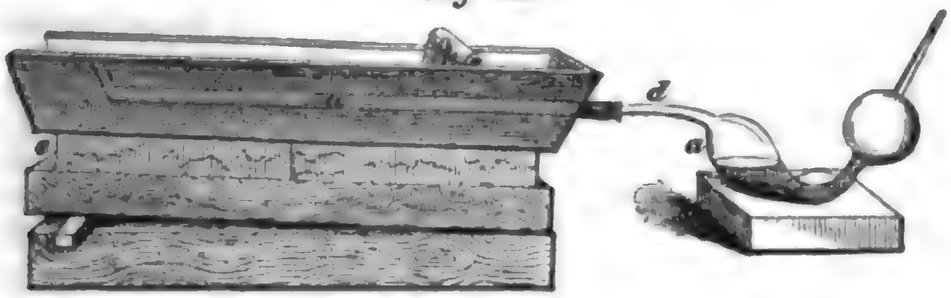
Estimation of Nitrogen by Will and Varrentrapp's Method.—Most azotised organic bodies heated with hydrate of potassium or sodium, give off the whole of their nitrogen in the form of ammonia, the carbon uniting with the oxygen of the alkaline hydrate to form carbonic acid, while the hydrogen combines with the nitrogen to form ammonia. If the quantity of nitrogen present is not sufficient to unite in this manner with all the hydrogen, the remainder is evolved as gas; but there is no organic substance, excepting those containing nitric acid, in which the quantity of nitrogen is too great to be completely converted into ammonia by the hydrogen thus liberated from the alkaline hydrate. In many cases, however, cyanide of potassium or sodium is formed in the first instance; but even then, if a sufficient excess of the alkaline hydrate is present, the cyanogen is decomposed when the heat becomes very strong, and the whole of the nitrogen is given off as ammonia. It is on these facts that Will and Varrentrapp's method of estimating nitrogen is founded.

As the hydrates of potassium and sodium are very deliquescent, and act strongly on glass at high temperatures, it is convenient to mix them with quick lime, which makes them more manageable, and diminishes their action on the glass. The mixture generally used is *soda-lime*, containing 1 pt. of hydrate of sodium, and 2 pts. of quick lime. It is prepared by adding the requisite quantity of quick lime to caustic soda-ley of known strength, evaporating to dryness in an iron pot, calcining the residue in a crucible, and afterwards rubbing it to fine powder in a warm mortar. It must be preserved in wide-mouthed vessels with good stoppers. If commercial soda is used for this purpose, it must be previously tested for nitric acid, as the presence of that compound would vitiate the analysis.

The substance to be analysed is mixed in a warm porcelain mortar, with a quantity of soda-lime sufficient to fill about two-thirds of a combustion-tube, from 16 to 18 inches long. The soda-lime must be previously heated over a lamp to expel any moisture or ammonia that it may have absorbed, and the mixture must be made by very gentle trituration, otherwise portions of it will adhere obstinately to the mortar and pestle. After it has been introduced into the tube, the mortar is rinsed with fresh soda-lime, and finally with pounded glass, to remove any small portions of adhering matter. Lastly, the tube is filled up with soda-lime to within an inch of the extremity, a plug of ignited asbestos being placed at the end to prevent the light powder from being carried forward by the vapours.

The ammonia is collected in a bulb-apparatus of the form shown in *fig.* 40, containing hydrochloric acid (specific gravity about 1·10), sufficient to half fill one of the larger bulbs. This apparatus is adapted to the combustion-tube in the manner shown in the figure, and the tube is gradually heated from end to end. Ammonia is then given off and is absorbed by the hydrochloric acid. Towards the end of the combustion, the heat must be very much increased, in order to decompose any cyanide of sodium that may have formed in the earlier stage of the process. When the combustion is finished, the point of the tube is broken off, and air drawn through the apparatus in the usual way. Bouis (Bullet. Soc. Chim. de Paris, i. 105) recommends to place at the closed end of the tube a mixture of oxalate of calcium and slaked lime (obtained by neutralising oxalic acid with milk of lime, boiling the precipitate with excess of lime, and drying rapidly at 110° C.) which, when decomposed at the end of the operation, evolves a stream of hydrogen that sweeps all the ammonia remaining in the combustion-tube into the acid placed to receive it.

Fig. 40.



The acid liquid is emptied into a capsule, and the bulbs are rinsed with alcohol, and then repeatedly with distilled water. Sometimes oily hydrocarbons are formed during the combustion, and collect on the surface of the acid liquid. In this case it is best, before proceeding further, to separate the oil from the acid liquid by filtration, the filter being previously moistened with water. Bichloride of platinum is now added to the acid solution, which precipitates the ammonia as chloroplatinate of ammonium, $NH^4Cl . PtCl^2$; the whole is evaporated to dryness over the water-bath; and the dry mass when cold, is treated with a mixture of 2 volumes of strong alcohol and 1 vol.

ether, which dissolves the excess of bichloride of platinum, and leaves the chloroplatinate of ammonium. This salt is collected on a weighed filter, washed with the same mixture of alcohol and ether, then dried at 100° and weighed; 100 pts. of it correspond to 6·279 pts. of nitrogen. Or, the salt with its filter may be ignited in a weighed crucible of platinum or porcelain, till the filter is completely burned to ashes and metallic platinum is left. The ignition must be performed with great care, commencing with a very gentle heat, which should be increased very gradually, because the vapours of sal-ammoniac and chlorine which escape are very apt to carry with them a small quantity of platinum: 100 pts. of platinum correspond to 14·204 pts. of nitrogen.

The process just described may be applied to most azotised organic bodies without further modification. Sometimes, however, when the proportion of nitrogen is large, as in urea, mellone, &c., the whole of the hydrogen is given off as ammonia. In this case, the quantity of uncondensable gas evolved is comparatively small, and towards the end of the process, the acid in the bulbs is very likely to be suddenly drawn back into the combustion-tube. This accident may be prevented by adding to the mixture a small quantity of sugar or tartaric acid, so as to dilute the ammonia with uncondensable gases.

Liquids containing nitrogen may be treated in the same manner, being enclosed in bulbs, as for combustion with oxide of copper.

There are some azotised organic bodies to which Will and Varrentrapp's process is not applicable,—those, namely, in which the nitrogen exists in the form of an oxide, generally as NO^2 (the so-called nitro-compounds): these bodies, when ignited with an alkaline hydrate, giving off only a portion of their nitrogen in the form of ammonia, so that the quantity found is always too small.

Other azotised bodies, when heated with soda-lime, give off, not ammonia, but organic bases free from oxygen, and more or less resembling ammonia. Thus indigo yields phenylamine (C^6H^7N), and many non-volatile organic bases, *e.g.* narcotine, morphine, quinine, and cinchonine, give off organic volatile bases. Many non-oxygenised organic bases, such as phenylamine, chinoline, &c., pass over ignited soda-lime without decomposition, or at all events do not yield all their nitrogen in the form of ammonia. Now all these volatile organic bases form platinum-salts, in which, as in chloroplatinate of ammonium, 1 atom of platinum corresponds to 1 atom of nitrogen. If, therefore, these bases are treated by Will and Varrentrapp's process, the resulting platinum-salts ignited, and the metallic platinum weighed, 100 pts. of it will correspond to 14·204 pts. of nitrogen, whatever organic base may have been formed in the decomposition. As, however, the platinum-salts of many of these bases are more soluble in alcohol than chloroplatinate of ammonium, it is best to wash them, not with the mixture of alcohol and ether above-mentioned, but with absolute ether to which only a few drops of alcohol are added. In all cases in which it is not certainly known that the body submitted to analysis gives off the whole of its nitrogen as ammonia, the chloroplatinate should be ignited after being weighed, and the residual platinum weighed again, so as to ascertain whether the chloroplatinate weighed was really chloroplatinate of ammonium. (NH^4PtCl^3 corresponds to 44·3 per cent. platinum.)

Instead of precipitating the ammonia with bichloride of platinum, its quantity may also be determined volumetrically, for instance, by receiving it in dilute sulphuric acid of known strength, and estimating the quantity of free acid remaining by means of a standard alkaline solution. Péligot uses for this purpose dilute sulphuric acid, containing 61·25 grms. of SO^4H^2, in a litre of liquid; neutralises it with a measured quantity of a solution of lime in sugar-water; and compares the quantity of the lime-solution required for this purpose with that which is required to neutralise the same volume of acid after absorption of the ammonia. Instead of the solution of lime in sugar-water, which quickly varies in strength, and must be standardised before each experiment, it is better to use a standard solution of caustic soda (see ACIDIMETRY, and ANALYSIS VOLUMETRIC). If an acid be used containing 1 at. SO^4H^2 in a litre of liquid, and a solution of soda containing 2 at. NaHO in the same volume of liquid, the quantity of acid saturated by the ammonia will be very readily found, and thence also the quantity of ammonia absorbed. These methods, being more rapidly executed than the platinum-determination, are especially applicable in the determination of nitrogen for technical purposes, in the valuation of guano for example.

Other modifications of Will and Varrentrapp's process have been proposed, for example, receiving the ammonia in tartaric acid,—but they do not appear to present any peculiar advantages.

ESTIMATION OF CHLORINE.

Organic bases combine with hydrochloric acid, forming salts (the hydrochlorate of morphine, for example), from the solutions of which chlorine may be completely precipitated by simply adding nitrate of silver. But many organic compounds contain chlorine in a form in which it cannot be precipitated as chloride of silver, until the compound is completely destroyed.

The mode of decomposition adopted in such cases is to ignite the compound with a caustic alkali or alkaline earth, generally with quick lime. The lime used for the purpose is obtained by subjecting marble to a strong red heat in a crucible. It must be tested for chlorine, and if that element is found in it, the lime must be slaked, and the chloride of calcium separated from it by washing with water, after which it is to be recalcined.

The organic compound, if solid, is mixed in a mortar with the pure pounded lime, the mixture introduced into a combustion-tube from 12 to 18 inches long, and the tube filled-up with pure lime, or (in order to diminish the quantity of lime which has to be subsequently dissolved in nitric acid) with a mixture of lime and pounded glass. The mixture is then burnt in the usual manner; afterwards, while the tube is still hot, the open end is closed by a cork, it is then wiped with a piece of filter-paper, and gradually introduced into a tall glass cylinder about one-third full of cold distilled water: the hot tube breaks on thus coming in contact with the water, and its contents fall into the cylinder, where the excess of lime is dissolved by nitric acid. The liquid is then filtered, if necessary, and the chlorine precipitated by nitrate of silver. Or, the contents of the tube when cold are turned out into a jar of distilled water, and the whole is dissolved by nitric acid. This method, however, is more subject to error than the first; for it is difficult to prevent a portion of the very fine dust of lime being carried away by the air while emptying the tube into the water.

Liquids containing chlorine are enclosed in bulbs in the manner already described (p. 232), and the vapours passed over the red-hot lime.

Bromine and *iodine* in organic compounds are estimated in like manner.

ESTIMATION OF SULPHUR.

Sulphur is sometimes contained in organic compounds in such a manner that it exhibits its usual reactions with metallic solutions; more generally, however, its separation can only be effected by the complete destruction of the compound. In some cases, oxidation with strong nitric acid will effect the decomposition, the sulphur being converted into sulphuric acid; but a more certain method is to fuse the compound with an alkaline hydrate or carbonate, mixed with nitre, chlorate of potassium, or oxide of mercury.

For non-volatile bodies, a few lumps of hydrate of potassium are fused in a silver crucible over a gas lamp, with about $\frac{1}{8}$ of nitre, a few drops of water being added to facilitate the fusion; a weighed quantity of the sulphuretted organic compound is then added in successive small portions, and the heat is gradually raised, small quantities of nitre being thrown in from time to time, if necessary, to burn away the carbon. The fused mass when cold is dissolved in boiling water, the excess of alkali neutralised with hydrochloric acid, chloride of barium then added, and the precipitate of sulphate of barium filtered, washed, and ignited with the usual precautions. (See SULPHURIC ACID.)

Sulphur-compounds may also, whether fixed or volatile, be burnt in a combustion-tube with a mixture of carbonate of sodium, with nitre, chlorate of potassium (Kolbe), or oxide of mercury (Russell, Chem. Soc. Qu. J. vii. 212),—non-volatile pulverisable solids being mixed up with the carbonate of sodium and the oxidising agent, volatile liquids being enclosed in sealed bulbs, and volatile solids and fatty bodies placed in platinum boats.

ESTIMATION OF PHOSPHORUS.

Phosphorus in organic bodies is estimated by burning the substance with a mixture of alkaline carbonate and nitre or chlorate of potassium, in the same manner as for sulphur, and precipitating the resulting phosphoric acid as phosphate of magnesium and ammonium. Similarly for *arsenic*.

Other non-volatile substances occurring in organic compounds are estimated by the ordinary processes adapted to each of them, in the residue left after the organic matter has been burnt away.

An easier method of estimating sulphur, phosphorus, chlorine, &c., in organic compounds, lately introduced by Carius (Ann. Ch. Pharm. cxvi. 1), consists in heating the substance with nitric acid, of specific gravity about 1·2, in a sealed tube. *Sulphur* is thereby, in nearly all cases, completely converted into sulphuric acid, and may be precipitated by chloride of barium; *phosphorus* and *arsenic* are converted into phosphoric and arsenic acids, and may be precipitated as ammonio-magnesium salts; *chlorine* is partly oxidised, partly separated in the free state, but may be completely converted into hydrochloric acid by means of a dilute solution of sulphurous acid or sulphite of sodium, and then precipitated by nitrate of silver; *bromine* and *iodine* are completely separated in the free state, and may be estimated in like manner; lastly, *metals* are converted into oxides or nitrates, and may be estimated by the ordinary methods of mineral analysis.

This method of oxidation by nitric acid in sealed tubes, is likewise applicable to many inorganic compounds, the sulphides of arsenic, for example. (For details, see the articles CHLORINE, PHOSPHORUS, SULPHUR, &c.)

DETERMINATION OF THE CHEMICAL FORMULA OF AN ORGANIC COMPOUND.

When the quantities of the several elements of a compound which make up a given weight, say 100 parts, are known, it is easy to calculate the *relative* number of atoms of these elements. For, since the actual weight of a substance (W) is equal to the weight of each atom (A), multiplied by the number (n) of the atoms ($W = n\,A$), it follows that the number of atoms is equal to the total weight divided by the atomic weight ($n = \frac{W}{A}$); so that, when the percentage composition is known, the relative numbers of the atoms—in other words, the empirical formula—will be found by dividing the percentage of each element by its atomic weight, and reducing the result to its simplest numerical expression.

For example, sorbic acid is found by Hofmann's analysis (Chem. Soc. Qu. J. xii. 46) to contain in 100 parts: 64·38 C, 7·20 H, and 28·42 O. Therefore:

$$\text{Number of Carbon-atoms} = \frac{64{\cdot}38}{12} = 5{\cdot}36 \text{ or } 3$$

$$\text{,, Hydrogen-atoms} = \frac{7{\cdot}20}{1} = 7{\cdot}20 \text{ or } 4$$

$$\text{,, Oxygen-atoms} = \frac{28{\cdot}42}{16} = 1{\cdot}77 \text{ or } 1$$

consequently, the simplest atomic expression of the constitution of sorbic acid is C^3H^4O.

Whether this is the real expression for the composition of the molecule, or whether it should be $C^6H^8O^2$, or $C^9H^{12}O^3$, or any other multiple of the first formula, must be determined by other considerations. In the case of an acid, we naturally look to the constitution of its salts, the barium- and silver-salts being generally selected as being the most easily prepared and analysed. The analysis of sorbate of barium gives:

	In 100 pts.		at. wt.		No. of atoms.
Carbon . . .	40·37	÷	12	=	3·36 or 6·08
Hydrogen . . .	4·02	÷	1	=	4·02 or 7·27
Barium . . .	37·89	÷	68·5	=	0·55 or 1
Oxygen . . .	17·72	÷	16	=	1·11 or 2
	100·00				

This approaches very nearly to the formula $C^6H^7BaO^2$, showing that the rational formula of sorbic acid is, not C^3H^4O, but $C^6H^8O^2$, supposing the acid to be monobasic, or $C^{12}H^{16}O^4$, if it is dibasic. Which of these hypotheses is correct must be determined by other considerations (ACIDS, p. 46). The monobasic formula is adopted because it is found that sorbic acid forms but one class of salts, one ether, one amide, &c.

The rational formulæ of bases are also determined by the constitution of their salts. The platinum-salts are most generally relied on, because they can be easily obtained pure, and the platinum can in most cases be determined with great accuracy. The rational formula of the base is that which corresponds to 1 atom of platinum. Thus the platinum-salt of *nitranisidine* gives numbers corresponding to the formula, $C^7H^8N^2O^3.HCl,PtCl^2$: hence the formula of the base is $C^7H^8N^2O^3$. In some cases, the gold-salts are better adapted than the platinum-salts for determining the constitution of an organic base. But any well defined and stable salt in which the amount of acid or acid-radicle can be directly and accurately determined, will answer the purpose equally well.

To determine the rational formula of a compound which is neither acid nor basic, recourse must be had to its derivation and to its modes of decomposition. Thus indigo yields by analysis numbers corresponding to the formula, C^8H^5NO. By oxidising it with nitric acid, we obtain *isatin*, $C^8H^5NO^2$ (= indigo + O); and isatin treated with potash yields the potassium-salt of *isatic acid*, $C^8H^6KNO^3$. Now, as isatic acid exhibits the characters of a monobasic acid, this formula shows that it contains 8 atoms of carbon; and consequently isatin and indigo, which are related to it in the manner just mentioned, must also contain 8 atoms carbon. Substitution-products formed under the influence of chlorine, nitric acid, &c. are often of great use in determining rational formulæ. Thus the composition of mesitylol may be expressed empirically by either of the formulæ, C^3H^4, C^6H^8 or C^9H^{12}. But this body, under the influence of nitric acid, yields the three substitution-products, nitromesitylol, $C^9H^{11}(NO^2)$, dinitromesitylol, $C^9H^{10}(NO^2)^2$, and trinitromesitylol, $C^9H^9(NO^2)^3$, the composition of which is utterly irreconcilable with the formula, C^3H^4, or C^6H^8. Again, the composition of *naphthalin* might be expressed empirically by the formula, $C^{10}H^8$, or C^5H^4; but the existence of the compounds, $C^{10}H^7Cl$, $C^{10}H^6Cl^2$, $C^{10}H^5Cl^3$, $C^{10}H^5BrCl^2$, $C^{10}H^4BrCl^3$, and $C^{10}H^4Br^2Cl^2$, shows clearly that the higher formula is the true one.

When a compound is volatile without decomposition, its atomic weight may generally be determined by means of its vapour-density. In nearly all cases, the molecule of a compound in the gaseous state is supposed to occupy 2 volumes (Atomic Volume), in other words, the vapour-density is half the weight of the molecule, and the formula of the compound must be calculated accordingly. Thus the vapour-density of alcohol, as determined by Gay-Lussac, is 1·6133, referred to air as unity, or $\frac{1·6133}{0·0693} = 23·25$, referred to hydrogen as unity. The double of this number, or 46·5 is therefore the weight of the molecule. Now the composition of alcohol, as determined by elementary analysis, is C^2H^6O, and the weight of the molecule calculated from this formula is 46. The formula of alcohol is therefore C^2H^6O and not any multiple thereof.

II. Proximate Organic Analysis.

The knowledge of the ultimate elements of which an organic body is composed, is not sufficient to give a complete idea of its constitution, unless the substance under examination is a definite chemical compound, such as sugar, alcohol, albumin, &c. In that case, all the knowledge that we wish to obtain, or indeed that we can obtain regarding the constitution of the body, is derived from its elementary analysis, together with the study of its chemical reactions; but when a complex organ, as a leaf or a root, or a vegetable or animal fluid, such as the sap, milk or blood, is to be examined, it is necessary, before proceeding to the ultimate analysis, to separate the several definite compounds or *proximate elements*, of which the complex substance is made up; just as in examining a sample of granite, it is not sufficient to know the relative quantities of silicon, aluminium, potassium, oxygen, &c., which it contains, but we require also to know something of the manner in which these elements are grouped in the form of definite minerals; in other words, to ascertain what proportions of quartz, felspar, and mica enter into the composition of the rock.

The ultimate analysis of organic bodies is, as we have seen, reduced to a very complete system; there is indeed no element occurring in an organic compound which cannot be detected with certainty, and estimated quantitatively within very narrow limits. But it is otherwise with the proximate analysis. With regard to vegetable substances in particular, nothing more than a few general directions can be given. In the case of animal bodies, some progress has been made towards the establishment of a systematic course of qualitative analysis, but much remains to be done before the method can approach in regularity and exactness to the processes of mineral analysis.

The substance, whether vegetable or animal, solid or liquid, is divided into two parts, one for the determination of the inorganic, the other for that of the organic constituents. The former is dried and incinerated (see Ashes) and the ash examined by the processes of mineral analysis. The former, if the analysis is to be quantitative, and in some instances also for qualitative analysis, is dried at a temperature between 100° and 110° or 115° C., great care being taken not to let the heat rise too high, as organic bodies are very easily decomposed by heat. Some bodies must be dried at the ordinary temperature over sulphuric acid. Liquids are first evaporated in shallow basins over the water-bath, and the residue is then dried at a somewhat higher temperature.

The dried residue or the original substance, is then subjected to the action of various solvents, generally of ether, alcohol and water. Gerhardt recommends these solvents to be used in the order here indicated: this of course implies that the substance is previously dried. Ether dissolves especially fatty and waxy substances, resins and camphors; alcohol dissolves the same substances with less facility, but on the other hand, it dissolves many substances which are insoluble in ether; water dissolves saccharine, gummy and amylaceous substances, and salts of organic acids. Benzol, oil of turpentine, chloroform and sulphide of carbon, are also used as solvents. Vegetable alkalis are extracted by dilute sulphuric or hydrochloric acid; organic acids by dilute ammonia or potash. The solutions of vegetable acids, and of certain other substances thus obtained, are often treated with acetate or subacetate of lead, in order to precipitate the organic principles in the form of insoluble lead-salts, which are then decomposed by sulphuretted hydrogen. Acetate of aluminium and ferric acetate are also used as precipitants.

The solutions obtained in this way generally contain a mixture of proximate organic principles, which must be separated by fractional distillation, precipitation, saturation, or crystallisation: when crystals are obtained, it is mostly of great service to examine them by the microscope, in order to determine their form, and ascertain whether they are homogeneous.

Fractional precipitation with acetate of lead is much used for the separation of the higher terms of the fatty acid series, stearic, palmitic, acid, &c. The mixture of fatty acids is dissolved in alcohol; the solution is partially precipitated with acetate of lead; the precipitate is decomposed by sulphuric acid; the fatty acids thereby separated are redissolved in alcohol, and again partially precipitated; and this series of operations is repeated till the fatty acid thus separated shows a constant melting point.

The method of *fractional saturation* applied by Liebig to the separation of some of the lower terms of the fatty acid series, may also here be noticed. When valeric and butyric acids occur together in a liquid, their separation may be effected by half saturating the mixture with soda, and distilling. If the valeric acid is in excess, pure valerate of sodium is left behind, and a mixture of butyric and valeric acids distils over; if, on the contrary, the butyric acid is in excess, the residue contains butyrate as well as valerate of sodium: but the distillate consists of pure butyric acid. On distilling the residue with excess of dilute sulphuric acid, the two acids pass over together, and by partially neutralising the distillate with an alkali, and again distilling, a further separation may be effected. At each stage of the process, the less volatile acid (the valeric) displaces the more volatile, and one only of the acids is found either in the distillate or in the residue, according as the more or the less volatile acid predominates. When a mixture of acetic acid with butyric or valeric acid is treated in this manner, different phenomena present themselves, the acetic acid, though the most volatile, exhibiting the greater tendency to displace the other two and remain in the residue. This peculiar behaviour is due to the formation of an acid acetate of sodium, $C^2H^3NaO^2.C^2H^4O^2$, which is not decomposed by either of the other acids. Hence, if the mixture contains more acetic acid than is sufficient to form an acid acetate with the quantity of soda added, the excess will pass over together with the whole of the butyric or valeric acid present, the residue consisting of pure acid acetate of sodium; if, on the contrary, the quantity of acetic acid is less than sufficient to convert the whole of the soda into the acid acetate, pure valeric or butyric acid will pass over, and the residue will contain acid acetate of sodium, mixed with butyrate or valerate.

Volatile oils are separated by fractional distillation. The roots, seeds, leaves, &c., containing them are macerated in water and distilled, and the oils which pass over with the aqueous vapour, are separated mechanically from the watery distillate, and subjected to fractional distillation, the portions which distil at constant boiling points or between narrow limits of temperature being collected apart. Many volatile oils have the composition of aldehydes, and these are separated from mixtures containing them, by agitation with a saturated solution of acid sulphite of sodium, with which they form crystalline compounds.

In most cases, however, more information will be obtained concerning the best method of procedure in any particular case, by consulting the methods which are actually in use for separating special substances from complex mixtures in which they occur, than from any general rules: see for example the articles **Alkaloids (detection of)**, **Bone-oil**, **Cinchona-bark**, **Opium**, for the methods of separating alkaloids; the articles **Bile**, **Oleic Acid**, **Stearic Acid**, **Uric Acid**, &c., for the methods of separating acids; and the articles **Albumin**, **Glycerin**, **Sugar**, &c., for the methods of separating neutral bodies.

Examination of Animal Substances: Zoochemical Analysis.—The general directions just given for the proximate analysis of complex organic bodies, are for the most part equally applicable to vegetable and to animal substances: but the proximate principles of the animal body being less numerous than those of the vegetable kingdom, where distinct proximate principles occur in every natural order and in many individual species, it is somewhat easier to lay down a systematic course for the qualitative analysis of animal substances. The following is the method given by Gorup-Besanez, in the *Handwörterbuch der Chemie*, 2te Aufl. i. 984.

a. For liquids.—The physical characters must first be examined. Any turbidity or sediment occurring in the liquid is to be examined by the microscope for the detection of crystals, or bodies of any other definite form. An acid reaction of the liquid indicates the presence of free acids or of acid salts; an alkaline reaction, that of free alkalis, alkaline carbonates or phosphates (as in blood, blood-serum, and serous transudates, or of ammonia resulting from decomposition (as in urine). A coagulum forming spontaneously, after a while, in a liquid originally clear, generally consists of fibrin; it may also consist of organised bodies, a question to be decided by examination with the microscope.

The liquid, clarified, if necessary, by filtration or straining, is now to be examined as follows.

1. A portion of it is heated in a test-tube to the boiling point, acetic acid being added, before the boiling heat is attained, in sufficient quantity to produce a faint acid reaction, in case the liquid was originally neutral or alkaline.

a. If no distinct coagulum is formed, albumin is absent: pass on to (2).

b. A distinct coagulum or turbidity is produced: Divide the liquid into two portions. To one portion add a few drops of dilute hydrochloric acid. If the precipitate disappears, albumin is absent, but earthy phosphates are probably present. Look for them by the microscope or by chemical tests.

If the coagulum or turbidity does not disappear, add hydrochloric acid and heat to the boiling-point; if it dissolves gradually, with blood-red colour, albumin is present: for a confirmatory test, add a few drops of nitric acid to a small quantity of the original liquid.

N.B. If the coagulum formed by boiling the liquid, or the liquid itself, has a reddish-tinge, hæmatin and globulin may be present. The coagulum is then to be digested in alcohol containing sulphuric acid, and the liquid treated with the tests specially adapted to the discovery of those compounds.

2. The liquid in which no coagulum is produced by boiling, or the liquid filtered from the coagulum in the contrary case, may still contain the following albuminoïdal substances: paralbumin and metalbumin, casein and globulin.

If only a turbidity was produced on boiling the liquid, paralbumin or metalbumin may be present. Add acetic acid during ebullition; if the liquid then becomes turbid or deposits flocks, and yields a turbid filtrate, if it also gives a precipitate with ferrocyanide of potassium and nitric acid, and the last-mentioned precipitate is insoluble in excess of nitric acid, paralbumin is present. Then look for metalbumin with alcohol and ferrocyanide of potassium. If alcohol produces a precipitate soluble in a large quantity of water, but ferrocyanide of potassium produces no precipitate, metalbumin is present.

If the liquid remains perfectly clear on boiling, it may still contain the following albuminoïd substances and their derivatives; casein, globulin, glutin, chondrin, pyin, and mucus.

A sample of the liquid is mixed with ferrocyanide of potassium. If it remains clear, casein and globulin are absent: pass on to (3).

If a precipitate is formed, test for casein with solution of chloride of calcium and boiling, also with calf's rennet; for globulin, by observing whether a precipitate is formed by neutralising the solution after it has been made acid or alkaline.

3. To a portion of the liquid add acetic acid. If it remains clear, pyin, mucus, and chondrin are absent: pass on to (4).

A precipitate is formed: test the solution with corrosive sublimate. If no precipitate is formed, pyin is absent. The occurrence of a precipitate indicates the presence of pyin, which may be verified by tincture of galls and neutral acetate of lead. If the corrosive sublimate produces merely a turbidity, chondrin is perhaps present. Concentrate a portion of the liquid: the formation of a jelly indicates chondrin, the presence of which may be confirmed by its behaviour to alum and metallic salts.

4. The liquid in which acetic acid produced no precipitate may yet contain glutin. Concentrate a portion strongly, and leave it to cool: the formation of a jelly will then indicate glutin, which may be further tested with corrosive sublimate.

5. The original liquid—or of it contained albumin, the liquid freed from that compound by boiling—is concentrated by a gentle heat to $\frac{1}{2}$ or $\frac{1}{3}$ of its volume, then heated to boiling and left to cool.

If no precipitate forms, the liquid is probably free from urates: pass on to (6).

If a precipitate is formed, add acetic acid. If the hitherto amorphous masses are then seen under the microscope to assume the form of rhombic tablets, uric acid is present and may be further tested with nitric acid and ammonia.

A crystalline precipitate not altered by acetic acid points to the presence of sulphate of calcium, or phosphate of magnesium, which may be further submitted to microscopic and chemical examination. The precipitate, if crystalline, may also contain allantoin, tyrosin, hippurate of calcium, and benzoic acid. Microscopical examination and the general behaviour of the substance must then determine the further tests to be applied.

6. The concentrated liquid in which no precipitate is formed by boiling and subsequent cooling, or the liquid filtered from such a precipitate, is evaporated to a syrup on the water-bath, and left to itself for a considerable time.

If crystals gradually form, it is left to stand as long as they continue to increase. They may consist of creatine, creatinine, glycocoll, leucine, allantoin, taurine, sarcosine, inosite, alkaline hippurates, chloride of sodium and other inorganic salts.

It must in the first place be determined whether these crystals are organic or inorganic. In the former case, they must be tested especially for nitrogen, sulphur and phosphorus (p. 221), their chemical character determined as nearly as possible, and the further examination regulated accordingly. In the latter case, they must be treated by the methods of inorganic analysis. If they blacken when strongly heated, but also leave a fixed residue, they probably consist of an organic acid combined with an inorganic base: in that case, the fixed residue will effervesce strongly with acids.

7. The syrupy residue itself, or the liquid separated from the crystals which have formed in it is evaporated nearly to dryness, and the residue exhausted with alcohol of specific gravity 0·833.

a. A portion of the alcoholic solution concentrated and then diluted with water, is tested with nitric acid containing nitrous acid, for bile-pigment:—*b.* A second portion treated in like manner, is tested with sugar and sulphuric acid for the acids of bile:—*c.* A third portion is evaporated nearly to dryness, the residue dissolved in water, and the solution examined by Trommer's or Fehling's test for sugar:—*d.* A larger portion of the alcoholic solution is evaporated to a small bulk, the cooled residue treated with nitric acid free from nitrous acid, and the vessel immersed in ice-cold water or in a freezing mixture. A laminar crystalline precipitate exhibiting the micro-crystalline characters of nitrate of urea, indicates urea (care must be taken to distinguish it from nitrates of the alkalis). A crystalline precipitate appearing after some time, or more quickly after previous heating, indicates hippuric or benzoic acid, the presence of which must be verified by the microscope and by chemical reactions:—*e.* Mix a portion of the concentrated alcoholic extract with a syrupy solution of chloride of zinc: if a crystalline precipitate forms, it may contain creatine and creatinine: if no such precipitate appears after a considerable time, creatine is certainly absent:—*f.* The last portion of the concentrated alcoholic extract, which will exhibit a strong acid reaction, if any free acid is present, is to be heated with oxide of zinc, filtered hot, and a drop left to evaporate on a glass plate: if lactic acid is present, the characteristic club and tun-shaped crystals of lactate of zinc will be seen by examination with the microscope. The presence of lactic acid may be confirmed by preparing a pure salt of the acid from a larger quantity of the liquid.

8. The residue insoluble in alcohol may contain, in addition to inorganic and so-called extractive matters, uric acid, guanine, hypoxanthine, and albuminates not precipitated by boiling. It must be exhausted with water, which takes up casein, pyin, and extractive matters, together with soluble salts, then with dilute potash solution, which dissolves uric acid, hypoxanthine, and guanine, and lastly, with dilute hydrochloric acid. What then remains may contain albuminates which have become insoluble, mucus, and perhaps also silica. All these substances must be further looked for by special tests.

9. Part of the original liquid is evaporated to dryness, and the residue, pulverised if possible, is exhausted with ether. The ethereal extract, chiefly containing fats in solution, is evaporated and further examined (see FATS and GLYCERIDES). The residue insoluble in ether is incinerated, and the ash examined by the methods of inorganic analysis.

β. Tissues and Organs.—In the analysis of animal tissues, it is absolutely necessary to operate with considerable quantities of material, not less than 20 pounds; otherwise a very tedious investigation may be gone through without any satisfactory result.

The tissue is first carefully comminuted and completely exhausted with cold water; the extract is freed from albumin by boiling, and to the filtered liquid a concentrated solution of caustic baryta is added as long as any precipitate or turbidity is produced. The precipitate may contain phosphate of barium, phosphate of magnesium, sulphate of barium, uric acid, and hypoxanthine. The filtrate is evaporated to a syrup over the water-bath, care being taken to remove any mucous films like casein that form during the evaporation. These generally consist of carbonate of barium or phosphate of magnesium, but may also contain uric acid, hypoxanthine, or barium-salts of organic acids; they must, therefore, not be thrown away. As soon as the filtrate is concentrated to the consistence of a thin syrup, it must be left to evaporate spontaneously. If small short colourless prisms form in it, they probably consist of creatine; as soon as they appear to be completely deposited, they are to be separated from the mother-liquor, recrystallised, and submitted to further examination.

The mother-liquor is then further evaporated, and mixed with small portions of alcohol, till a milky turbidity is produced, after which the mixture is left to itself for a few days; if granular, laminar, or needle-shaped crystals form in it, they may contain, besides creatine and phosphate of magnesium, inosate of potassium and inosate of barium. To obtain the inosic acid, dissolve the deposit in hot water, add chloride of barium, purify the inosate of barium which separates by crystallisation, and separate the inosic acid by precipitation with dilute sulphuric acid.

The liquid separated from the deposit of inosates is now to be mixed with a fresh portion of alcohol, whereupon it generally separates into two layers, the lower being syrupy, the upper more mobile. The upper layer is decanted, and the lower is mixed with an equal volume of ether, which generally causes a fresh separation. The lower stratum thus formed may contain alkaline lactates, inosite, and salts of the volatile fatty acids; the upper, creatinine and leucine. The ether-alcoholic liquid is evaporated and left to crystallise. If the residue gradually deposits fine laminated crystals, dilute it with a little alcohol, filter off the mother-liquor, and treat the crystals with boiling alcohol; they may contain creatine and creatinine. The creatine separates immediately as the filtrate cools; the creatinine crystallises from the mother-liquor.

The heavy syrupy liquid mixed with the mother-liquor of the creatine and creatinine is supersaturated with dilute sulphuric acid, in order to precipitate all the baryta, and the filtrate is distilled to obtain the volatile acids. The residue of the distillation, if shaken up with ether, may perhaps yield lactic and succinic acids.

The residue of the distillation, after being freed from these acids, is mixed with strong alcohol, till it becomes turbid, and left at rest. Sulphate of potassium then crystallises out, and on repeatedly adding fresh portions of alcohol, more sulphate of potassium, together with inosite, which must be separated from the sulphate of potassium, as far as possible by mechanical means, and then by recrystallisation from a small quantity of warm water. To obtain hypoxanthine and uric acid from the baryta-precipitates, viz. that which separated in films at the beginning of the process, and that which was produced by adding sulphuric acid to separate the volatile acids treat the united precipitates with boiling potash-ley, filter, acidulate with hydrochloric acid, redissolve the resulting precipitate in potash, and add sal-ammoniac. Uric acid is then precipitated as urate of ammonium, while hypoxanthine remains in solution, and may be obtained by evaporation as a yellowish-white powder.

If the filtrate from the coagulum of albumin, after being evaporated to a syrup, does not yield any well developed crystals, but after standing for some time, masses having a crystalline aspect, soft and unctuous to the touch, and appearing under the microscope as yellowish refracting spherules, the presence of leucine may be suspected. These masses are then to be separated from the mother-liquor, which, after standing for a longer time, deposits more of them, and the entire product strongly pressed between porous tiles and purified by repeated crystallisation from boiling alcohol. If tyrosine is present, it covers the filtrate, after it has been freed from the albumin-coagulum and evaporated, with numerous stellate groups of slender needles, which for the most part remain undissolved when treated with alcohol. They may be dissolved in boiling water, whence they separate on cooling,—purified by solution in hydrochloric acid, with addition of acetate of potassium, and boiling,—and then further examined.

The mother-liquors from the leucine and tyrosine deposits are examined as above for volatile acids, lactic acid, succinic acid, inosite, &c.

Another process for the examination of animal tissues is given by Städeler and Cloëtta:

The extracts obtained by maceration and pressing are boiled with a few drops of acetic acid to coagulate albumin and colouring matter of blood, and the strained liquid, after being evaporated over the water-bath to $\frac{1}{10}$ of its bulk, is precipitated with subacetate of lead. The precipitate, which may contain uric acid and inosite, is collected on a filter and washed; the filtrate is freed from excess of lead by sulphuretted hydrogen, and evaporated to a syrup; the residue, which generally contains alkaline acetates, is freed from these compounds by digestion in cold weak alcohol; sulphuric acid diluted with alcohol is then added as long as a precipitate of alkaline sulphates continues to form; and the excess of sulphuric acid is removed by careful addition of baryta-water. The clear filtrate evaporated till it no longer becomes permanently turbid when mixed with an equal volume of absolute alcohol, is heated till the turbidity disappears, and then left at rest. Any crystals which separate must be further examined: they may consist of creatine, but also of tyrosine and taurine, which last compound has lately been found by Cloëtta in the tissue of the lungs. The mother-liquor of the crystals, if carefully evaporated to a smaller bulk, deposits any leucine that may be present.

The precipitate produced by subacetate of lead is washed, suspended in water, and decomposed by sulphuretted hydrogen. If the liquid filtered from the sulphide of lead deposits, after some time, small white crystalline grains, exhibiting under the microscope the forms of uric acid, they must be collected and examined for uric acid by the murexide test (URIC ACID). The liquid filtered from the uric acid is evaporated over the water-bath, till a sample mixed with alcohol becomes permanently turbid. The entire liquid is then mixed with an equal volume of alcohol, and warmed till the turbidity disappears. If after some days, a deposit forms on the bottom and sides of the vessel, consisting of crystalline masses, which, when recrystallised from water, form rhombic prisms insoluble in alcohol and ether, having a pure sweetish taste, and leaving no residue when burnt, inosite is probably present, and must be sought for by other tests. [For further details, and for the quantitative analysis of animal substances see Lehmann, Lehrb. d. physiolog. Chem. 2te Aufl. Leipzig, 1853; Heintz, Lehrb. d. Zoochemie, Berlin, 1853; Robin et Verdeil, Traité de Chimie anat. et physiol. Paris, 1858; Gorup-Besanez, Anleitung zur zoochem. Analyse, 2te Aufl. Nürnberg, 1854.]

ANALYSIS (VOLUMETRIC) of LIQUIDS and SOLIDS. The method usually employed by chemists to determine quantitatively the constituents of a mixture, consists in separating them out one after the other, either in the pure state, or in the form of some compound of known composition, and weighing the products. Every one who has occupied himself with such separations knows how much time they usually require; indeed the value of an analytical result is very often much less than that of the time and trouble spent upon its determination. We are indebted to the sagacity of Gay-Lussac for the introduction of a new principle in analytical chemistry, which in many instances obviates the inconvenience mentioned. This consists in submitting the substance to be estimated to certain characteristic reactions, employing for such reactions liquids of known strength, and, from the quantity of the liquid employed, determining the weight of the substance to be estimated by means of the known laws of equivalence. Let us, for example, consider the problem which suggested to Gay-Lussac the idea of this method. Suppose it be required to determine the amount of silver in an alloy of silver and copper. The older analytical method consists in dissolving a weighed quantity of the alloy in nitric acid, precipitating the silver as chloride by the addition of hydrochloric acid, then filtering, washing, fusing, and weighing the resulting chloride of silver. From the known fact that chloride of silver contains $\frac{108}{143{\cdot}5}$ of its weight of silver, the amount of silver in the alloy is calculated. The same result is evidently obtained by preparing a solution of chloride of sodium of known strength, and ascertaining how much of the solution is necessary and sufficient to precipitate the silver as chloride of silver from a solution of a weighed quantity of the alloy in nitric acid. The weight of the precipitated silver may be determined from the amount of the chloride of sodium employed; because it is known that 58·5 parts by weight of chloride of sodium are exactly sufficient to convert 108 parts of silver into chloride of silver.

The liquid reagents of known strength employed in determinations of this nature are called "standard solutions." The amount of standard solution employed in a determination may be estimated either by weight or by volume; but inasmuch as the latter method has been found easier of application, it is now universally employed; and hence the method of analysis based upon the use of standard solutions is called "volumetric analysis." At first glance it would seem that nearly all analytical methods based upon weight might be transformed into processes by volume, as in the case of the silver determination above quoted. This is, however, not always possible. A reaction to be applicable in volumetric analysis must satisfy two conditions. (1.) It must not occupy much time; precipitations, for instance, which take place gradually are at once to be rejected. (2.) The termination of the reaction must be recognisable with ease and certainty. Hence the number of possible volumetric processes is much limited. On the other hand numerous reactions inapplicable in weight-analysis furnish excellent means for volumetric determinations.

It is proposed in this article to give a short introduction to volumetric analysis, and for this purpose the subject will be divided into three parts:

I. Description of the necessary apparatus.
II. General rules for the preparation of standard solutions.
III. Description of the most important volumetric methods as yet discovered.

I. *Apparatus: description, use, and verification.*—Besides the apparatus necessary for ordinary chemical operations, such as beakers, basins, &c., the performance of volumetric analysis requires: (1.) a delicate balance and weights. (2.) Graduated glass vessels for the measurement and preparation of the standard solutions. A balance is necessary for the preparation of the standard solutions, and for weighing the substances to be analysed. A good analytical balance capable of weighing 100 grammes, is quite sufficient for both purposes. To those who have many volumetric analyses to perform, a small light sensible balance with short arms is of great use. Such balances admit of more rapid weighing than can be obtained by the ordinary laboratory balances.

The absolute magnitude of the units of weight and measure adopted, may of course be chosen at pleasure. But the French decimal system of weights and measures offers so many advantages, chiefly on account of the simple relation which it establishes between the units of measure and weight, that its employment in the sequel in all data of weight and measure needs no justification.

In order to be able to measure the standard solutions accurately, certain precautions are to be observed which we will now proceed to consider more particularly.

When an aqueous solution is poured out of a vessel, the vessel is, as is well known, never completely emptied; a small portion of the solution remains always upon the the sides, even after the vessel has been long held in an inclined position. In using a measure for liquids we must, therefore, be careful to note whether the *dry* vessel, when filled up to a certain line, holds the required volume, or whether such volume is delivered from the vessel when it is emptied in a certain manner. In the first case the vessel is said to be graduated for the contents; in the second for delivery (*à l'écoulement*). The reading off is performed by bringing the eye and the surface of the liquid into one horizontal line, and noting what division of the volumetric instrument is opposite to the liquid surface. Now aqueous liquids which are enclosed in cylindrical glass vessels, always show a concave surface, which is the more strongly curved the narrower the vessel. But a curved surface is of course opposite to *many* points of the scale at once. In order to avoid the ambiguities which are here introduced a definite method of reading off must be invariably adopted. The following has been found practically the best. A small piece of black paper is fastened a few millimetres below the surface of the liquid by means of a caoutchouc ring; the instrument is brought into an exactly vertical position, one eye is closed, and the other brought to the right elevation. The meniscus then appears by transmitted light, sharply bounded below by a black line, by means of which it is easy to see with what point of the scale the former coincides (see ANALYSIS OF GASES). In order to ensure a fixed point of sight the eye, the meniscus, and a distant horizontal line, of about the same elevation as the eye, are either brought into one horizontal line, or the instrument is placed at a short distance before a vertical strip of mirror, and the eye is brought into such a position that the image of the pupil and that of the meniscus may coincide as nearly as possible: the scale is then read off.

It must be mentioned that the volume of every body varies with the temperature, and that consequently the divisions on a measure for liquids, as well as the strength of a standard solution, are applicable for one temperature only. The expansion of the glass is so small that it may be always neglected in volumetric analyses. A glass vessel, for instance, which holds a liter at 15° C. contains at 15° ± 10°, one litre ± 0·27 c.c.: now 0·27 c.c.; are only the $\frac{1}{4000}$ of a litre. The expansion of liquids is greater, and must be taken into account in exact experiments.

This is especially to be attended to when volumetric instruments are to be graduated by determining the weight of water which they hold. In this case the correction for the expansion of water by heat is not the only one to be made. Since one gramme is by definition the weight in vacuo of one cubic centimetre of water at + 4° C., the volume of a given quantity of water in c.c. is never expressed by the same number as its *apparent* weight in grammes, even at + 4° C. There is of course no necessity for employing the *real* cubic centimetre in volumetric analyses; but, as everything connected with weights and measures should be as precise as possible, we think it advisable to use the words litre, cubic centimetre, &c., in their strict sense.* We therefore give the following table, by means of which the apparent weight of a certain required volume of water may easily be found.

---

* There are, even in scientific researches, cases in which *absolutely* correct measures must be employed; for instance, 1 litre of air of 0° C. has the weight of 1·293 grms., only when its tension is equivalent to the pressure of a mercury column 0·76 *real* metres high, the litre being the volume of a quantity of water of 4° C., which balances *in vacuo* the kilogramme employed.

The weight of 1000 c.c. of water of t° C. when determined by means of brass weights in air of t° C. and of a tension of 0·76 metres, is equal to $1000 - x$ grms.

t°	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
x	1·25	1·20	1·15	1·13	1·12	1·12	1·14	1·16	1·21	1·27	1·34	1·43	1.52	1·63	1·76	1·89

t°	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
x	2·04	2·20	2·37	2·55	2·74	2·95	3·17	3·39	3·63	3·88	4·13	4·39	4·67	4·94	5·24	

When the barometer stands at $76 \pm n$ centim., every x is to be replaced by $x \pm 0{\cdot}014\,n$. The variations of atmospheric pressure may however be neglected, unless a very great degree of exactness is required.

If the strength of a standard resolution is known for one temperature, the strength corresponding to another temperature can only be calculated, if the rate of expansion by heat of the liquid is known. It would lead to entirely wrong results if such calculations were founded on the known expansion of pure water, as experiment has shown that even weak solutions of salts and acids expand far more than water (see Gerlach "Specifische Gewichte der Salzlösungen, &c.," Freiberg). As long as the expansion of the commonly used standard solutions is not directly determined, it is advisable to estimate the strength of such solutions not only by volume, but also by weight, which is easily done by weighing a known volume of the liquid immediately after its strength has been determined. The ratios of the *weight* of the solution to the weight of active substances in it, is of course independent of temperature.

It is a matter of course that such corrections are appropriate only where the errors from other sources are not greater than the corrections themselves.

We may now proceed to describe the separate instruments.

1. *Pipettes.*—Glass vessels of forms shown in *figs.* 40* and 41, provided with a single mark upon the narrow neck, and which are only graduated for delivery. In using them, they are filled, at a little above the mark, by suction, and then closed above with the forefinger of the right hand. The lower point is brought in contact with a wet piece of glass; the liquid is allowed to flow out, by very gentle displacement of the finger, as far as the mark; and the finger is then removed, to allow it to run out into the vessel employed. The drop of liquid in the point of the pipette is to be kept in exactly the same conditions as during the marking of the pipette; *i. e.* it is either totally neglected, or it is partly removed by holding the point against the wet side of the glass, or it is to be blown out entirely. If the same method of evacuation be always faithfully followed, we may assume that, with all thin liquids, equal volumes remain adhering to the sides of the vessel.

It is convenient to be provided with such pipettes containing 100 c.c., 50 c.c., 20 c.c., 10 c.c., and 5 c.c. Pipettes of 10 and 5 c.c. may conveniently have the form of *fig.* 41, larger ones the form of *fig.* 40*. It seldom happens that we have to make pipettes ourselves, as they may be bought at a low price; but they should always be verified. This is easily done by filling them with water of a known temperature, pouring this into a tared flask, and weighing. The volume of the water may then be found from its weight by means of the table above given.

2. *Pipettes* which are divided throughout their whole length and graduated for delivery. It is sufficient to have one of 50 c.c., which is divided in half c.c. (*fig.* 42), and several of 2 to 3 c.c., divided into $\frac{1}{10}$ c.c. (*fig.* 43).

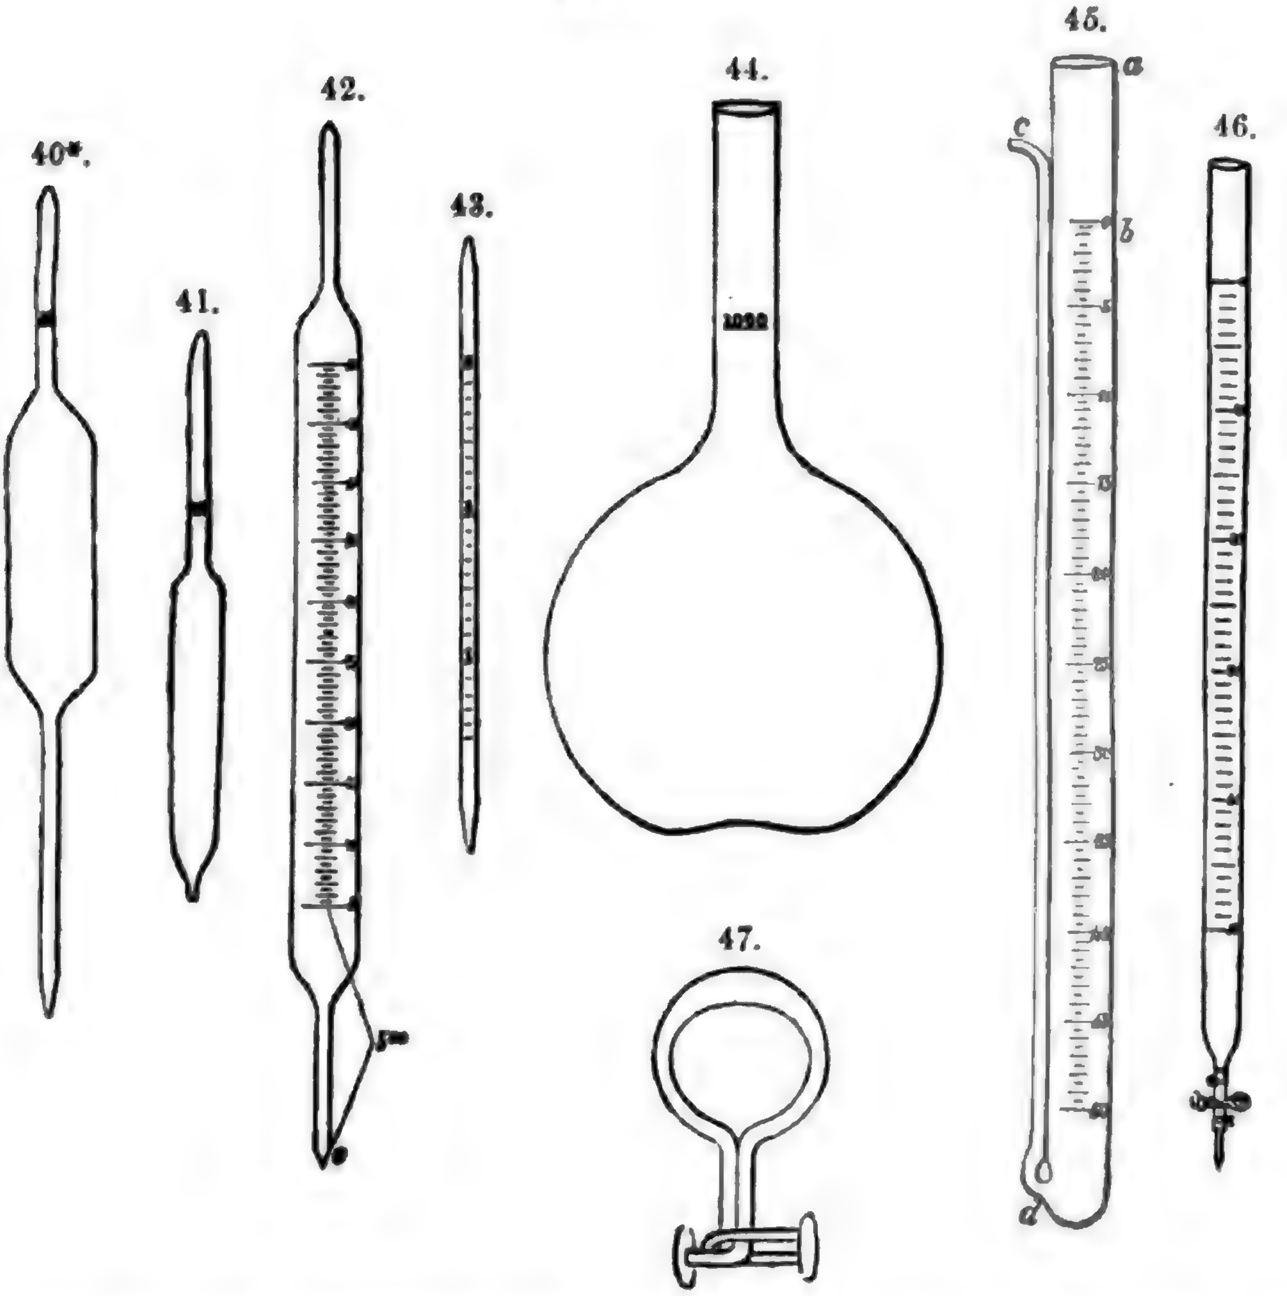
3. *Flasks*, graduated for the contents (*fig.* 44), in various sizes, from $\frac{1}{10}$ litre to 5 litres. They may be easily made by making an arbitrary mark upon the neck of the flask, and then measuring the volume by pipettes. It is more exact to weigh the contained water. It is convenient if, but not absolutely necessary that, the volumes of these flasks should be whole numbers, such flasks being used only for the preparation of standard solutions.

4. For measuring the liquids used in an analysis the *burette* is most generally employed. This is an ingenious instrument invented by Gay-Lussac. Upon a glass tube (*fig.* 45) about 16 – 18 mm. wide and 30 centim. long, a narrow tube is fused at *d*, carried up *close* along the wide tube to about 2 ctm. from its upper end, and there (at *c*) bent and cut off in the manner shown by the figure. The divisions of $\frac{1}{2}$ c.c. begin about one ctm. below *c*, and the instrument is graduated "for delivery." In using the burette it is washed out with some of the standard solution, then filled to 0; the point *c* is slightly greased, and the required quantity of liquid is poured out of the narrow tube.

After some practice it is easy to allow the liquid to flow out either in a stream or in drops. The volume must not be read off before the surface has attained a constant height. Tenths of cubic centimetres may, after some practice, be easily judged of by the eye in burettes graduated to half cubic centimetres. It is erroneous to suppose that greater accuracy is attained by employing narrower tubes. The gain in accuracy due to the increased distance of the divisions is lost, because in narrower tubes, the meniscus is less sharply defined, and the quantity of liquid adhering to the sides is less constant. A burette of the dimensions given, contains 50 to 60 c.c., an amount more than sufficient for most analyses: larger burettes are inconvenient. If more than 50 c.c. liquid are required in analysis, the greatest portion is measured off in a pipette. (40*.) and the remainder added from the burette. In cases where greater accuracy is required than can be attained by the burette, the latter is replaced by the use of several pipettes.

Mohr has substituted for Gay-Lussac's burette a simple divided tube (*fig.* 46), provided below with a caoutchouc tube, which is closed by a spring clamp (*fig.* 47) (*Quetsch-Hahn*) made of brass wire. Where a great number of analyses of the same kind have to be performed, Mohr's burette is much to be preferred to Gay-Lussac's. In scientific laboratories, however, where a greater diversity of analyses occur, the old form is preferable, inasmuch as caoutchouc is acted upon by some solutions which are frequently employed.

Figs. 40*—47.



The verification of a burette is performed either by the balance or by the pipettes described in (1).

II. *Preparation of the Standard Solutions.*—Standard solutions may be divided into (1) such as are immediately prepared by weighing a substance of known composition, dissolving it and diluting to a certain volume; (2) such as are prepared by approximate mixture and subsequent exact analysis. The preparation of the first kind requires no description. The preparation of the second may be effected by a kind of successive approximation, which is best described by an example.

Let it be required to prepare a standard solution of sulphuric acid containing t grammes of hydrate of sulphuric acid SO^4H^2 in 1 litre. The table given by Bineau of the relation between the specific gravity and strength of sulphuric acid affords the best means for determining the strength to the first approximation. Pure sulphuric acid (monohydrate, SO^4H^2) is diluted with about its own weight of water; the mixture is allowed to cool, and its specific gravity is quickly and accurately determined by measuring 100 c.c. in a pipette, weighing this, and dividing the weight (in grammes) by 100. If the temperature be observed, the percentage of monohydrated sulphuric acid (p) may be determined by the table, to within a hundredth of its true value. According to the result of this determination every $\frac{t}{p}\,100 = q$ grms. of the solution are diluted with water up to 1 litre. From Bineau's table (see SULPHURIC ACID) the specific gravity (S) of the required solution may be seen. To every q grms. of acid, $1000\,S - q = w$ grammes of water have to be added. An analysis performed with this mixture generally shows that it contains not t but t^1 grms. in 1 litre. Two cases are now possible:

(1) t^1 is greater than t. It is clear that the quantity t^1 of sulphuric acid contained in 1 litre is sufficient for $\frac{t^1}{t} = (1 + \Delta)$ litre. With every 1 litre of the mixture, Δ litre of water must be mixed, in order to bring it to the right strength. (2) t^1 is less than t. From t^1 grms. of sulphuric acid only $\frac{t^1}{t} = (1 - \Delta)$ litre of standard solution can be formed. Hence 1 litre of our mixture may be regarded as a mixture of $(1 - \Delta)$ litre of right standard solution and Δ litre of water. Hence to every litre of the solution as much of the acid of p per cent. must be added as is sufficient to form the right standard solution, with Δ of litre water; and since by mixing q grms. of the p per cent. acid with w grms. of water, we had obtained a mixture of nearly the right strength, it follows that the quantity of strong acid which must be added to every litre is $\left(\frac{1000\,.\,\Delta}{w}\,q\right)$ grammes, neglecting an error which need not be considered, if Δ is a small fraction.

After performing these operations, we must determine by experiment how nearly we have arrived at the required strength, and, if necessary, make a second correction. If the corrections required are great, it will be almost invariably found, on performing the analysis, that the strength required has not been exactly attained, however carefully the mixture of the liquids may have been made. This is the case even if the above described approximate synthesis is replaced by a theoretically exact one, this cause of the inaccuracy being, that in the measurement and mixture of large quantities of liquids, small errors of measurement and losses are difficult to avoid, and that the contraction of the mixture has been neglected. If, on the other hand, the solution to be corrrected is already so nearly right, that its strength differs by only 1 or 2 *per cent.* from that which is required, the result will be satisfactory, even if the volume of the liquid taken was only approximately determined, provided the analysis was performed accurately, and the measurement of the small quantities of water or acid which were added, were made with sufficient care.

If, for instance, we consider the case (1) and assume that the volume of the acid to be corrected was found to be n litres, while in fact it was $n\,(1 + \alpha)$ litres, the quantity of water to be added would then be, not $n\,\Delta$ litres but $n\,\Delta\,(1 + \alpha)$. The resulting volume of the mixture would accordingly be too small by $n\,\Delta\,(1 + \alpha) - n\,\Delta = n\,\Delta\,\alpha$. If, for instance, it is found that $\alpha = \frac{1}{50}$, which seldom occurs, if moderate care is employed, and $\Delta = \frac{1}{100}$, then the volume of the mixture would be $n\,\frac{2}{1000}$ litres too small, and consequently the amount of sulphuric acid in 1 litre would be too large by about $\frac{1}{5000}$ of its actual quantity. Similar considerations are applicable to case (2), and lead to the conclusion that in the preparation of large quantities of liquids, according to the method just described, large measures accurately divided are not necessary. Such processes are conveniently performed in large cylindrical bottles, which are divided down the side with divisions corresponding to entire decilitres. As the liquid in such cases is not transferred from one vessel to the other till it is quite prepared, loss is easily avoided.

The strength of a solution is best noted by giving the number (n) of gramme-atoms of the active substance which it contains in 1 litre. By "gramme-atom" we understand a number of grammes equal to the atomic weight of the substance ($H = 1$), for instance, 108 grammes silver, 28 iron, 35·5 chlorine, &c. It is clear that the calculations are hereby simplified. For instance, 1 litre of solution of silver, containing *n* atoms (= *n* × 108 grms.) of silver exactly precipitates *n* × 35·5 grms. of chlorine, *n* × 80 grms. of bromine, *n* × 127 grms. of iodine. It is also evident that calculation will be facilitated by making *n* a small number. If it can be done without loss of time, it is in fact advisable so to adjust the strength of the standard solution that $n = 1, \frac{1}{2}, \frac{1}{10}$, &c.

It is of the highest importance that the standard solutions should remain of constant strength. To ensure this condition, they must be carefully protected from evaporation and other hurtful influences. Large quantities may be preserved in bottles of 1 or 2 litres capacity, provided with well ground stoppers. Bottles which are not in daily use should have have their stoppers greased and bound over with bladder or sheet caoutchouc.

III. *Description of the most important Volumetric processes hitherto employed.*—Among the many volumetric methods hitherto discovered, those only are of general scientific interest by help of which the analysis of a whole series of bodies can be made with one, or at least, a few standard solutions. These alone will be more particularly considered here. For the many methods applicable in special cases, reference must be made to the several articles of this work.

Volumetric determinations may be classified as follows, according to the principles on which they are based: —

1. *Analysis by Precipitation.*—The quantity of the substance to be determined, is derived from that of the reagent required to separate it out in an insoluble state.

2. *Analysis by Saturation.*—The quantity of a base or an acid is measured by the quantity of acid or base which is necessary to convert it into a neutral salt.

3. *Analysis by Oxidation and Reduction.*—The quantity of substance to be determined is found by the quantity of chlorine, bromine, iodine, or oxygen to which it is equivalent (regarded as oxidant), or by the quantity of chlorine, bromine, iodine, or oxygen which it requires to pass from a lower to a higher stage of oxidation.

1. ANALYSIS BY PRECIPITATION.—Of the numerous methods belonging to this division, we will here consider those only which depend upon the insolubility of the combinations of silver with the halogens (chlorine, bromine, iodine, cyanogen).

If the neutral or slightly acid solution of a chloride, bromide, iodide, or cyanide, is mixed with a solution of nitrate of silver, it is well known that an insoluble chloride bromide, &c., of silver is precipitated, while a nitrate remains in solution. For instance

$$NO^3Ag + ClNa = ClAg + NO^3Na.$$

All these silver precipitates have the common property of forming, on violent agitation, a curdy mass which rapidly subsides. Hence it is possible to recognise exactly the point at which the precipitation is completed. The reactions mentioned may, therefore, be employed, on the one hand, to determine chlorine, bromine, &c., by means of a standard silver solution, and on the other, to determine silver by standard solutions of chlorides, bromides, &c.

Special processes for the determination of Hydrochloric Acid and Chlorides.

Necessary reagents.

1. Chemically pure silver in the form of foil or wire.

2. A silver solution (nitrate) containing $\frac{1}{10}$ gramme-atom (10·8 grm.) silver in 1 litre. It is easily prepared by dissolving 10·8 grm. of silver in excess of nitric acid and diluting to 1 litre.

3. A solution of $\frac{1}{100}$ grm.-atom = 1·08 grm. silver in 1 litre.

4. A solution of chloride of sodium of $\frac{1}{10}$ grm.-atom (= 5·85) in 1 litre.

a. 5·85 grm. pure recently fused chloride of sodium is dissolved in water and diluted litre.

b. A solution of chloride of sodium saturated at ordinary temperatures, has a composition almost independent of the temperature: it contains in 1 litre, 318·4 grm. of NaCl. 18·37 c.c. $\left(= \frac{1000 \times 5{\cdot}85}{318{\cdot}4}\right)$ diluted to 1 litre, gives accordingly the standard solution required.

The chloride of sodium solution must, if properly prepared, be exactly equivalent to the silver solution (2). We must never neglect to try whether this is really the case by the method to be described below, and if necessary to make the proper corrections.

5. A solution of chloride of sodium containing $\frac{1}{100}$ grm.-atom in 1 litre = 0·585 grm.

6. Freshly prepared chloride of silver: this is obtained by mixing equal volumes of (2) and (4), shaking vigorously and pouring off the clear liquid.

Performance of the Analysis.—Let us at first assume that we have an approximate knowledge of the amount of chlorine in the substance to be examined. In this case a weighed quantity is introduced into a bottle of clear glass with a well-fitting stopper, dissolved in water or nitric acid, and the previously calculated quantity of strong solution of silver (2) is added from a pipette. The quantity of substance, and that of the water employed in its solution or dilution, are to be so taken that 100 c.c. of the mixture may contain 0·4 grm. to 1 grm. silver, and less than about 3 gms. of the dissolved salt. If a mixture has to be examined which is poor in chlorine, this relation is no longer possible. In such cases, enough freshly precipitated chloride of silver (6) must be added to bring the quantity of silver present up to that mentioned. Small quantities of silver-precipitates disseminated through much liquid do not evince that adherence and consequent tendency to subsidence which is necessary for the accurate performance of this mode of analysis. Solutions which are poor in chlorine, such as mineral waters, must be concentrated by evaporation previous to analysis. It is also advisable in such cases not to employ a standard solution of silver, but to weigh metallic silver and dissolve it in a minimum of nitric acid.

The mixture obtained as above is now to be violently and continuously shaken, till it has lost its first milky appearance, and forms a mixture of curdy chloride of silver in the midst of a clear solution. A speedy clarification is evidence of an excess of silver; slow subsidence indicates the reverse.

As soon as the chloride of silver has sufficiently subsided, ½ c.c. of strong solution of silver must be added, in order to determine whether chlorine is still present in the solution. If no precipitation occurs, the ½ c.c. silver solution is neutralised by the addition of ½ c.c. solution of chloride of sodium; the liquid is then shaken, and ½ c.c. of solution of chloride of sodium being added shows whether silver is in solution. Let us assume, for example, that the addition of the chloride of sodium has shown the presence of silver in considerable quantity. The amount of solution of chloride of sodium, which is exactly equivalent to this, cannot of course be known; but in every case we are sure of the existence of some maximum value (V c.c.) which certainly includes it. $\frac{V}{2}$ c.c. of chloride of sodium solution is then added, the mixture is shaken, and ½ c.c. of the same solution being added shows whether the precipitation with the first quantity was complete or not. In the first case, $\frac{V}{4}$ c.c. of silver are added; in the second $\frac{V}{4}$ c.c. of chloride. In both cases, the completion of the precipitation is tested by the addition of ½ c.c. of test solution. By continually adding half the possible maximum of the necessary reagents, we soon arrive at a point when less than ½ c.c. of one of the two solutions is present in excess. When this point is arrived at, cubic centimetres are added singly of the weaker ($\frac{1}{100}$ atomic) solutions, until the last cubic centimetre leaves the liquid quite clear, This last c.c. is not at all considered, and the one preceding it is considered only of the value of ½ c.c. In this way, a result is obtained, the error of which corresponds to less than ½ c.c. of the weak standard solution. It is easily seen that a systematic procedure like that given is quite essential, in order to arrive quickly at a result; by planless addition of standard solutions, we may lose much time without arriving at any result. As long as $\frac{1}{10}$ atomic solutions are added, it is scarcely necessary to wait for a complete subsidence of the precipitate previously formed. The white cloudy freshly precipitated chloride of silver is easily distinguished from the previously precipitated, violet-coloured, and coagulated chloride. As soon, however, as we begin to work with $\frac{1}{100}$ atomic solutions, we must always wait for the complete clarification of the liquid before adding a fresh quantity of solution. Weak precipitations are best seen by holding the vessel against the light, with a piece of black paper obliquely behind it. The precipitation can be considered complete only when the last cubic centimetre of solution gives no more turbidity after ½ to 1 minute's standing.

Those who make such analyses for the first time, will do well to place in several flasks some chloride of silver (6) and 100 c.c. water, then add to the several flasks ¼, ½, 1, 2 milligrammes of silver; shake, and after subsidence add to each flask 1 c.c. of the $\frac{1}{100}$ atomic solution of chloride of sodium. By this means the judgment is greatly assisted in the subsequent actual reactions.

Experience has shown that it is not expedient to work with less than ½ grm. of silver at once, and that no greater accuracy is obtained by adding less at once than 1 c.c. of the $\frac{1}{100}$ atomic solution; the termination of the reaction is thereby only rendered more indistinct.

If it be desired to arrive at the utmost accuracy in such determinations, a second analysis may be made by dissolving 1 grm. or more of silver in nitric acid, adding the quantity of substance necessary for its precipitation, as found from the previous analysis, and completing the precipitation by means of the $\frac{1}{100}$ atomic solution. The determination of atomic weights, performed in this way by Marignac and Pelouze, shows to what great accuracy the process may be brought.

It has been hitherto assumed that the amount of chlorine in the substance is approximately known. If this is not the case, the definite determination must be preceded by a trial upon a small quantity of the substance. The more exact such trial is made, the quicker will be the performance of the final determination.

The calculation of the analysis is very simple. The number of atoms of silver, diminished by the number of atoms of chloride of sodium, added as standard solution, is equal to the number of chlorine-atoms contained in the substance.

That which is here described for chlorine is applicable, *mutatis mutandis*, to bromine, iodine, and cyanogen.

The determination of silver by means of chlorine also follows immediately from the above, and requires no further explanation.*

2. Analysis by Saturation.—All methods belonging to this division depend upon the fact that potash, soda, ammonia, baryta, strontia, and lime combine easily and directly with acids, and that the corresponding carbonates are fully decomposed in contact with stronger acids, with evolution of carbonic acid. The solutions of the neutral salts which the above named bases form with strong acids are without action upon litmus, while the smallest excess of acid or alkali is immediately detected by its reddening or blueing that vegetable colour.

Reagents.—1. Pure anhydrous *monocarbonate of sodium*. If this salt be kept ready prepared in powder, it must always be ignited before use. Carbonate of sodium, fused in a platinum crucible, and cast in slabs, is less hygroscopic, but its use must be avoided, since Scheerer has shown that carbonate of sodium loses on fusing a considerable part of its carbonic acid.

2. Standard solution of *hydrochloric acid*, containing nearly or exactly 36·5 grms. HCl (1 atom) in 1 litre. This may be prepared in several ways.

a. The most exact method is to determine the specific gravity of a sample of concentrated pure hydrochloric acid, deduce its strength by means of Ure's table† (see Hydrochloric Acid, under Chlorine), add the proper amount of water and determine *exactly* the strength of the mixture by means of silver solution, as described in a preceding paragraph.

b. A concentrated acid, whose strength is approximately known from its specific gravity, is so far diluted that it contains, as nearly as can be effected by this means, 20·2 *per cent.* of HCl. If the liquid so obtained be quickly boiled in a narrow necked flask, or in a retort in contact with platinum (not in an open basin), a time soon arrives after which hydrochloric acid and water evaporate in the same proportion in which they are contained in the residue. If about one half be evaporated we may be certain that the point mentioned is attained. The percentage strength of the residue depends upon the contemporary barometric pressure, according to the following table, derived from experiments made on this subject by Roscoe and Dittmar. (Chem. Soc. Qu. J. xii.)

Height of barometer in metres	0·73	0·74	0·75	0·76	0·77	0·78	0·79
Percentage strength of residue in HCl . .	20·30	20·28	20·26	20·24	20·22	20·20	20·18

It will be seen that in cases where the barometer stands at about 0·76, the percentage of HCl may, without incurring great error, be taken as 20·24. 180·3 grms. of such an acid are accordingly equivalent to 36·5 gr. of HCl.

c. Concentrated hydrochloric acid of known specific gravity is so far diluted with water that it contains rather *more* than 36·5 gr. HCl. In a measured quantity (V c.c.) of this acid, carbonate of sodium is dissolved in the cold in the proportion of 53 milligrammes to every 1 c.c. of the acid. A few grammes of sulphate of sodium are then added, and the whole is boiled to expel the carbonic acid. The sulphate of sodium is added to prevent the evolution of hydrochloric acid.

The liquid so prepared contains, besides the neutral salts, only the excess of acid

---

* Gay-Lussac's method of determining silver has recently been investigated by Mulder (see Mulder, "Die Silberprobir-methode," etc., Leipzig bei Weber). He has made the singular observation, that a mixture of exactly equivalent quantities of Ag and NaCl-solution gives precipitates wth *both* reagents. Of either of the two solutions a quantity equivalent to $\frac{1}{2000}$ of the silver just precipitated is to be added, before the formation of precipitates ceases. Stass has, in the course of his determinations of atomic weights, made a similar observation; but according to him, the limits of the state of indifferent equilibrium are narrower. These observations show that in order to attain the highest possible degree of accuracy, a strictly empirical procedure must be adopted.

† For an acid whose strength is between twenty and thirty per cent. the relation between specific gravity s, and percentage p, is given by the equation—

$$p = 200\,(s-1) + 0{\cdot}3.$$

whose quantity has to be determined in order to find the strength of our test-acid. For this purpose the mixture is coloured slightly red with solution of litmus, and an arbitrarily diluted caustic soda solution is added while the liquid is hot, till the last drop causes a decided blue colour (without mixture of violet). The quantity of soda (t c.c.) required to produce the effect is noticed.* On the other hand, a fixed volume (v) c.c. of the test-acid is measured, and in exactly the same manner, the quantity (t^1 c.c.) of caustic soda required for its neutralisation is determined.

From the last test, we have found that 1 c.c. of the arbitrarily diluted soda is equivalent to $\frac{v \text{ c.c.}}{t^1}$ of our acid. Hence we had previously added $\frac{t}{t^1} v$ c.c. more of this acid than is necessary for the neutralisation of V. 53 miligrm. of carbonate of soda, *i. e.* $\left(V - \frac{vt}{t^1}\right)$ c.c. of test acid would have exactly sufficed to neutralise the weighed quantity of carbonate of sodium. If, accordingly, we dilute $\left(V - \frac{vt}{t^1}\right)$ c.c. of acid to V c.c., then 1 c.c. of the mixture will contain exactly 1 milligramme-atom of HCl. In most cases, however, it is better not to perform this dilution, but to note that 1 c. c. test-acid contains $\left(\frac{V}{V - \frac{vt}{t^1}}\right)$ 36·5 milligrammes of HCl.

3. *Test Sulphuric acid.*—It is not necessary to have this as well as the hydrochloric test-acid. Nevertheless it has over the latter the important advantage of being wholly non-volatile when boiled in dilute solution. It can be prepared according to the method described for hydrochloric acid under (c).

4. *Test Caustic soda,* which is, volume for volume, exactly or nearly equivalent to the test-acid. Carbonate of sodium is rendered caustic in the ordinary manner, and so far concentrated that the requisite strength is nearly attained. A small quantity more of milk of lime is then added, the liquid allowed to cool (the air being excluded), and the clear liquid drawn off by a syphon. For the exact determination of its strength, 50 c.c. test-acid are poured into a porcelain basin, a few drops of litmus are added, and then the soda-solution is poured in from a burette till the colour begins to deepen. A decided reaction is recovered by addition of 1 c.c. of test-acid; about 2 grms. of sulphate of soda are then added (if hydrochloric acid is being employed); the liquid is heated to boiling, and soda is again poured in, till the liquid exhibits a distinct blue colour. The calculation of the result requires no explanation.

5. *Solution of Litmus.*—Powdered litmus is digested in the cold with twenty times its weight of water, the solution filtered, and so exactly saturated, that 1 c.c. of the litmus solution diluted with about 100 c.c. water, is turned decidedly red by $\frac{1}{20}$ c.c. of test-acid, and decidedly blue by the same quantity of test-alkali.

Acidimetry.—Free acids in aqueous solutions, if these be free from magnesia, alumina, and the heavy metals, and are not deeply coloured, may be determined in a manner which will be sufficiently clear from paragraph 4. If hot solutions are used, the caustic soda may without injury contain a little carbonic acid. But if we are compelled to work in the cold, in consequence of the presence of salts of ammonia, or because the acid to be determined cannot be prevented from evaporating by addition of sulphate of sodium, caustic soda must be employed which is almost perfectly free from carbonate. But even in such case, the termination of the reaction is not so easily recognisable as when the solution is warm. It is best detected by dropping in the soda rather quickly and without intermission, till the liquid, after stirring, remains distinctly blue for some seconds. The gradual change of this colour to violet is no evidence of the solution not being neutral. Such change depends upon the subsequent action of carbonic acid upon the litmus. In the determination of weaker acids, such as the organic, the same exactitude of reaction is not observed as occurs in the determination of sulphuric, nitric, hydrochloric, and other strong acids. It must be also noticed that many substances somewhat modify the blue colour which is the criterion of completed reaction. In presence of many substances, such as ammoniacal salts, &c., the change of colour from red to blue does not occur so quickly and decidedly as when these substances are absent; and in a few instances, as when acetic acid is present, the real point of saturation is not reached until after the change of colour has taken place. In order to render the analysis, in such cases as these, as accurate as possible, it is advisable to make a control experiment under the same conditions as occur in the real determination. Thus, for instance, if the strength of an acetic acid be required, it will not be sufficient to make an analysis in the ordinary way, because the neutral, acetates of sodium and potassium have an alkaline reaction, and this will mask the true point of saturation; it is best, therefore, to prepare a solution of acetic acid of

---

* The change of colour is best seen in a porcelain basin, or in a flask standing on white paper.

known strength—by adding a known quantity of standard sulphuric acid to excess of acetate of sodium, and to determine how much standard soda-solution is necessary to bring about a definite change of colour in this acid solution. The strength of the soda-solution being thus empirically determined with acetic acid, the real analysis can be made without any reference to hypothesis.

Alkalimetry.—Caustic alkalis and their carbonates are easily determined in a manner which is so analogous to the method given (2, *c.*) for the preparation of standard acid, that a fuller description is unnecessary. If many such determinations are to be made, it is advisable to employ test-sulphuric (not hydrochloric) acid, and so to dilute the soda that it saturates the test-acid, volume for volume. If ammonia is to be determined, the reneutralisation by soda must be performed in a perfectly cold solution.

Baryta, Strontia, and Lime, and their carbonates, are determined exactly as the the fixed alkalis. But hydrochloric acid must be employed and no sulphate of sodium can be added, otherwise sulphates of these earths are precipitated, and such precipitates influence the litmus reaction. If only a small excess of acid has been used, the quantity of hydrochloric acid lost by a boiling of short duration is very inconsiderable. If this excess of acid does not occur in the first analysis, it may be made to do so in a second one (see page 117).

3. ANALYSIS BY OXIDATION AND REDUCTION.—It is known that most elements combine in various proportions with oxygen or its substituents; that lower oxides or chlorides are converted into higher oxides or chlorides, by the direct or indirect addition of oxygen or chlorine; and that these higher compounds often give up a portion of their oxygen or chlorine when in contact with reducing agents. Amongst the innumerable reactions of this kind, all those can be employed which occur quickly, and in which the termination of the reaction may be recognised with distinctness. Amongst the numerous methods of volumetric analysis of this kind hitherto proposed, we shall mention only the most important. These may be divided into two classes: (*a*) those in which permanganic acid is the oxidant,—(*b*) those in which iodine acts as oxidant.

(*a*). With PERMANGANIC ACID:

1. *Determination of Iron.*—If a solution of permanganate of potassium be added to a strongly acid and dilute solution of a protosalt of iron, the Mn^2O^4K gives up $\frac{5}{8}$ of its oxygen to the iron, converting it into sesquisalt, and is itself converted into a manganosum- and a potassium-salt of the acid added; *e. g.*:

$$2Mn^2O^4K + 10SO^4Fe^2 + 8SO^4H^2 = 2SO^4Mn^2 + SO^4K^2 + 5(SO^4)^3Fe^4 + 8H^2O.$$

The deep purple red colour of the permanganic acid is continually destroyed as long as any protoxide of iron is present; but as soon as all the protoxide of iron is converted into sesquioxide, the next drop of the reagent, even if the solution is very dilute, gives a distinct rose-red coloration. Hence it is clear that protoxide of iron may be determined by means of permanganate of potassium. A convenient standard solution is obtained by dissolving about 8 grammes of the commercial crystallised salt in 1 litre of water; 1 c.c. of such solution oxidises, according to the relative purity of the salt, from 12—14 milligrammes of iron present in the form of protoxide. On account of this uncertainty, and because the solution gradually though slowly decomposes, a fresh estimation of the strength of the solution must precede every series of iron determinations. For this purpose, 0·5 grm. of pure iron (thin harpsichord wire is almost perfectly pure) is dissolved in a great excess of pure dilute sulphuric acid, the air being as far as possible excluded. Mohr recommends the double salt, $SO^4FeNH^4 + 3H^2O$, as a standard. The air-dry salt does not oxidise in air: it contains $\frac{1}{7}$ of its weight of iron. The solution is then allowed to cool, and is diluted with water free from air to between 0·4 and 0·5 litres. Chameleon solution is added from a burette to this liquid, till the colour of the last drop no longer disappears. From the result it is easy to calculate how many milligrammes of iron are oxidised by 1 c.c. of the chameleon solution. In order now to determine the quantity of iron in a given substance, so much of the substance as will contain about 0·5 gr. of iron is dissolved, if possible, in water or sulphuric acid; hydrochloric acid should be used only when it cannot be avoided. If all the iron is dissolved as protoxide, the solution is diluted to about 0·4 or 0·5 litres, and examined just as was done in the case of the standard solution above described. If the iron is present partly or wholly as sesquioxide, this must, previous to the dilution by boiling with zinc free from iron, be completely reduced to the state of protoxide. The reduction may be considered complete when the solution has become completely or nearly colourless. If any metals such as arsenic, copper, &c. are hereby precipitated, they must be removed by quick filtration through bibulous paper.

That the determination may be accurate, it is necessary—1. That the solution be very dilute, in order that the yellow colour of the sesquioxide of iron formed may not interfere with the distinctness of the reaction. If hydrochloric acid be present, more water than usual must in general be added, because in concentrated solutions, hydrochloric acid reduces permanganic acid.

$$Mn^4O^7 + 14HCl = 7H^2O + 10Cl + 4MnCl$$

2. An excess of acid—if possible, of sulphuric acid—must be present. The object of this is not only to make the colour of the sesquioxide of iron faint, but also to prevent the oxygen of the air and the small quantity of air in the water used for the dilution, from exerting an oxidising action during the operation.

It is scarcely necessary to mention that protoxide of iron may in this manner be determined in the presence of sesquioxide. The principal advantage of this determination consists in the fact that the presence of many substances, which often greatly complicated weight-analyses, does not interfere with its simplicity and accuracy. Even the iron contained in ferrocyanides may be determined by means of permanganate of potassium.

The behaviour of permanganic acid towards protoxide of iron may serve for the indirect estimation of many substances which are capable of oxidising proto-salts of iron. It is only necessary to allow the substance to act upon a known quantity of iron in excess dissolved as protoxide, and to estimate the amount of protoxide unacted upon, in the manner just described. Free chlorine, the active chlorine in chloride of lime, the higher oxides of manganese[*], nitric acid, &c., may be determined in this way. We shall subsequently discuss other and better methods of estimating these substances, and will not therefore here enter into further particulars.

2. *Determination of Copper.*—The solution of the substance in water or nitric acid is mixed with a quantity of tartrate of potassium and sodium sufficient to prevent precipitation by the subsequent addition of an excess of caustic potash. The alkaline liquid is heated to boiling, and milk-sugar is added, till all the copper is precipitated as suboxide. This is collected on a filter, washed with hot water, and digested, together with the filter, in strong hydrochloric acid and chloride of sodium. The resulting solution of $NaCl + Cu^2Cl$, is to be diluted and treated with permanganate of potassium, as in the determination of iron. The filter, if the operation be quickly performed, has no action upon the permanganic acid. Since in this reaction, 4 atoms of copper take up one atom of oxygen from the permanganic acid, every volume of our solution will oxidise as many atoms of copper (31·7 grms.), as it does of iron (28 grms).

$$5Cu^4O + Mn^4O^7 = 10Cu^2O + 2Mn^2O$$
$$\text{and} \quad 10Fe^2O + Mn^4O^7 = 5Fe^4O^3 + 2Mn^2O.$$

3. *Determination of Oxalic acid.*—When oxalic acid and permanganic acid are brought together in acid solutions, the former is oxidised to carbonic acid, the latter reduced to protoxide of manganese, which unites with the acid present:

$$Mn^4O^7 + 5C^2H^2O^4 + 2SO^4H^2 = 10CO^2 + 2SO^4Mn^2 + 7H^2O.$$

Hence oxalic acid may be determined by means of permanganate of potassium in a dilute solution containing an excess of free sulphuric acid, in a manner exactly similar to that described under iron. For the determination of the permanganic acid, either pure, air-dried, crystallised oxalic acid, $C^2H^2O^4 + 2H^2O$, or pure iron, is employed. A volume of test-solution which oxidises x atoms (x . 28) of iron, will convert $\frac{x}{4}$ atoms of oxalic acid (x : 31·5) into carbonic acid and water.

The behaviour of permanganic acid towards oxalic acid may be employed for the valuation of commercial peroxide of manganese: 1 grm. of the *very finely* powdered peroxide is mixed with a weighed quantity (about 1·5 gramme) of crystallised oxalic acid and a considerable excess of pure dilute sulphuric acid, and warmed till the peroxide of manganese is decomposed. Water is added, the solution allowed to cool, and the excess of oxalic acid determined as above: 1 atom of peroxide of manganese transforms 1 atom of oxalic acid into carbonic acid:

$$Mn^2O^2 + C^2H^2O^4 + SO^4H^2 = SO^4Mn^2 + 2CO^2 + 2H^2O.$$

(*b*). METHODS IN WHICH IODINE ACTS AS OXIDISING AGENT.—Iodine in aqueous solution, in presence of oxidable substances, often acts upon the elements of water so as to form hydriodic acid with its hydrogen, while the oxygen acts upon the substance present. Now as the smallest quantity of free iodine may be recognised by its property of blueing starch-solution, whereas hydriodic acid and the iodides are without action upon starch, the substances mentioned may often be determined by mixing their

---

[*] The determination of nitric acid becomes exact only when the reaction takes place in an atmosphere of hydrogen, but this precaution being taken, N^2O^5 oxidises exactly 12Fe. (Fresenius.)

aqueous solutions with starch-solution, and then adding a standard solution of iodine in iodide of potassium, until permanent blue coloration occurs. In order that this reaction may succeed, the substance to be oxidised must, even in very dilute solution, possess the property of decolorising the iodide of starch which has been locally formed. For examples of determinations of this kind, we will take the following.

Hyposulphurous acid, as potassium-, or sodium-salt, in neutral or alkaline solutions (made alkaline by bicarbonates of the alkalis), acts upon iodine in such a manner that tetrathionates of alkalis and metallic iodides are produced, *e.g.*:

$$2S^2O^3Na^2 + 2I = 2NaI + S^4O^6Na^2.$$

Arsenious acid, in the form of an alkali-salt, is converted by iodine into arsenic acid, in a solution made distinctly alkaline by carbonate or bicarbonate of an alkali-metal. Iodine must be added till the iodide of starch formed is no longer decolorised on the addition of bicarbonate of sodium; 4 atoms of iodine (508 pts.) oxidise 1 atom of arsenious acid (198 pts.):

$$As^2O^3 + 4I + 2H^2O = 4HI + As^2O^5.$$

Sulphurous acid, may be determined like hyposulphurous acid in solutions rendered feebly alkaline by an alkaline carbonate. The product formed is sulphuric acid:

$$SO^2 + 2I + 2H^2O = 2HI + SO^4H^2.$$

If we endeavour to determine *free* sulphurous acid by iodine, very divergent results are obtained when the solution is strong. In such cases, the quantity of sulphurous acid converted into sulphuric acid varies very much, according to the quantity of water present and the rapidity with which the iodine is added. If, however, before adding the iodine, the solution is so far diluted with water free from air, that less than 0·4 grm. of sulphurous acid is contained in 1 litre of water, the reaction, $2I + 2H^2O + SO^2 = 2HI + SO^4H^2$, occurs with perfect regularity.

The circumstances under which this reaction takes place, were determined by Bunsen (Ann. Ch. Pharm. lxxxvi. 265), and applied to a series of very accurate volumetric determinations, the most important of which we shall here explain.

Analyses by means of Iodine and Sulphurous Acid.

Reagents.—1. Pure iodide of potassium. 2. Pure hydrochloric acid. 3. Freshly prepared, thin, very clear starch-solution.* A dilute solution of iodide of potassium, mixed with starch and hydrochloric acid, must give a mixture which remains colourless for several minutes.

4. A standard solution of iodine in iodide of potassium, 5 grms. of commercial iodine, and 10 to 12 grms. of iodide of potassium, are dissolved in about 20 c.c. water, and as soon as all the iodine is dissolved the solution is diluted to 1 litre.

5. A solution of sulphurous acid in distilled water. This must be so diluted that about 10 volumes of it are necessary to decolorise 1 volume of the iodine-solution (4). This solution should be prepared in quantities of 10 to 20 litres, and allowed to stand about an hour excluded from the air, before use, so that the oxygen contained in the dissolved air may be absorbed by the sulphurous acid. It may be advantageously kept in an earthenware vessel, provided with a tap at the bottom, and a fine drawn out tube above to allow the air to enter. The strength of such a solution may be considered as constant during the performance of one analysis.

The first question is to determine *exactly* the strength of the iodine-solution, already approximately known. If we had a small quantity of perfectly pure iodine of known weight, this might be easily done by comparing such iodine with the standard-solution by means of the same sulphurous acid. Such a quantity of iodine to serve as a measure, is obtained by boiling between 200 and 400 milligrammes (= *A*) of pure anhydrous bichromate of potassium with fuming hydrochloric acid, and collecting the evolved chlorine in a solution of iodide of potassium (for one part of the bichromate about 20 parts iodide of potassium are employed). 1 atom (294·8) of bichromate liberates under these circumstances 6 atoms of iodine (6 × 127·0):

$$Cr^4K^2O^7 + 14HCl = 7H^2O + 2KCl + 2Cr^2Cl^3 + 6Cl$$
$$6Cl + 6KI = 6KCl + 6I$$

In order to perform this operation without loss, the following method is adopted.

On a glass tube of about 4—5 mm. internal diameter, a bulb of about 30 c.c. capacity is blown, and a flask is thus obtained of the form shown in *fig.* 48. To a short piece of the same tubing, a longer and narrower tube is fused, drawn out at *d*, and bent as shown in the figure. If the neck of the flask and the adapter-tube be ground flat and connected with caoutchouc, in such a manner as to bring them close together, an appa-

---

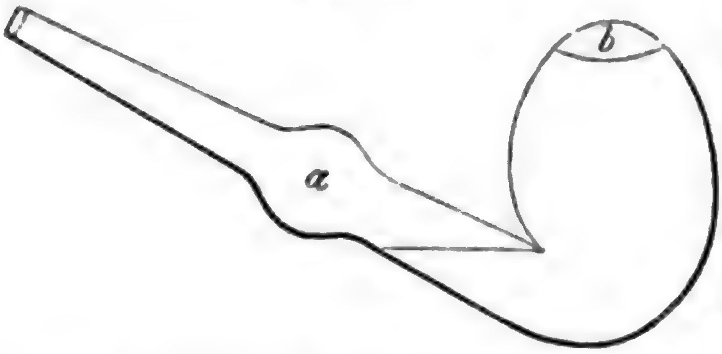
* Starch-solution, when filtered and saturated with chloride of sodium, may be kept a long time without decomposition. (Mohr.)

ratus is obtained for the evolution of chlorine, which is scarcely inferior to one consisting wholly of glass. The caoutchouc tube before use must be freed from adhering sulphur by boiling with very dilute caustic soda and thorough washing with water.

A retort of about 150 c.c. capacity (*fig.* 49) serves to hold the solution of iodide of potassium. The neck of the retort is widened at *a*, to receive any solution driven back by the expelled air. In order to make the determination, we bring the bichromate of potassium into the flask, which is then filled to $\frac{2}{3}$ with fuming hydrochloric acid; the delivery-tube is attached, and placed so far in the retort (filled up to the commencement of the neck with iodide of potassium solution), that the chlorine which is not immediately absorbed must collect at *b*. The flask is first gently heated till the decomposition is complete, then more strongly, in order to drive over every trace of chlorine into the iodide of potassium solution by means of the gaseous water and hydrochloric acid. The retrogression of the iodide can scarcely take place if some care is taken, because it can only occur very slowly, in consequence of the small volume of the apparatus and the fineness of the point *d*. After the hydrochloric acid vapours have been evolved for about five minutes, it may be assumed that all the chlorine is expelled. Without discontinuing the boiling, the delivery-tube is withdrawn from the retort, and the vapours are conducted into some fresh solution of iodide of potassium, the boiling being continued for a few moments longer. If this solution remains uncoloured, the operation may be regarded as successful.

Fig. 48.

Fig. 49.



The contents of the retort (coloured deep brown by iodine) are quickly cooled, and poured out into a beaker glass, and portions of 400 to 450 c.c. of the dilute sulphurous acid are successively added, without loss of time, until the liquid is colourless. The measurement of the sulphurous acid is effected in a flask which contains, up to a mark on its narrow neck, from 400 to 450 c.c., but whose capacity need not be accurately known. The flask is rinsed out with the sulphurous acid, filled up to the mark, and emptied in a definite manner, which should be strictly adhered to during the same analysis. Direct experiments have shown that the volume of the liquid delivered is sufficiently constant.

The liquid decolorised by sulphurous acid contains an excess of this body. Starch and then normal iodine-solution are therefore added till blue coloration occurs. Let the volume of the latter necessary for this be t^1 c.c. Immediately afterwards, one of the measures of sulphurous acid previously employed is taken, and the volume (t c.c.) of standard iodine-solution determined which is necessary for its oxidation. If, then, the number n of the flasks of sulphurous acid which were added to the iodide of potassium solution from the retort has been noted, the strength of the normal solution may be easily calculated.

Let us call, for brevity, the contents of the flask the "volume." From the result of the determination just given, we find that nt c.c. normal iodine-solution were necessary for the oxidation of n volumes sulphurous acid. For such oxidation, t^1 c.c. of the same iodine-solution, together with the quantity of iodine produced by the distillation of A milligrammes of bichromate of potassium with hydrochloric acid, were also sufficient. This amount of iodine $\left(A.\ \frac{3 \times 127}{147 \cdot 4}\right)$ millg. is therefore equivalent to $(nt - t^1)$ c.c. of iodine solution. Hence 1 c.c. of the latter contains

$$\frac{A \times 3 \times 127}{147 \cdot 4\ (nt - t^1)} \text{ milligrammes of free iodine, or}$$

$$\frac{A \times 3}{147 \cdot 4\ (nt - t^1)} = T \text{ milligramme-atoms of free iodine.}$$

Inasmuch as all subsequent analyses depend upon these determinations, the latter must be performed two or three times, and the mean taken of the results (which should nearly agree). The most various analyses may be performed by means of an exactly determined iodine-solution. We will take the following examples.

1. The determination of *sulphurous*, *hyposulphurous*, and *arsenious* acids has been already described.

2. *Sulphuretted hydrogen* may be determined similarly to sulphurous acid, in a solution containing less than 0·4 grm. in 1 litre; but from some unexplained cause the results are only approximately exact. The reaction which here occurs is represented by the equation: $H^2S + 2I = 2HI + S$.

3. Determination of free *Iodine*, *Bromine*, and *Chlorine*. Iodine dissolves directly in a solution of iodide of potassium; bromine and chlorine form bromides and chlorides, liberating an equivalent of iodine. The quantity of the latter is determined by adding excess of sulphurous acid (n volumes), then starch, and finally solution of iodine (t^1 c.c.), until the well-known reaction occurs. If now t c.c. of iodine solution were necessary for the oxidation of 1 volume of sulphurous acid, the liberated iodine must be equivalent to $nt - t^1$ of iodine-solution, or the chlorine, bromine, or iodine must have the value of $(nt - t^1)T$ milligramme-atoms.

4. Determination of the *Oxides of Chlorine which contain less than five atoms of Oxygen for two atoms of Chlorine.* All these substances are decomposed by iodide of potassium and hydrochloric acid in the following way:

$$Cl^2O^x + 2xHCl = xH^2O + 2(x + 1)Cl.$$

The free iodine is determined according to (3). Commercial bleaching powders are tested for the amount of active chlorine which they contain, by treating them with an excess of iodide of potassium and enough hydrochloric acid to cause a slightly acid reaction. Each atom of active chlorine liberates an atom of iodine:

$$CaClO + CaCl + 2HCl + 2KI = 2CaCl + H^2O + 2KCl + 2I.$$

5. *Chlorates.*—According to Bunsen's experiments, these salts when distilled with hydrochloric acid do not give up free oxygen, but only free chlorine and lower oxides of chlorine. If the products of distillation be received in excess of iodide of potassium, the final result is the liberation of 6I for ClO^3H. Such iodine may be determined according to (3).*

6. *Iodates.*—One atom of free iodic acid decomposes with 5 atoms of hydriodic acid to 3 atoms of water and 6 atoms of free iodine ($HIO^3 + 5HI = 6I + 3H^2O$). This reaction may serve for the determination of iodic acid. On the other hand, pure iodate of potassium may be conveniently employed for determining the strength of the normal iodine-solution. (Bunsen.)

7. *Metallic oxides* containing a portion of their oxygen in such a state that it liberates an equivalent quantity of chlorine on boiling with strong hydrochloric acid, may be determined by boiling them with fuming hydrochloric acid, collecting the chlorine in iodide of potassium, and determining the iodine set free according to (3). To this class belong all peroxides, the higher oxides of manganese, chromic acid, and other metallic acids, &c. &c. In analysing manganic oxides, a weak hydrochloric acid of about 20 *per cent.* must (exceptionally) be employed, because on using fuming hydrochloric acid, chlorine is apt to escape. The calculation scarcely needs any explanation. The amount of free chlorine, if we retain the usual symbols, amounts to $(nt - t^1)T$ milligramme-atoms. Half this number of atoms of active oxygen are therefore present, and these stand in a known simple numerical relation to the number of atoms of the substance to be determined.

8. *Metallic oxides* which may be peroxidised by chlorine, are determined by boiling them with a weighed *excess* of bichromate of potassium and hydrochloric acid, receiving the excess of chlorine in iodide of potassium solution, and determining it according to (3). As an example of the calculation, let us take the determination of protoxide of iron. Let the amount of bichromate of potassium employed be A milligrammes; this ($\frac{A}{147{\cdot}4}$ milligramme-atoms), if iron had been absent, would have liberated $\frac{3\,.\,A}{147{\cdot}4}$ milligramme-atoms of free iodine. If instead of this, we actually find only $(nt - t^1)\,T$ milligramme-atoms, then:

$$\frac{3\,.\,A}{147{\cdot}4} - (nt - t^1)\,T$$

milligramme-atoms of chlorine must have served for the oxidation of the iron. Or:

$$\left\{\frac{3\,.\,A}{147{\cdot}4} - (nt - t^1)T\right\}.\ 2 \times 28$$

milligrammes of iron must have been present.

---

* If perchloric acid were produced in this reaction (and its *entire* absence has not yet been proved), the method, as applied to chlorates, would not give accurate results. Bunsen, in his Memoir, gives only one determination of chlorate of potassium, which, however, agrees very well with theory.

Having become acquainted with the most important volumetric methods we may now consider a point in connection with the calculation of the results. If a long series of determinations of the same kind have to be performed successively, the time necessary for their calculation is of great consequence, and it is important to consider the best way of simplifying it as much as possible. This may generally be effected by so choosing arbitrary magnitudes which occur in the calculation, as the weight of the substance, the strength of the normal solution, &c., that the mathematical expression for the result may be as simple as possible. The following examples will illustrate this:

1. A number of soda determinations have to be made with an acid which contains 1·017 milligramme-atoms of sulphuric acid ($SO^4H^2 = 98$) in 1 c.c. If a milligrammes of soda be employed in the analysis, and if the volume of the acid used in neutralisation be k c.c. then the soda contains $\frac{k \times 1{\cdot}017 \times 62 \times 100}{a}$ *per cent.* of anhydrous soda (Na^2O). If now 1·017 × 62 × 100 milligrammes of soda be weighed each time, then the fraction $\frac{1{\cdot}017 \times 62 \times 100}{a}$ is $= 1$, and the percentage of the soda in caustic soda is $= k$, that is, simply equal to the number of c.c. of the standard acid used.

2. In the previous division (8), we have considered the determination of iron by means of iodine-solution and sulphurous acid. If ϵ milligramme of the iron compound be employed for the analysis, the percentage (x) of iron is derived from the formula

$$x = \frac{2 \times 28 \times 100 \left\{\frac{3\,A}{147{\cdot}4} - (nt - t^1)T\right\}}{\epsilon}$$

in which the letters have the signification before given. It is clear that the calculation is considerably simplified if (1) T be a round fractional number, for instance, $\frac{1}{10}$, (2) if A be made a simple multiple of 147·4, for instance, 5 × 147·4 milligrammes. (3). By taking ϵ so as to be a simple submultiple of 2 × 28 × 100, for instance, 30 × 28 milligrammes.—W. D.

ANALYSIS (VOLUMETRIC) of GASES. This branch of analysis has of late attracted much attention from chemists; but the chief improvements and developments relating to it are due to Professor Bunsen. Previous to his researches on the subject, the processes adopted for measuring and analysing gases were so exceedingly imperfect, the inaccuracies introduced so numerous, and even the reagents made use of so defective, that only the most variable results could be obtained; now, on the contrary, gases may be analysed with an accuracy which cannot be equalled in any other branch of chemistry. So far indeed as accuracy and simplicity of manipulation are concerned, Bunsen's method leaves little to be desired; but it is long and tedious, even a simple analysis requiring some days for completion. The necessary calculations for the reduction and correction of the observations are also numerous and require considerable time and attention.[*] To obviate these inconveniences, several methods have of late been proposed, by which the composition of a gas may be accurately determined in a very much shorter time, and without the calculations formerly necessary.

The arrangement of the subject adopted in this article is: first a description of the apparatus and general method proposed by Bunsen; then that of the more recent and expeditious methods; and lastly, the processes, which to a certain extent are common to all the methods, for separating and estimating the different gases.

According to the method of Professor Bunsen, the gases are collected and measured in graduated tubes over mercury. For this purpose, two straight glass tubes are used; one of them, which should be about 250 mm. long and 20 mm. in diameter, is termed the absorption-tube, and the other which is from 500 to 600 mm. long, and 20 mm. in diameter, is termed the eudiometer (*figs.* 50, 51). The absorption-tube is provided with a sort of lip as shown in the figure, to enable the operator to pass the gas easily out of this tube into the eudiometer. As this latter tube is the one in which the combustible gases are exploded, two platinum wires must be fused into the closed end of it, for the passage of the electric spark. This is done by strongly heating the end of the tube in the blowpipe lamp, and then just touching it at the point where the wire is to be introduced, with a hot platinum wire; to this the glass strongly adheres, and by this means is drawn out to a fine thread, which, on being cut off close to the eudiometer, is found to be hollow; through this hole a platinum wire is introduced, and the glass carefully fused all round it. A second platinum wire is then by similar means fused into the opposite side of the eudiometer. These wires should not project straight across the tube, as they are then apt to become bent and moved from their proper distance

---

[*] For a more detailed account of Bunsen's method of analysis, and for further information on gasometry in general, we would refer the reader to Bunsen's "Gasometry," translated by Roscoe. (Walton and Maberly.)

apart on filling the tube with mercury;—if straight, they would also prevent the eudiometer from being properly cleaned: it is consequently most convenient to have them bent so as to lie against the rounded top of the eudiometer. The ends of the wires should be at the distance apart of about 1 to 2 m.m. In order to ascertain whether the wires have been properly fused in, so that the contact of the platinum and glass may be perfect and no probability of leakage can occur, the eudiometer is filled and inverted in a mercury trough, and then, while held in a vertical position, sharply rapped against the bottom of the trough; this communicates a movement to the mercury in the tube, which sinking for a moment leaves a vacuum at the top, whereupon if the wires are not fused in absolutely air-tight, a row of small bubbles will be seen rising from the defective point.

Fig. 50.

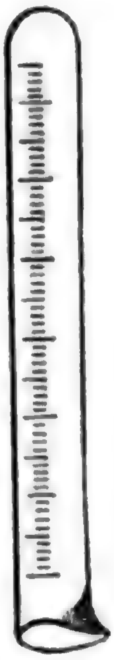


Fig. 51.

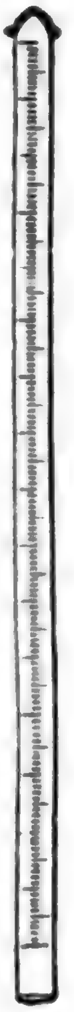
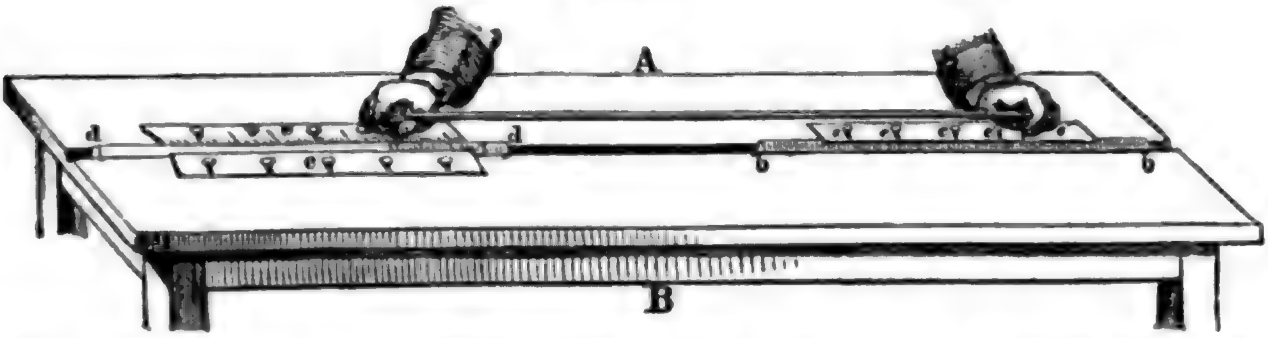


Having proved the tube to be air-tight, the next operation is to etch, by means of hydrofluoric acid, a millimetre scale on it and on the absorption-tube. This may easily be done by the following process, which was also suggested by Professor Bunsen. The tube to be etched is heated up to the temperature at which bees-wax melts over a fire, being held by means of a stick which passes through a cork fitted into the open end of it. The tube is then covered as uniformly as possible with melted wax, which is best done by painting it all over with wax, by means of a brush or feather. During the cooling, it should be continually turned round in the hand, so as to keep the wax equally distributed over the whole surface. If the tube when cold is found to be completely covered with wax, it is then ready for etching.

Fig. 52 represents the apparatus used for this purpose, A B is a table or large board, with a groove running along it of such size that the tube to be graduated will lie easily in it; *d d* represents this tube, which is firmly held in its place by two brass plates *e e*, screwed down upon it. At the other end of the groove, a standard tube *b b*, is also firmly fixed by means of a brass plate, and on this tube is the scale which is to be exactly copied on the wax covering the tube *d d*. This is done by means of a long bar of wood, to one end of which is fixed a steel point, and to the other a kind of knife. The rod is held by the ends as shown in the figure, the right hand guiding the knife. In using the apparatus, the steel point is allowed to fall into one of the divisions on the standard tube, which are purposely deeply etched, and while it is held there, a cut is made by means of the knife on the wax covering the tube. The length of this cut, and the consequent breadth of the scale, is regulated by the distance between the two brass plates *e e*. As soon as this first stroke has been made, the wooden rod is gently moved a little forwards until the point falls into the next mark on the standard tube; then a second cut is made in the wax, and so on. The steel point should always rest against the brass plate *e e*, which will then serve to keep it in the same straight line. In order to render the reading of the scale more easy, it is convenient to have every fifth stroke on it longer than the others; which is easily accomplished by having slits made in the brass plate *e*, at the distance of 5 mm. apart, so that when the knife arrives at one of these slits, it passes further across the tube than in other cases. Before removing the waxed tube, it must be carefully examined, and if any false strokes are seen, they may be removed by applying a thin heated wire to the spot: then, when the wax has cooled, a fresh stroke may be made. The tube is now removed, and at each centimetre, the figures indicating the number of millimetres from the top are scratched in the wax by means of a needle. If any of the wax has been removed from the tube by the pressure of the brass plates, these places must be carefully re-covered, and the tube is then ready to be exposed to the hydrofluoric acid.

Fig. 52.



This is most conveniently done in a kind of long narrow leaden dish. Powdered fluor-spar is strewed along the bottom, and a large excess of sulphuric acid added; heat may then be applied. As soon as the gas comes off abundantly, the lamp is removed, the tube laid over the dish resting on two wire supports, and the whole is covered with a sheet of paper. When the tube has remained there about three minutes it should be removed and one of the divisions examined by passing the nail over it, to ascertain to what extent the etching has taken place. In from three to six minutes, most tubes will be sufficiently acted on. The etching may also be accomplished without applying heat to the hydrofluoric mixture; in this case the tube must be left in contact with the acid for several hours. This latter method yields perhaps the most distinct graduation. In order to render the scale still more clear, it should be rubbed over with a mixture of vermilion and copal varnish, which fills and hardens in each of the divisions, rendering them very evident to the eye.

Since no tube is of precisely the same diameter for any length together, the scale thus etched bears evidently no constant relation to the cubic capacity of the tube. In order then to ascertain to what extent the capacity varies in different parts of tube equal volumes of mercury must be poured into it, and the space they occupy read off on the scale. *Fig.* 53 represents a convenient form of apparatus for always obtaining, these equal volumes of mercury. *a* is a small glass tube fixed in a handle and capable of containing about that amount of mercury which is required to fill the eudiometer through 20 mm. of its length. *c* is a glass plate, on the top of which the two ends of a strip of caoutchouc are fastened by sealing wax, so as to form a loop which is slipped over the thumb. By turning the stopcock, which allows the mercury to flow from the reservoir *b*, the glass measure, the top of which must be ground perfectly even, is completely filled, and the mercury rises in a curve above the top; on depressing the plate *c*, the excess is expelled and the tube obtained perfectly full: care must, however, be taken that no bubbles of air remain adhering to the sides. In filling the measure, it is well to allow the end of the tube *e* to rest on the bottom of it, and only gradually to withdraw it when nearly full of mercury. The tube to be calibrated is firmly held in a perpendicular position by means of a clamp, and the measures of mercury are then carefully poured in, any bubbles of air which may remain adhering to the tube, being removed by means of a small stick or piece of whalebone. After each addition of mercury, the height which it occupies on the scale is read off. In order to prevent errors from parallax, this should be done by means of a telescope fastened to a clamp which moves on a perpendicular support. In all readings-off, it is the position of the highest part of the mercury meniscus on the scale that is observed. This process for determining the cubic capacity of the tube should always be gone through twice, and the mean of the two series of observation taken as the basis of calculation. An example will best show how these calculations are made and the results tabulated. The height of the mercury in the tube after the successive additions of the measured quantity is,

Fig. 53.

	diff.
9·1	
23·0	13·9
36·6	13·6
50·15	13·55

In the second column is expressed the height which this constant quantity of mercury occupied. This varies of course with the capacity of the tube, increasing as the tube diminishes, and diminishing as the tube increases in size. One of these differences, generally the largest, is taken as the standard, say 13·9, that is, 13·9 volumes of mercury have been found to occupy on the scale:

mm.
1 × 13·9 — 9·1
2 × 13·9 — 23·0
3 × 13·9 — 36·6
4 × 13·9 — 50·15

This gives the relative values of the scale at these particular points, and it only remains to interpolate the respective values of each division between these successive points. In the first instance, between 9·1 and 23·0, each millimetre will represent exactly 1 volume of mercury; but in the second instance, where the 13·9 vols. of mercury occupy only a length of 13·6 mm. where the tube in fact is broader, each division will have a value equal to $\frac{13\cdot9}{13\cdot6} = 1\cdot022$, and this number represents the capacity of each millimetre between 23·0 and 36·6. Again the capacity of each division between 36·6 and 50·15 is $\frac{13\cdot9}{13\cdot55} = 1\cdot025$. In this way is formed a table, which, although perfectly arbitrary, is relatively correct, the amount of error arising from the alteration of the size of the tube between each reading-off of the height of the mercury, being quite inappreciable, when the measured quantity does not extend over more than about 20 mm. The following table is calculated from the foregoing observations. In the first column, the divisions on the scale are given, in the second their arbitrary value.

As it is always the highest point of the meniscus of the mercury that is read off on the scale, both in calibrating the tube and afterwards in measuring the amount of gas it may contain, a slight correction must be applied to every observation to correct the error which would otherwise arise from the convexity of the mercury. By referring to *fig.* 54, it will easily be seen how this error arises. (1) In calibrating the tube: if *a o a'* represent the meniscus, it is the number on the scale coinciding with the line *c c'*, that is read off, although the tube is not full up to that point by the space *a c c' a'*; and (2), in analysing a gas, when the tube is in the reverse position, the same number on the scale would be read off, although the meniscus of the mercury only coincided with the curve *n o n'*, leaving in fact a space as much below *c c'* unoccupied by mercury in this instance, as was left above it in the former one. Hence after referring to the table to ascertain the relative value of any reading-off, there must be added to it a quantity equal to the whole space *a n a' n'*. What this number is, which has always to be added can easily be ascertained by the following process. The eudiometer being fixed in a perpendicular position with its closed end downwards, a small quantity of mercury is poured into the tube, and its height carefully noted; a few drops of a dilute solution of corrosive sublimate are now added, the effect of which is entirely to destroy the meniscus, and render the surface of the mercury perfectly flat: the height $x\,x'$ at which it now stands in the tube is read off. Twice the difference of these two readings is then the quantity to be added to each observation after referring to the table of capacities.

Fig. 54.

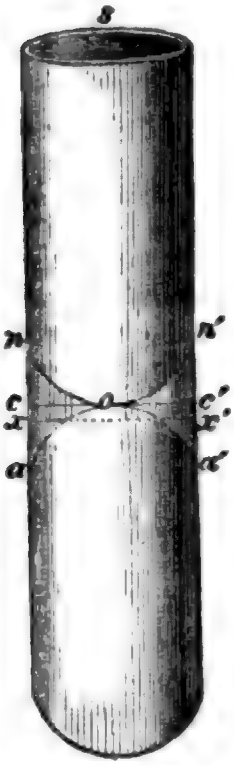

Fig. 55.

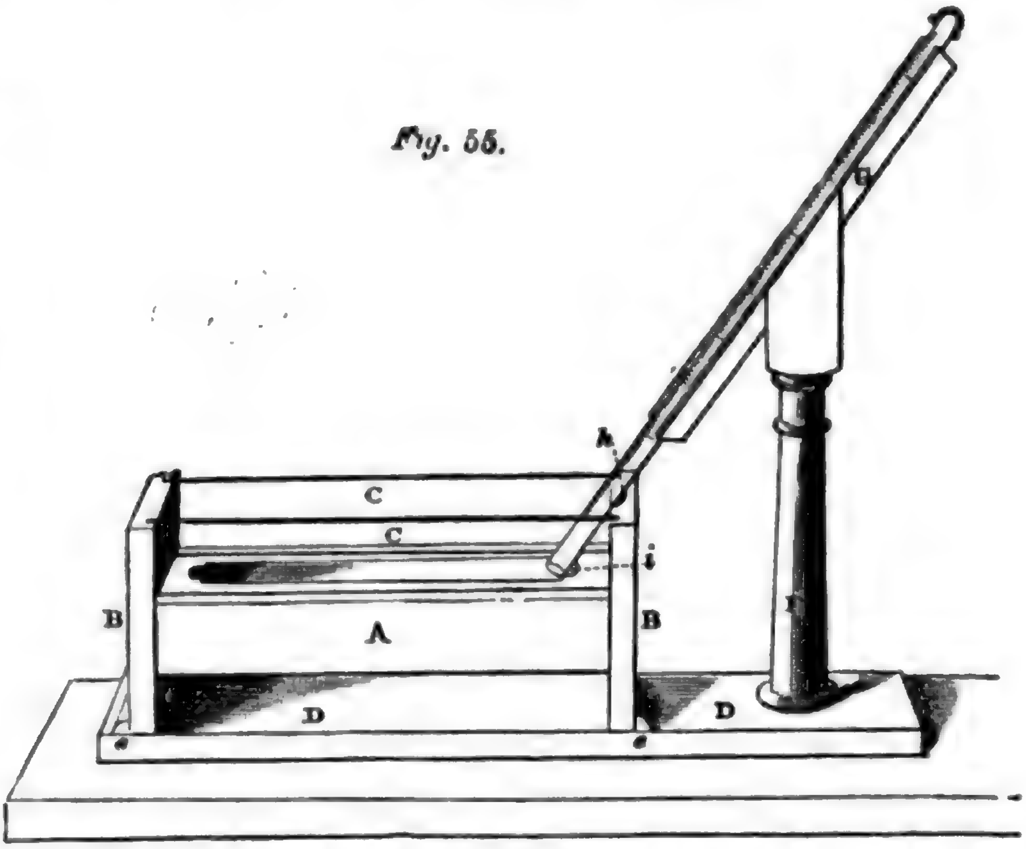


The most convenient form of mercury-trough is that proposed by Bunsen, and represented in *fig.* 55. It is about 350 mm. long, and 80 mm. broad. The two sides C C, are made of thick glass plates, and the lower part of it A, is formed out of a single piece of wood hollowed out. In order to economise the amount of mercury necessary, the inside of the trough is made round at the bottom instead of being square. G forms a convenient support for the eudiometer. Before using the trough, it should be well rubbed with corrosive sublimate and mercury, or else small bubbles of air are apt to remain adhering to the wood, and may afterwards rise into the eudiometer.

Fig. 56.

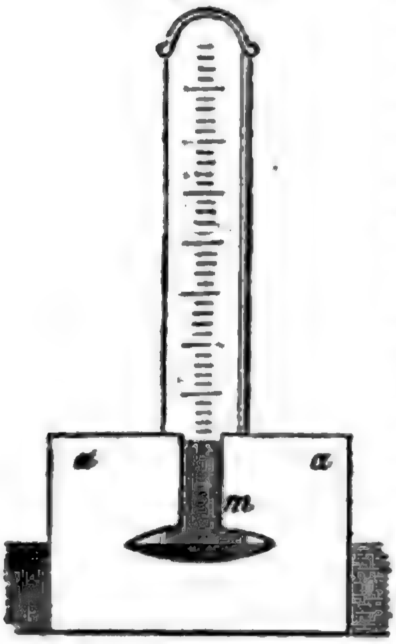
A good thermometer and barometer are of course indispensable. The length of the degrees on the thermometer scale should be such that the position of the mercury, to a tenth of a degree centigrade, may be easily read off by means of the telescope. The barometer generally used is of the syphon form (*fig.* 56). The scale is etched on the glass and the closed end is bent as shown in the figure, so that the scale on the two limbs is in the same straight line. The thermometer *t*, is placed in the open end of the barometer, and held in its place by a small piece of whalebone, which acts as a spring. Before reading off the height of the barometer and thermometer, the latter should be gently moved a little up and down, thus communicating to the mercury in the barometer a slight movement, which overcomes any adhesion between the mercury and the glass.

The kind of room which is used as a gas-laboratory when this process is adopted, is a point of very considerable importance. It should have a northerly aspect, and the walls should be thick; in fact, the room must be protected in every way from sudden changes of temperature. The mercury trough and barometer should stand on a table immediately in front of a window, if possible a double one. The table is provided with a rim round it, in order to prevent the loss of any mercury that may happen to be spilt upon it. Between every two operations in the analysis, at least half an hour must be allowed to elapse, in order that all parts of the apparatus may return to the temperature of the room. Great care must be taken in filling the eudiometer and absorption-tube with mercury, that no air remains adhering to the sides of the tube. This is most easily avoided by introducing the mercury through a funnel, to which is attached a narrow glass tube reaching very nearly to the top of the eudiometer; the mercury then rises gradually, the funnel being kept full, and expels the air very thoroughly from the tube. A small bubble of air will however generally be found to remain in contact with the platinum wires in the eudiometer; this must be got rid of by placing the thumb over the open end of the tube, and holding it in an inclined position; then, by means of a sudden jerk, the bubble may be detached from the wires, and by merely inverting the eudiometer, allowed to escape.

All the readings-off, as before stated, are made with the help of a telescope, which should be at a distance of seven or eight feet from the tubes. Care should always be taken that the division to be read off is nearly in the middle of the field of the telescope, or a slight error may arise from parallax. It is therefore convenient to have the telescope provided with a cross wire.

At each stage of the analysis, four observations have to be made: 1st, the height of the mercury in the gas-tube; 2nd, the height of the mercury in the trough as measured on the scale of the gas-tube; 3rd, the temperature; and 4th, the atmospheric pressure. The barometer and thermometer are always read off last; for before doing this, it is necessary to approach the table in order to move the thermometer, as before described, and the heat given out from the body would increase the volume of gas in the tube. In order to read off accurately the level of the mercury in the trough, it is necessary so to place a piece of white paper between the glass side of the trough and the tube, that it may reflect the light from the window on to the scale. *Fig.* 57 shows how this is conveniently arranged, the scale being seen through the slit *m*.

Fig. 57.



After each operation in the analysis, before leaving the tubes to cool, a rapid observation should be made with the telescope, in order to see that the scale on the eudiometer is in its right position, passing apparently exactly through the highest point of the meniscus, and also that the height of the mercury both in and outside the tube can be easily read off.

In order to render the observations thus made at different temperatures and pressures comparable, they must be reduced to a common standard, the one generally employed being dry air at 0° C., and under a pressure of 1 metre of mercury. If v represent the volume of gas as taken from the table, m the error of the meniscus, b the height of the mercury in the gas-tube above that in the trough, $t°$ the temperature, and B the height of the barometer, the following formula will give the corrected volume V', under the standard temperature and pressure: $\dfrac{(V + m)(B - b)}{(1 + 0{\cdot}00366t°)} = V'$.

There is also another point which must not be overlooked in the calculation, viz. the effect of the tension of water-vapour. If the gas is saturated with moisture, and the temperature at which the observation of its volume was made is known, it is then only necessary to refer to the table of tensions of aqueous vapour and extract the number corresponding to that temperature: this must be deducted from the height of the barometer. Thus, the formula for the reduction of gases saturated with aqueous vapour is $\dfrac{(V + m)(B - b - T)}{1 + 0{\cdot}00366t°} = V'$, where T is the tension of aqueous vapour for the temperature $t°$. To ensure a gas being completely saturated with moisture, a drop of water is always introduced into the eudiometer before filling it with mercury.

In order to show more clearly how these calculations are made, the following example taken from Bunsen's Gasometry, is cited, of the measurement of the same quantity of air, first saturated with moisture and afterwards dry.

		Moist.	Dry.
Observation at the lower level of the mercury . .		565·9 mm.	565·9 mm.
Observation at the upper level in the eudiometer .		317·3	310·7
Height of the column b to be subtracted from barometer		248·6	255·2
The divisions 317·3 and 310·7 correspond to the volumes in the table of capacity . . .	V .	292·7	286·0
Correction for the meniscus	m	0·4	0·4
Temperature of the air	t	20·2 C.	20·2 C.
Height of the barometer	B	0·7469 m.	0·7474 m.
Tension of aqueous vapour for 20·2 C. . .	T	0·0176 m.	

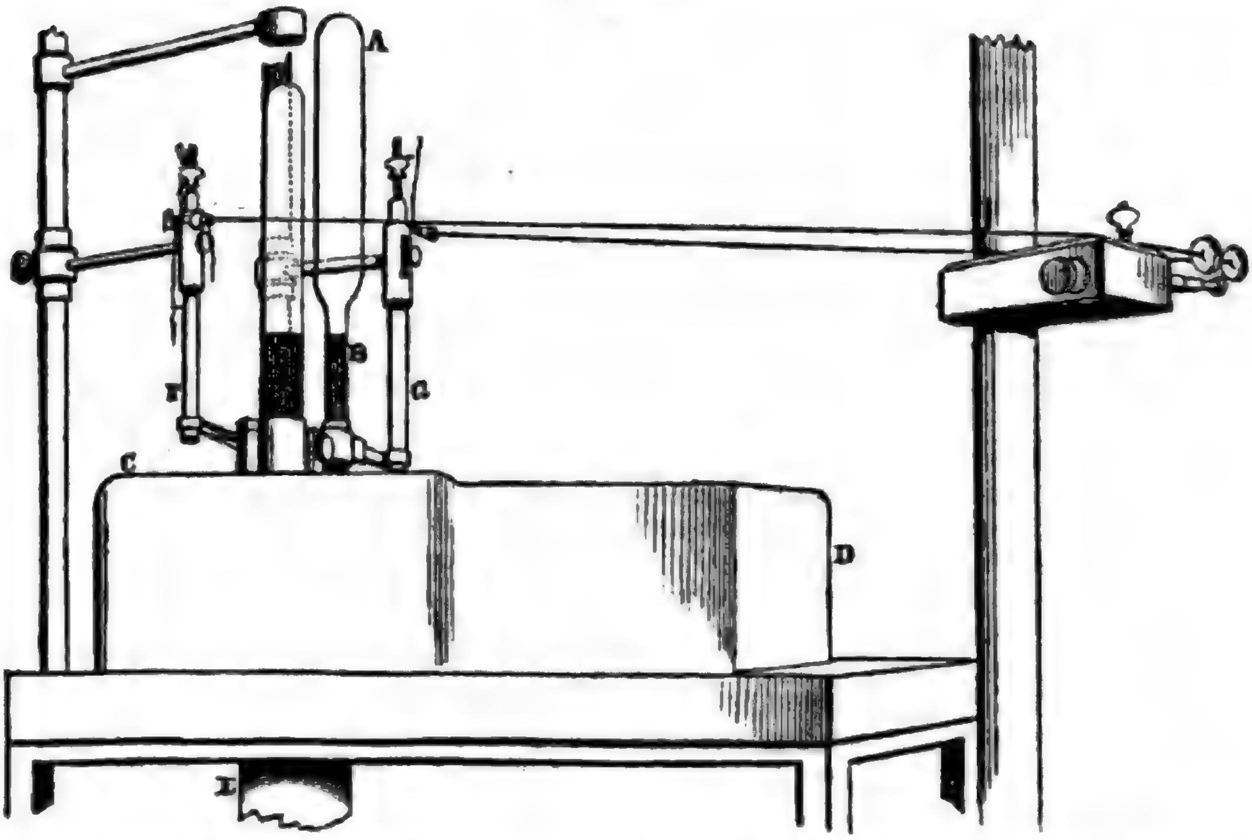
$$\begin{array}{rll}
\log.(V + m) = \log.\ 293{\cdot}1 & = & 2{\cdot}46702 \\
+ \log.(B - b - T) = \log.\ {\cdot}4807 & = & 0{\cdot}68187 - 1 \\
+ \text{compl.} \log.(1 + 0{\cdot}00366t) = \text{compl.} \log.\ 1{\cdot}0739 & = & \underline{0{\cdot}96903 - 1} \\
\log.\ V' & & 2{\cdot}11792 \\
V' & & 131{\cdot}20.
\end{array}$$

For the dry air we have:

$$\begin{array}{rll}
\log.(V + m) = \log.\ 286{\cdot}4 & = & 2{\cdot}45697 \\
+ \log.(B - b) = \log.\ 0{\cdot}4922 & = & 0{\cdot}69214 - 1 \\
+ \text{compl.} \log.(1 + 0{\cdot}00366t) = \text{compl.} \log.\ 1{\cdot}0739 & = & \underline{0{\cdot}96903 - 1} \\
\log.\ V & & 2{\cdot}11814 \\
V' & = & 131{\cdot}26.
\end{array}$$

A modification of Bunsen's method has been proposed by Messrs. Williamson and Russell (Proceedings of the Royal Society, vol. ix. p. 218), whereby the effect of any alteration in the barometer or thermometer on the gas during the analysis is entirely eliminated: moreover, the gas operated on is always read off saturated with aqueous vapour, so that no calculations are necessary for reducing the volume to a standard temperature and pressure. The principle on which this simplification depends is, that of always retaining the gas at the same degree of elasticity. If, for instance, a fall of temperature has occurred, then by diminishing the pressure on the gas a certain amount, its elasticity will remain unaltered; and for a rise in temperature, the pressure must be correspondingly increased to retain the gas at the same volume. This equally applies to any alteration in the barometer. The means adopted for ascertaining exactly how much the pressure on the gas has to be increased or diminished for any variations of the barometer or thermometer, is simply to introduce a standard quantity of air into a tube over mercury, and mark off the height of the mercury on the tube, at the normal temperature and pressure; then, at any other temperature or pressure, by raising or lowering the tube in the mercury-trough, so as exactly to bring the mercury again to the same mark, the elasticity of the air is maintained constant. The gas in the eudiometer is always read off at this constant degree of expansion, and this is done merely by raising or lowering it in the trough, until the column of mercury within the eudiometer is of exactly the same height as that in the tube containing the standard amount of air. *Fig.* 58 represents the apparatus used in this method. A B is the tube containing the standard amount of air, and is termed the "pressure-tube:" the upper part of it is six or seven inches long, and of about the diameter of an ordinary Bunsen's eudiometer; the lower part B is of about the same length, but only $\frac{3}{8}$ inch internal diameter. Into this pressure-tube is introduced such a quantity of mercury that, when it is inverted in the trough, the mercury stands at a convenient height in the narow tube; at this point, the mark is made which indicates the height of mercury needed at any temperature or pres-

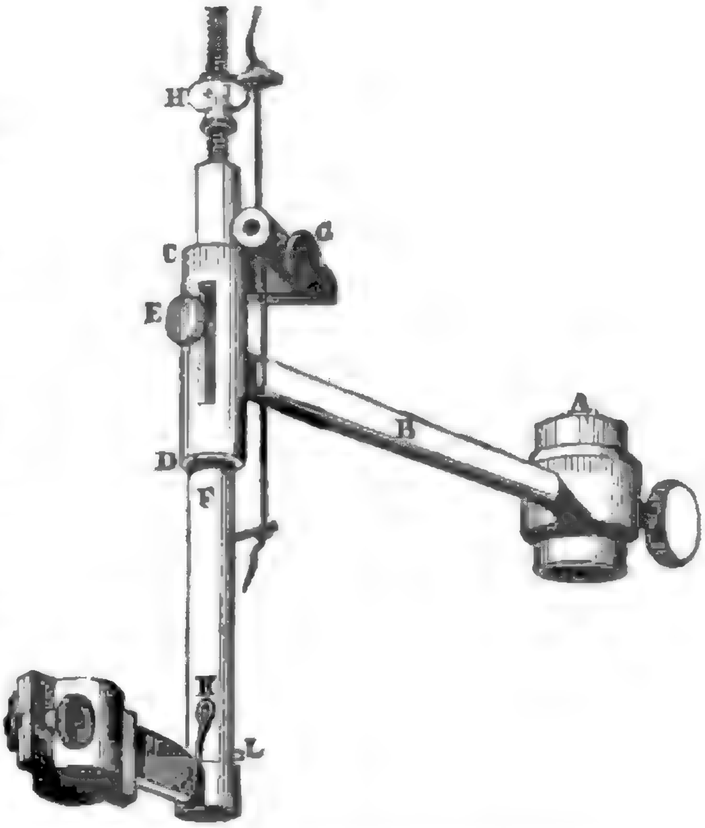
Fig. 58.



sure, to reduce the enclosed air to its original volume. The mercury-trough C D differs from the ordinary form in being provided with a well E, at one end, in which the eudiometer is to be raised or lowered so as to bring the gas it contains to the same pressure as the air in the pressure-tube. Both the eudiometer and the pressure-tube are held in a perpendicular position by means of clamps F and G, which slide on upright rods. Each clamp is provided with a simple kind of slow movement, by which the tube can be raised or lowered by the operator, whilst he is looking through a telescope at a suitable distance.

Fig. 59 is an enlarged view of one of the clamps, which shows more distinctly how the slow movement is produced. A is the part which slides up and down the vertical rod; it is furnished on the inside with a small steel peg, which moves in a groove, thus causing the arm always to remain in the same plane. C D is a tube through which the rod F, carrying the clamp, passes. E is a screw which retains the rod F in its place, and by means of which the friction on the rod passing through the tube can be increased at pleasure. G is a small cylinder fixed to C D; on turning this round to the right or to the left, the string above or below is wound on to it, and consequently the rod F raised or lowered. In order that the heat from the body may not affect the volume of the gases in the tubes, thin iron rods, some six feet in length, are screwed into these cylinders, and rest on the arm carrying the telescope, as shown in *fig.* 58. H is merely an arrangement for tightening the string. K is a peg so placed with regard to the stop L, that when, by turning the clamp round, it is pressed against the stop, the tube is then in the right position for applying the final adjustment and reading off. In operating with this apparatus, the pressure-tube is placed immediately in front of the eudiometer, and the clamp moved up or down the vertical rod till the top of the mercury inside about coincides with the mark on the stem of the tube; in the same way, the eudiometer is so adjusted that the internal column of mercury is of about the same height as that in the pressure-tube. The iron rods are then screwed on, and the whole allowed to cool.

Fig. 59.



The method adopted in reading off the amount of gas is, while looking through the telescope, first to turn the rod connected with the pressure-tube so as to bring the mercury exactly up to the mark on the stem, then raise or lower the eudiometer so that the meniscus of the mercury inside it may coincide precisely with the meniscus in the pressure-tube. This is easily done, as the diameter of the pressure-tube is considerably smaller than that of the eudiometer, and the meniscus in the latter can be clearly seen on both sides of the meniscus of the pressure-tube. It is convenient also to have a second pressure-tube, the stem of which should be about three times as long as that of the one already described. By this means, when only a small amount of gas has to be measured, it can be read off at a greatly reduced pressure, and consequently with greater absolute accuracy. In order to render the reading made with one pressure-tube comparable with those made with the second, it is only necessary to measure the same amount of gas at each of these degrees of expansion, this at once establishes the proportion in which any amount of gas read off, at the greater degree of expansion, for instance, will have to be diminished in order to render it comparable with gas read off at the lower degree of expansion. This method yields very accurate results, and they are obtained with less trouble than by Bunsen's method, and without any tedious calculations.

The method and apparatus next to be described is that proposed by MM. **Regnault** and **Reiset** (Ann. Chim. Phys. [3] xxvi. 333). Its peculiar advantage is, that analyses may be made by it with very much greater rapidity than is possible by either of the methods previously described, and also that it does not require a room to be set apart for gas analysis.

The economy of time is effected in two ways: first, by surrounding the gas-tubes with water, which almost immediately causes their contents to assume the same temperature as that of the external medium; secondly, by the use of liquid reagents instead of solid, which are necessarily used in Bunsen's method.

The form and principle of M. Regnault's apparatus will be easily understood from *figs.* 60 and 61. It consists essentially of two parts, which can be easily joined and separated. In the one part, the gas is subjected to the action of the liquid reagents, and this is termed the laboratory or absorption-tube; in the other, the gas is measured, and it is termed the measuring-tube; these are represented in the figures by *f g*, and *a b*. The measuring tube *a b*, is from 15 to 20 mm. internal diameter. It is divided into millimetres, and terminates above in a fine capillary tube *a r*, while the lower end is luted into a cast iron piece *NN*, having two tubulations, *b* and *c*, and a stopcock *R*. To the second tubulation *c*, is luted a straight tube *c d*, open at both ends, of the same diameter as the tube *a b*, and divided also into millimetres. The stopcock *R* is bored through in two directions at right angles to one another, as shown in *figs.* 62, 63, and 64, so that by turning the key in different positions, communication can be established between the two tubes *a b* and *c d*, or the mercury can be

Fig. 60.

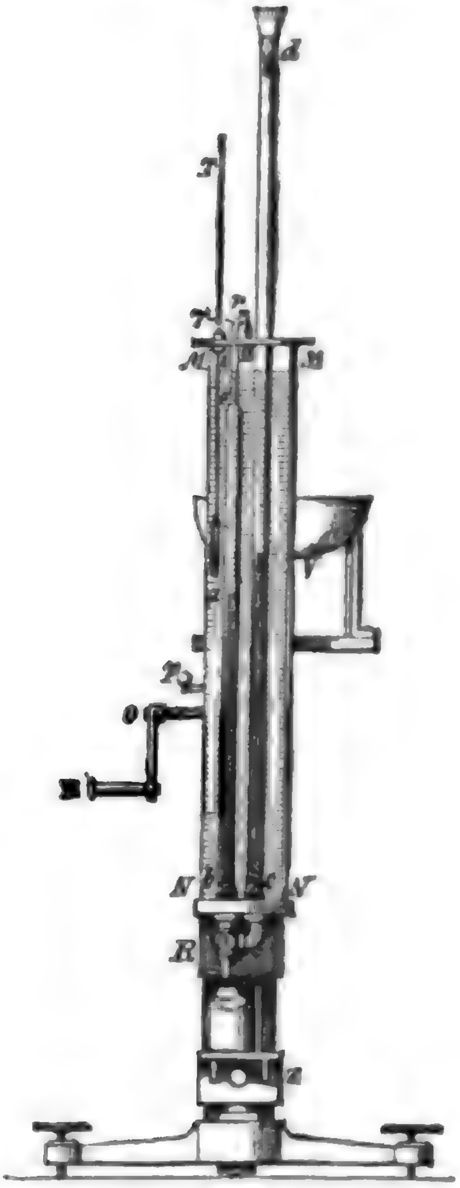


Fig. 61.

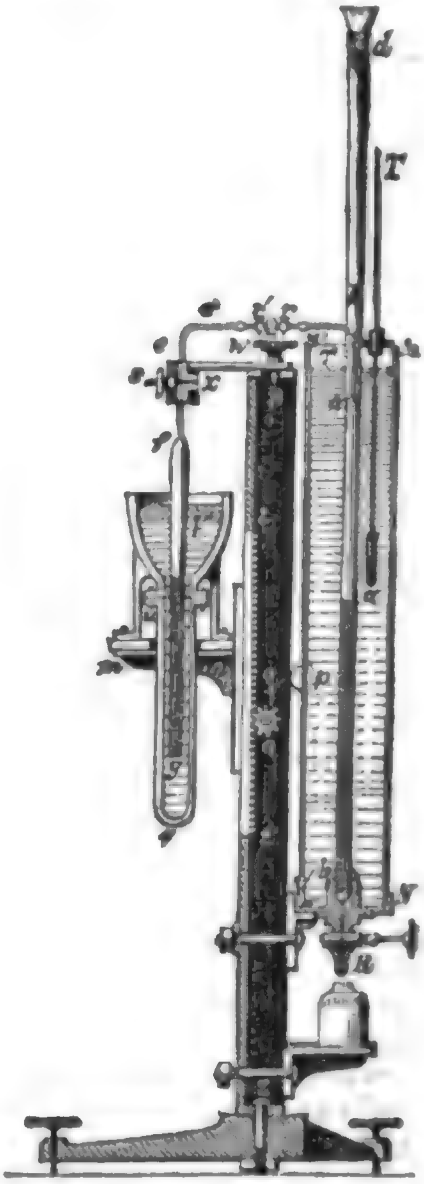
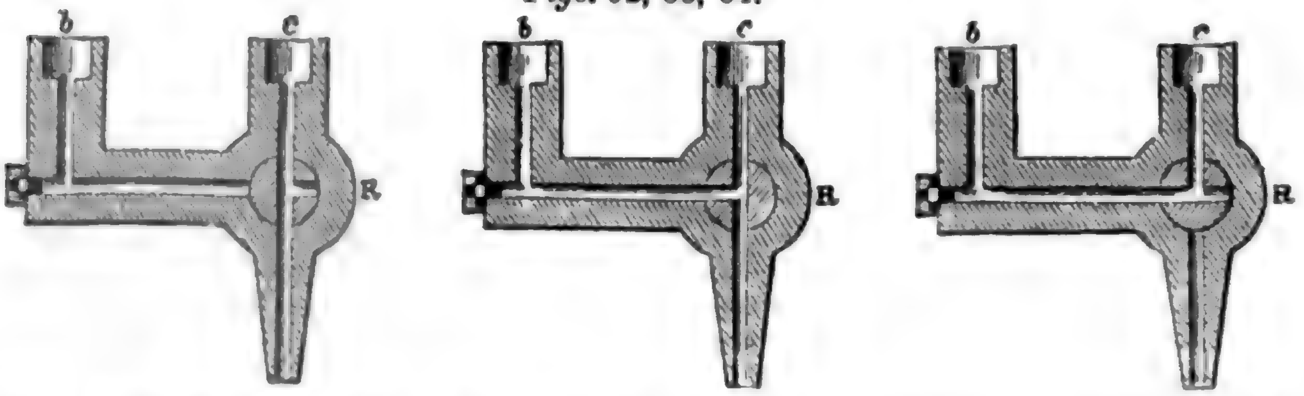


Figs. 62, 63, 64.



allowed to flow from either. These tubes are surrounded by a glass cylinder filled with water, in which the thermometer T is immersed. During the analysis, the thermometer must of course indicate a constant temperature; should any alteration have taken place, the original temperature must be restored by the addition of hot or cold water.

The whole apparatus is fixed on a cast-iron stand z z, furnished with levelling-screws. The absorption tube *g f*, is open at the bottom and terminated above by a curved capillary tube *f e r′*. This tube dips into a small mercury trough *V*, of cast iron, or what is still better, gutta-percha, *Figs.* 65 and 66 represent more clearly the form of this trough. When in its place, it rests on a small iron bracket, which by means of the rack *i i*, and the pinion *o*, to which the handle B is attached, is easily moved up and down. It is retained in any position by the rachet *q*, to which, in order to facilitate its working, a weight is fixed, and as this is turned from one side to the other, the rachet is thrown in or out of gear with the pinion. To the ends of the capillary tubes, which terminate the absorption- and measuring- tube, are carefully luted two small steel stopcocks, *r r′*, the ends of which exactly fit each other, and have the shape represented in *fig.* 67, in section. In order to render the joining of the two as air-tight as possible, a little melted caoutchouc is applied to the faces *a b* and *a′ b′*, which are then pressed together as tight as possible by means of a screw clamp, represented in *fig.* 68. The laboratory-tube is held in a vertical position by the clamp *u*, which is lined with cork, and can be adjusted to the required distance from *z z*, by means of the screw *s*. The measuring-tube *a b* is provided with two platinum wires, as in the ordinary eudiometer. The following account given by Regnault (Cours de Chimie, iv. 77) of an analysis of a mixture of air and carbonic acid will perhaps best explain how the apparatus is used.

Fig. 65.

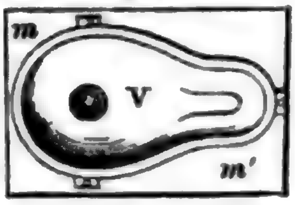


Fig. 66.

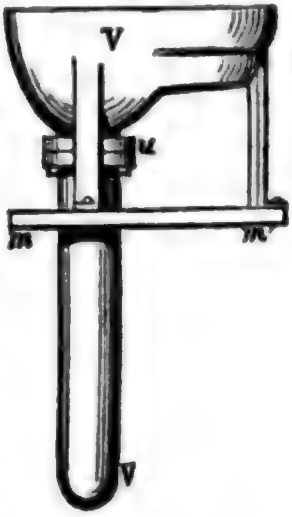

The first operation is to fill the measuring-tube: this is done by pouring mercury into the tube *c d*, until it begins to escape through the stopcock *r*, which is then closed. The laboratory-tube is next filled by plunging it into the mercury-trough *V*, the stopcock *r′* being open. To fill the capillary-tube *f e r′*, the best method is simply to apply the mouth to the open end of it and suck the mercury up, then close the stopcock. The tube being now perfectly full of mercury, it is fixed in its place and the clamp screwed on to the stopcocks.

Fig. 67.

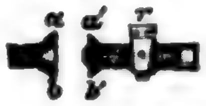

Fig. 68.

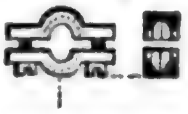


The gas to be analysed is now introduced into the laboratory-tube, the trough *V* having been lowered to such a position that the end of the laboratory-tube only reaches to a short distance under the mercury; the gas is then easily passed up into it. This being done, the trough is again raised and the mercury allowed to flow out of the measuring-tube, by which means the gas is forced over into the measuring-tube. When the mercury reaches the capillary tube *f e*, the stopcock *r* is nearly closed, thus causing it to rise but slowly, and when the column of mercury arrives at a certain mark σ on the horizontal part of the capillary tube, the stopcock *r′*, is closed. The level of the mercury is thus brought to a given division α, of the tube *a b*, and the difference of height of the two columns can immediately be read off on the scale of the tube *c d*. The water should be well agitated by blowing air into it through a tube which descends to the bottom of the cylinder. The height of the thermometer and barometer must also be observed.

In order that no calculation should be necessary for estimating the tension of aqueous vapour, the gas is always saturated with moisture; this is done by moistening the sides of the measuring-tube *a b*: the mercury, in passing through, merely removes the excess of water, and always leaves a small quantity adhering to the sides of the tube. Let t be the temperature of the water, which, as before stated, must be stationary during the analysis, f the tension of the aqueous vapour at this temperature; v the volume of the gas; H the height of the barometer; and lastly, h the difference of the height of the mercury in the two tubes. $H + h - f$ is then the elasticity of the gas when dry. Having thus measured the quantity of gas taken, the next operation is to absorb the carbonic acid present. The trough *V* is again lowered and by means of a bent pipette, a single drop of a strong solution of caustic potash is introduced into the laboratory-tube. Mercury is then poured into the tube *c d*, and the stopcock R turned so as to establish communication between the tubes *a b* and *c d*. On opening the stopcocks *r r′*, the gas is then forced back into the laboratory-tube.

As the mercury in it sinks, the caustic potash moistens the sides of the tube, thus exposing a very large absorbing surface. In a few minutes, the whole of the carbonic acid is absorbed; and the absorption may be rendered still more speedy and certain, by raising the trough and opening the stopcock r, so that the gas may again be drawn into the measuring tube and afterwards forced back a second time into the laboratory-tube, thus bringing it in contact with a fresh surface of potash. It has been shown that after this operation has been repeated twice, no appreciable amount of carbonic acid remains unabsorbed. As it is essential that none of the absorbing liquid should ever pass over into the measuring-tube, the error arising from an amount of gas remaining in the capillary tube $f\,e\,r'$, is best eliminated by always making this a constant quantity, which is done by closing the stopcock r', when the column of liquid reagent or mercury arrives at a certain mark σ.

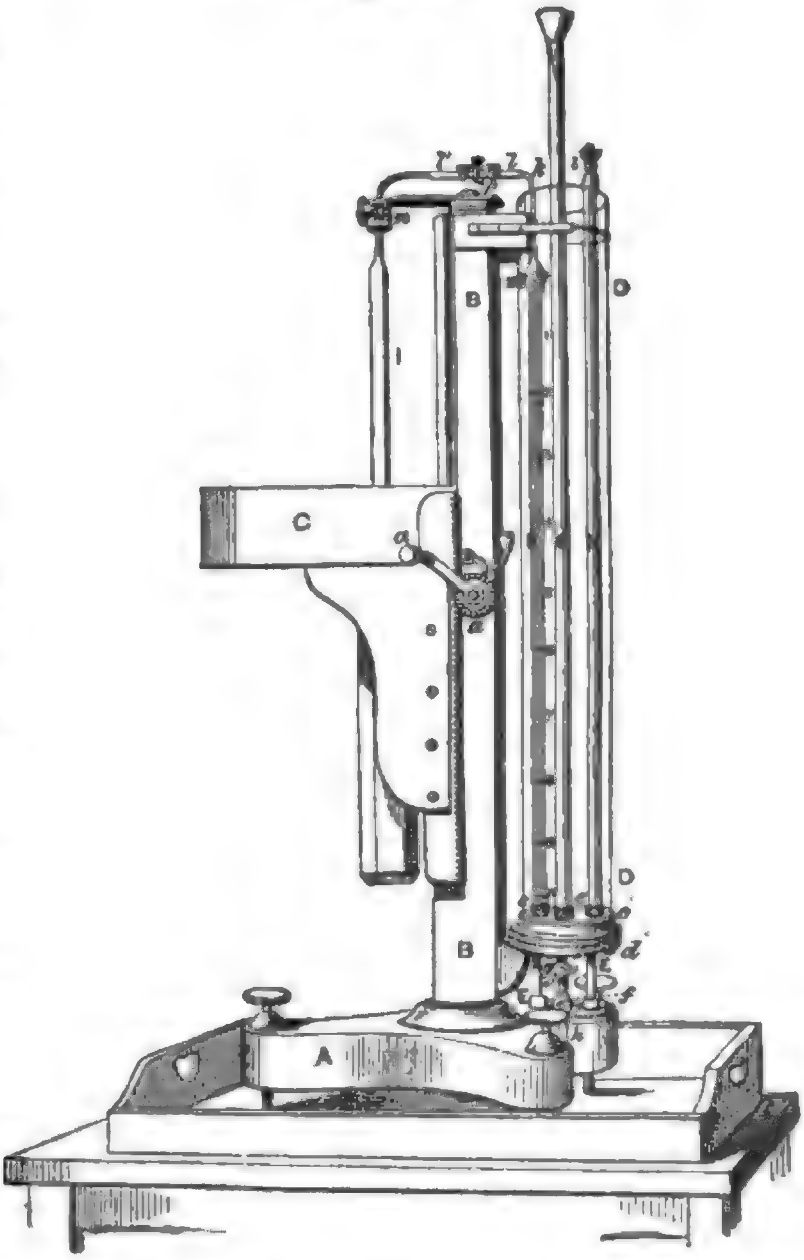
The absorption being completed, the level of the mercury in the tube $a\,b$ is again brought to the mark α, and the difference of height h' of the mercury in the two tubes $a\,b$ and $c\,d$, is read off. H' the height of the barometer, is also noted. If the temperature of the water in the cylinder has changed, it must be restored to the original temperature t, by the addition of hot or cold water. The elastic force then of the gas deprived of carbonic acid and dry, is $H' + h' - f$; and consequently $(H + h - f) - (H' + h' - f) = H - H' + h - h'$, is the diminution of elastic force, caused by the absorption of the carbonic acid; and $\dfrac{H - H' + h - h'}{H + h - f}$ represents the proportion of carbonic acid in the gas when dry.—The proportion of oxygen in the remaining gas has now to be determined. The laboratory-tube is detached, thoroughly washed, and dried, first by means of paper, and afterwards by bringing it into connection with an air-pump. It is then again filled with mercury and fitted on to the measuring-tube. The trough U is now raised, and the stopcock R opened. On now turning the cocks $r\,r'$, the mercury in the laboratory-tube passes into the capillary-tube $a\,r$, and is allowed to proceed as far as a given mark τ; when it reaches this mark, the stopcocks $r\,r'$ are closed. The mercury in the measuring-tube is then again brought to the point α, and the difference of the level h'' and the height of the barometer H'' read off. $H'' + h'' - f$ is therefore the elastic force of the dry gas now in the apparatus, a small quantity (about $\frac{1}{3000}$) of the whole having been lost by detaching the laboratory-tube. This second measurement prevents any inaccuracy thence arising.

A proper quantity of hydrogen is now introduced, and a uniform mixture of the whole produced by passing the gas two or three times backwards and forwards from the laboratory-tube into the measuring tube. When thoroughly mixed, the column of mercury is again brought to the mark τ, and the gas in the measuring tube to the point α. The difference of height h''' of the two columns of mercury is read off, and the height H''' of the barometer. $H''' + h''' - f$ is therefore the elastic force of the mixture of hydrogen, oxygen, and nitrogen. The capillary-tube $r\alpha$, is now completely filled with mercury, so that none of the gas shall escape combustion, and an electric spark passed through the mixture. After the explosion, the stopcocks $r\,r'$ are carefully opened and the gas subjected to a slight pressure, so that the mercury is forced back along the capillary-tube till it arrives at the point τ; the stopcocks are then again closed, and the gas expanded as before to the mark α. Its elasticity will now be represented by $H'''' + h'''' - f$. Consequently $(H''' + h''' - f) - (H'''' + h'''' - f) = H''' - H'''' + h''' - h''''$, is the elastic force of the gaseous mixture which disappeared during the combustion; $\frac{1}{3}(H''' - H'''' + h''' - h'''')$ is the elastic force of the oxygen contained in the dry gas, of which the elastic force was $H'' + h'' - f$; and $\frac{1}{3}\dfrac{H''' - H'''' + h''' - h''''}{H'' + h'' - f}$ is the proportion of oxygen contained in the gas when freed from carbonic acid, whence the proportion of oxygen in the original gas may be easily deduced.

As the gas is made to occupy a constant volume during the whole analysis, this entirely removes the necessity of calibrating any of the tubes. This apparatus may, however, be used in a different way, and then the calibrating of the tube $a\,b$ becomes necessary. In this case, instead of always bringing the gas to a constant volume and reading off the pressure it supports, the pressure is retained constant, and the difference of volume read off. The calibration of the tube $a\,b$ is effected by filling it completely with mercury, and then allowing a small quantity to flow out through the stopcock R, collecting and weighing this, then reading off on the tube the height through which the mercury has fallen. The temperature of the water in the cylinder should be kept constant during the whole operation.

The apparatus of MM. Regnault and Reiset leaves but little to be desired with regard to the rapidity with which analyses can be made; but this rapidity is to a certain extent obtained at a sacrifice of accuracy, considerable change in the bulk of gas operated on being represented by only a small change in the amount of pressure. In a comparison made by Messrs. Frankland and Ward, of the methods of Bunsen and Regnault, it was shown that an error of $\frac{1}{10}$ of a millimetre in the first observation would cause in Regnault's method an error in the percentage amount, seven times as great as would be the case when Bunsen's method was adopted. There is also considerable practical difficulty in maintaining the water in the cylinder at precisely the same temperature for any length of time together.

Fig. 69.



Messrs. Frankland and Ward have constructed (Chem. Soc. J. vol. vi. p. 197) another form of apparatus for the analysis of gases, which, in mechanical construction and in the method of working it, is very similar to the apparatus of Regnault and Reiset, but possesses at the same time many important advantages over it. The effect of atmospheric pressure on the gas is entirely removed; the principle adopted in measuring the amount of gas yields very accurate results; the gas may be expanded to almost any amount, rendering this apparatus one of considerable importance. *Fig.* 69 is a drawing of the apparatus. "It consists of the tripod A, furnished with the usual levelling screws, and carrying the vertical pillar B B, to which is attached on the one side the movable mercury-trough C, of gutta-percha, with its rack and pinion *a a*, and on the other the glass cylinder D D, with its contents. The cylinder is 36 inches long, and 4 inches internal diameter; its lower extremity is firmly cemented into an iron collar *c*, the under surface of which can be screwed perfectly water-tight upon the bracket-plate *d*, by the interposition of a vulcanised caoutchouc ring. The circular iron plate *d* is perforated with three apertures, into which the caps *e e e* are screwed, and which communicate below the plate with the T-piece E E. This latter is furnished with a double-waycock *f*, and a single-waycock *g*, by means of which the tubes cemented into the sockets *e e e*, can be made to communicate with each other, or with the exit pipe *h* at pleasure." F, G and H are three glass tubes which are firmly cemented into the caps *e e e*. F and H are each 15 to 20 mm. internal diameter, and to avoid any difference in the capillary action, are selected of as nearly the same bore as possible. The tube G is somewhat wider, and may be continued to any convenient height above the cylinder. H is accurately graduated into millimetres, and is furnished at the top with a small funnel *i*, into the neck of which a glass stopper, about 2 mm. in diameter, is carefully ground. The tube F terminates at its upper extremity in the capillary-tube *k*, which is carefully cemented into the small steel stopcock *l*. F has also fused into it at *m* two platinum wires, for the passage of the electric spark. After this tube has been firmly cemented into the cap *e*, its internal volume is accurately divided into ten equal parts. This is done first by filling it with mercury from the supply tube G, up to its junction with the capillary tube *k*, and then allowing the mercury to run off through the nozzle *h*, until the highest point of the meniscus stands at the division 10 previously made, so as exactly to coincide with the zero of the millimetre scale on H. The weight of the mercury thus run off is carefully determined, and the tube is again filled as before, and divided into ten equal parts, by allowing the mercury to run off in successive tenths of the entire weight, and marking the height of the top of the meniscus after each abstraction of the metal, by screwing a small copper ring on to the tube at that point. By using proper precautions with regard to temperature, &c., an exceedingly accurate calibration can be made in this way. In practice, however, it is found much easier to make the calibration in the following manner. The ten copper rings are screwed on to the tube first, at about equal distances apart, but without any relation to the capacity of the tube, which is afterwards ascertained by expanding the same volume of gas down to each of the ten divisions, and reading off the height of the column of mercury in the tube H in each instance. The way in which the laboratory tube J is joined to the rest of the apparatus is precisely similar to that adopted by MM. Regnault and Reiset, and already described.

When the instrument is thus far completed, it is requisite to ascertain the height of each of the nine upper divisions on the tube above the lowest or tenth division; this is very accurately effected in a few minutes by carefully levelling the instrument, filling the tube G with mercury, opening the cock *l*, and the stoppered funnel *i*, and placing the cock *f* in such a position as to cause the tubes F H to communicate with the supply-tube G. On now slightly turning the cock *g*, the mercury will slowly rise in each of the tubes F and H; when its convex surface exactly coincides with the ninth division on F, the influx of metal is stopped, and its height in H accurately observed; as the tenth division on F corresponds with the zero of the scale upon H, it is obvious that the number thus read off is the height of the ninth division above the zero point. A similar observation for each of the other divisions upon F completes the instrument.

Before using the apparatus, the large cylinder D D is filled with water, and the inside of the tubes F and H are once for all moistened with distilled water, by the introduction of a few drops into each, as in Regnault's apparatus. The three tubes being then placed in communication with each other, mercury is poured into G until it rises into the cup *i*, the stopper of which is then firmly closed. When the mercury begins to flow from *l*, that cock is also closed. The tubes F and H are now apparently filled with mercury, but a minute and imperceptible film of air still exists between the metal and the glass: this is effectually got rid of by connecting F and H with the exit-tube *h*, and allowing the mercury to flow out until a vacuum of several inches in length has been produced in both tubes. By allowing the instrument to remain thus for an hour, the whole of the film of air above mentioned will diffuse itself into the vacuum, and will become visible as a minute bubble in each tube, on allowing the vacuum to be filled up from the supply-tube G. By opening for a moment the stopper *i* and the cock *l*, whilst G is full of mercury, these bubbles are expelled. The absorption or laboratory-tube I being then filled with quicksilver, and attached to *l* by the screw clamp, the instrument is ready for use.

The method of introducing the gas, applying the absorbents, and passing the gas from one tube to the other, is in this apparatus so precisely similar to that adopted in using Regnault's apparatus, and before described, that it need not be further dwelt upon. The method of reading off the amount of gas is, however, different, and requires a few words of explanation. When the gas has been passed over into the tube F, mercury is allowed to flow out of the stopcock *f*, until a vacuum of two or three inches in length is formed in H, and the metal in F is just below one of the divisions; the cock *f* is then reversed, and the mercury very gradually admitted from G until the highest point in F exactly corresponds with one of the divisions on that tube; that this is really the case, must afterwards be ascertained by viewing it through a telescope. The height of the mercury in the tube H is then read off. If the division on the tube F, to which the gas has been expanded is, for instance, the fourth, then, from the number read off on the tube H must be deducted the height of this fourth division above the zero point of the tube. The remainder will express the volume of the gas; but in order to compare this with subsequent readings made at other divisions upon F, the number thus obtained, which represents the pressure of the gas, is reduced to what it would have been had the gas been expanded to the tenth division of F. This is very simply done, by merely multiplying the number representing the pressure of the gas by a fraction whose denominator is 10, and numerator the number of the division to which the gas has been expanded; thus, in the case above cited, the multiplier would be 0·4.

The following are the results of an analysis of air made by Messrs. Frankland and Ward.

Volume of air used. (Determined at fifth division on F.)

Observed height of mercury in H	673·0 mm.
Height of fifth division above zero	383·0
Corrected pressure of gas	290·0
	·5
Corrected pressure of gas at tenth division	145·0

Volume after the admission of hydrogen. (Determined at sixth division.)

Observed height of mercury in H	772·3 mm.
Height of sixth division above zero	304·0
Corrected pressure of gas	468·3
	·6
Corrected pressure of gas at tenth division	280·98

Volume after explosion. (Determined at fifth division.)

Observed height of mercury in H	763·3
Height of fifth division above zero	383·0
Correct pressure of gas	380·3
	·5
Corrected pressure of gas at tenth division	190·15

Results.

Volume of air used	145·00
Volume of oxygen	30·276

Hence:

Nitrogen	79·120
Oxygen	20·880
	100·000

Greatly superior as this form of apparatus is to that of Regnault, and capable as it is of yielding accurate and rapid results, still there are defects in it which detract somewhat from its practical value. The principal of these is the great difficulty there exists in always maintaining the apparatus in a perfectly air-tight condition, especially as the stopcocks *l′* and *l* have to be joined and separated once or twice during an analysis. Considerable inconvenience has also been found to arise from the very fragile nature of the laboratory-tube; this, even when full of mercury, is only supported by the capillary tube, to which it is fused, and consequently the slightest blow or pressure upon it is apt to cause it to separate at this point of junction. Some difficulty is also experienced in keeping the water in the cylinder at exactly the same temperature during the whole course of the analysis. Regnault, as before stated, suggests adding hot or cold water till the required temperature is obtained; this is an operation which takes considerable time, and without much care is likely to lead to fallacious results. Dr. Frankland has proposed using a stream of water direct from the street main, which enters the cylinder at the bottom, and is allowed to flow off by an exit-tube near the top. This is a great improvement upon Regnault's method, but even with this arrangement, slight variations occasionally occur.

Having now described the principal forms of apparatus used in the analysis of gases, we shall proceed to state the methods to be adopted for the separation and quantitative estimation of the different contituents which may occur in a gaseous mixture. Gases which have a strong affinity for any particular reagent, are estimated directly by introducing the reagent into the absorption-tube; but since many gases are not absorbable in this manner, another and indirect method has to be adopted, as for instance, in the case of hydrogen, which is estimated by exploding it with oxygen and observing the diminution of volume thence ensuing.

The following list will show which gases are estimated directly and which indirectly. Two of the number, namely oxygen and carbonic oxide, will be found in both lists, as they can be estimated by either method.

Gases estimated by the direct method.

Hydrochloric acid (anhydrous).
Hydrobromic acid.
Hydriodic acid.
Hydrofluoric acid.
Hydrosulphuric acid.
Sulphurous acid (anhydrous).
Carbonic acid (anhydrous).
Oxygen.
Carbonic oxide.
Olefiant gas.
Nitric oxide.

Gases estimated indirectly.

Nitrogen.
Oxygen.
Hydrogen.
Carbonic oxide.
Light carburetted hydrogen.
Ethyl.
Methyl.

The gases estimated by absorption may, for analytical purposes, be conveniently divided into three groups.

1st Group: — *Hydrochloric acid; Hydrobromic acid; Hydriodic acid.* These are absorbable by means of sulphate of sodium.

2nd Group: — *Hydrosulphuric acid; Sulphurous acid; Carbonic acid.* These are absorbed by caustic potash, but not by sulphate of sodium.

3rd Group: — *Oxygen; Nitric oxide; Carbonic oxide; Olefiant gas.* These are neither absorbed by sulphate of sodium nor by caustic potash. With regard to the manner of applying the reagent, if the apparatus of Regnault or Frankland be used a few drops of a very strong solution of the reagent are introduced into the laboratory-tube, by means of a bent pipette, as little of the liquid being used as possible, to prevent any appreciable loss arising from its absorbing power. But in using Bunsen's method, or that proposed by Williamson and Russell, the reagent must be introduced in a solid form if possible, or if necessarily a liquid, some porous substance must be saturated with it.

Estimation of the Gases of the 1st Group.—The sulphate of sodium is introduced into the gas by first melting it in its water of crystallisation, and then dipping into it the end of a platinum wire which has been bent into a short coil; this is repeated several times until a ball of the sulphate of sufficient size is obtained. If much of these acids is believed to be present, the ball should be of a large size, or else the sulphate of sodium is apt to become deliquescent, and run down the sides of the tube. All aqueous vapour must also be carefully removed from the gas before introducing the sulphate of sodium. This is best accomplished by means of a ball of phosphoric acid, which may easily be made by dipping the coiled end of a platinum wire into hot liquid phosphoric acid; a drop adheres to the wire, and then as the acid cools the size of the ball is increased to about that of a large pea, by turning it round in the viscous melted mass. The thickness of the platinum wires used in these experiments should be such that the balls of reagent may be easily pushed into the eudiometer without the wire bending. Great care must also be taken that the surface of the ball is as smooth as possible, or adhering air will be introduced into the gas, and some of the gas removed on withdrawing the ball. Oxide of bismuth or zinc may also be used for absorbing the members of this group. A ball of these substances is best made by applying the moist oxide to the end of the platinum wire, and then igniting it in the flame of a spirit-lamp. The results obtained with these absorbents are, however, generally not quite so accurate as those obtained with the sulphate of sodium. The different members of this group cannot be separated by any eudiometrical process. If several of them occur together, the ball of sulphate of sodium used for their absorption must afterwards be dissolved in water, and the solution analysed in the ordinary way.

Estimation of the Gases of the 2nd Group.—As stated above, the members of this group are all absorbed by caustic potash. A ball of this substance is made by fusing caustic potash and adding sufficient water to render it, when cold, soft enough to receive an impression from the nail; the end of the platinum wire bent into a coil is then placed in a bullet-mould of convenient size, and the fused potash poured in. If the ball should adhere firmly to the mould when cold, as is sometimes the case, heat must be applied; it will then easily be removed. On using a potash-ball for absorbing gases, it must always be moistened with water before introducing it into the gas. When much gas has to be absorbed by this means, the potash-ball should, after some hours, be removed from the eudiometer, washed, and then again introduced. It should be allowed to remain some four to six hours in contact with the gas, in order to ensure complete absorption.

Hydrosulphuric acid.—This gas is best absorbed by means of a ball of peroxide of manganese. The manganese is very finely powdered and made into a thin paste, with water; this is introduced into a bullet-mould with the platinum wire in it, and then dried on a hot sand-bath. If, however, this ball were at once introduced into a gaseous mixture, it would, from its porous nature, absorb an appreciable amount of other gases besides hydrosulphuric acid. To obviate this, the ball before being used should be thoroughly moistened with a syrupy solution of phosphoric acid; care must however be taken that this does not soften the ball, or it may fall to pieces on attempting to introduce it into the eudiometer. There is also another method of estimating this gas, but it is applicable only when sulphurous acid is not present. A potash-ball containing a large quantity of water, but not moistened externally, so that, on withdrawing it, none of the potash remains in contact with the mercury, is introduced into the eudiometer: this absorbs the hydrosulphuric and carbonic acid, if any is present. "Distilled water acidulated with acetic acid, is then boiled in two flasks until all the dissolved air has been removed; the contents of one flask is then poured, whilst boiling, into the other, filling it up to the top of the neck. The flask is then well closed with a cork covered with a plate of caoutchouc, so that no bubble of air is left between the liquid and the caoutchouc plate. As the liquid cools, the cork is pushed further into the neck, in order to prevent the formation of a vacuous space and the possible entrance of air. The ball of potash, cut off from its platinum wire immediately on withdrawal from the gas, is allowed to dissolve in this liquid when cool, and a few drops of a clear solution of starch are added." * The amount of hydrosulphuric acid present is then determined by means of a standard solution of iodine. In order to free the determination from any error which might arise from impurities in the potash, the experiment is repeated exactly in the same way with a ball of the same potash, but containing no sulphide of potassium. The amount of iodine used in this case is then subtracted from the amount used in the former experiment.

Sulphurous acid.—This gas is estimated by exactly the same methods as those adopted for hydrosulphuric acid.

Carbonic acid.—Caustic potash is the reagent always used in determining the amount of this gas in any mixture. The method of preparing the ball, and the necessary precautions in using it, were described when speaking of potash as the general absorbent of this group.

Estimation of the Gases of the 3rd Group.—This group consists of four gases not absorbable either by sulphate of sodium or by caustic potash. They will be treated in the order in which they would have to be separated from a gaseous mixture.

Oxygen.—This gas may be estimated either directly or indirectly, the method to be adopted in any particular case depending on the quantity present, and the nature of the gases with which it is mixed. If other combustible gases are present, or if there is only a small amount of oxygen in the mixture, it is always better to estimate it directly. The method to be adopted in determining it indirectly will be described further on. Phosphorus was formerly the substance generally used to free a gaseous mixture from oxygen; but owing to the tension of the vapour of the phosphorus acid formed, the difficulty of removing it, and the action which many gases have in preventing the union of phosphorus and oxygen at ordinary temperatures, the use of this reagent is apt to lead to incorrect results. A much better method of absorbing oxygen is to use pyrogallate of potassium. It may be introduced into the absorption-tube either by means of a papier-maché ball, or if liquid reagents are used, a few drops of a strong solution of the acid are first introduced and some caustic potash added to it.

The papier-maché ball is made by thoroughly macerating some bibulous paper in water, then, having introduced the platinum wire into a bullet mould, and tied the two handles together so that it cannot open, as much of the pulp is forced in round the platinum wire as possible. After being dried on a sand-bath, a hard compact ball is thus formed; this is thoroughly saturated with the pyrogallate of potassium, and then immediately introduced into the gas. The absorption of oxygen by this means is not always very rapid, and it is often necessary to withdraw the ball from the eudiometer, again saturate it with the pyrogallate solution, and introduce it a second time into the eudiometer.

Nitric oxide.—This gas and oxygen can, of course, never occur together. The best method of estimating it, is first to convert it into nitrous acid and then absorb the acid thus formed, by potash. For this purpose, a few bubbles of oxygen are introduced into the gas in the absorption-tube, and afterwards potash, either in the solid or liquid form. When the absorption is complete, a further quantity of oxygen is added; if after this addition, no absorption is caused by the potash, then an excess of oxygen is present, but if absorption again takes place, more oxygen must be added. Having in this manner ascertained that the whole of the nitric oxide is removed, it then only remains to absorb the excess of oxygen present, by means of pyrogallate of potassium, as before described. When this gas is mixed with nitrous oxide, olefiant gas, or hydride of ethyl, this method, according to Dr. Frankland, gives good results; but in the presence of other hydrocarbons, it is possible that the nitrous acid and peroxide of nitrogen might exercise an oxidising action on them, and thus vitiate the results. Protosulphate of iron was also formerly used as an absorbent for nitric oxide; but it does not yield very satisfactory results.

Carbonic oxide.—Like oxygen, this gas is also estimated sometimes directly, sometimes indirectly. At present, its direct estimation only will be treated of. This is best effected by means of a concentrated solution of subchloride of copper. A papier-maché ball, similar to the one used for the pyrogallate of potassium, is the best means of introducing the solution into the absorption-tube, when the liquid alone cannot be used. This gas is, however, generally estimated by the indirect method, which yields extremely accurate results.

---

* Bunsen's Gasometry, p. 86.

Olefiant gas.—This gas, together with all others of the formula C^nH^{2n}, is easily and rapidly absorbed by means of anhydrous sulphuric acid, dissolved in about an equal weight of the monohydrated acid. This mixture is best introduced into the gas by saturating a coke bullet with it. The bullet is made by taking a finely powdered mixture of equal parts of cannel coal and coke, or anthracite coal, and after introducing the platinum wire, compressing as much as possible of the mixture into the bullet-mould, which is then carefully and slowly heated to redness. By this means a hard and compact ball is easily formed. Before introducing it into the acid mixture, it should always be warmed to expel any moisture present, and after being saturated with acid, must be introduced into the gas as quickly as possible. The ball, when withdrawn after some hours from the eudiometer, should still give off dense white fumes, on coming in contact with air, thus showing that an excess of acid was present. Owing to the tension of the sulphuric acid introduced, and the sulphurous acid which is formed, the bulk of gas in the absorption-tube generally increases instead of diminishes, on first introducing the coke bullet. To remove the acid vapours thus formed, after withdrawing the coke bullet, a potash-ball must be introduced.

After the coke bullet has been withdrawn, although at present there is no direct method known for separating and estimating singly the different hydrocarbons having the general formula C^nH^{2n}, still, if two of them occur together, the amount of each can be easily determined by an indirect method to be described further on.

Gases estimated indirectly.—In estimating the gases belonging to this class by Bunsen's method, the long eudiometer is always used. After having completed the absorptions in the short tube, a portion only of the gas is introduced into the eudiometer, the amount depending on the nature of the gases operated on. In most cases, a volume occupying about 120 mm. on the scale, will be found convenient. Certain precautions are, however, necessary in using the tube for exploding gases. In order to close securely the open end of the eudiometer, so that no gas may be forced out at the moment of explosion, a small round piece of cork or wood, of rather greater diameter than the eudiometer, is covered on one side with a thick piece of caoutchouc, and the other is so shaped that it rests firmly on the bottom of the mercury-trough. Before exploding the gas, the eudiometer is tightly pressed down on to the caoutchouc, and held firmly in this position by a wooden arm pressing on the top of it. In order to prevent any air adhering to the surface of the caoutchouc, which, after the explosion, owing to the diminution of pressure, might be sucked up into the eudiometer, the caoutchouc, before introducing it under the mercury, should always be moistened with a solution of corrosive sublimate, which causes the mercury to adhere closely to it, and entirely removes the possibility of any air being introduced into the eudiometer.

It will be found convenient, as it saves much time and calculation, to form for the eudiometer a table of volumes. This is done by introducing a small tube full of air, and then reading off the height at which the mercury stands; a second tube full is then introduced, and the height of the mercury again read off, and so on till the eudiometer is filled with air. By noting down the level of the mercury in the tube after each addition of air, the successive differences of these numbers express the bulk of the same amount of gas under different pressures, these pressures depending on the height of mercury in the eudiometer.

The following is part of a table formed in this way:—

Vols.	Height of mercury.	Differences.
1	53	2
2	96	43
3	131	35
4	161	30
5	187	26

The use of this table is to enable the operator to see at a glance the amount of gas to be added when the mixture is to be exploded; for instance, suppose the height of the mercury in the eudiometer was 131, and the nature of the gas such that about 2 vols. of oxygen had to be added, in order that an explosion of the proper degree of intensity should take place; by referring to this table the operator would see at once that oxygen must be added till the mercury falls to 187. As the object of the table is only to show about how much gas has to be added under different circumstances, any great degree of accuracy in forming it is not necessary. The readings-off of the heights of the mercury, after each addition of air, may be made without the telescope, and any alteration in the heights of the thermometer and barometer during the operation need not be taken into account.

The explosion of the gaseous mixture is best effected by means of an electric spark, for obtaining which, a small Leyden jar is charged from an electrophorus or an electrical machine, or else by the still simpler method adopted by Bunsen, which consists merely in rubbing a large porcelain tube with a piece of silk on which some amalgam is spread. Ruhmkorff's coil may also be advantageously used for exploding gases.

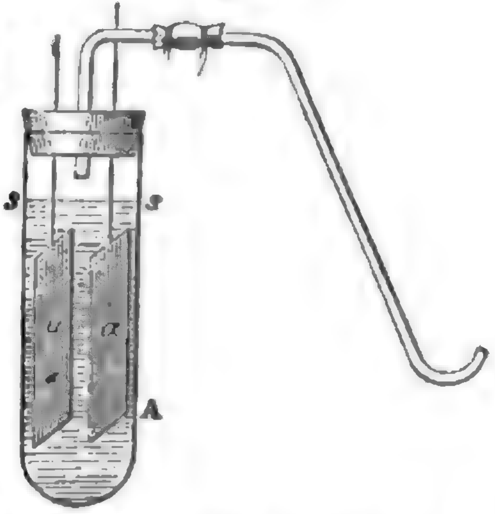
Before filling the eudiometer with mercury, a drop of water should always be introduced into the top of it, so that the volume of gas may be read off saturated with aqueous vapour.

Nitrogen.—This gas, from its incombustible nature, can, of course, be estimated only by removing all others with which it is mixed, and measuring the amount remaining; but although it cannot be made to combine with oxygen, so as to remove it entirely from a mixture, still, as is well known, the oxidation of it does often take place to a considerable extent, and, if not properly guarded against, is likely to lead to very serious errors in the analysis of gases. In fact, the discordant and incorrect results obtained by the earlier experimenters on the composition of the atmosphere, did no doubt arise in great measure from this cause. It became then a point of great importance to ascertain whether this oxidation of nitrogen always took place when mixtures containing it were exploded, and if not, what must be the relative amounts of combustible and incombustible gases present, in order that no trace of any oxide of nitrogen should be formed. We are indebted to Professor Bunsen for a series of experiments on this subject, which remove all uncertainty in the matter. By taking mixtures of atmospheric air and electrolytic detonating gas in different proportions, he has clearly shown that when for every 100 volumes of non-combustible gas 26 to 64 volumes of combustible gas are taken, no oxidation of the nitrogen takes place.

To determine the presence of nitrogen in a mixture, the following is the process to be adopted:—Having removed all absorbable gases and measured off a suitable quantity in the eudiometer, some pure oxygen is introduced, and the volume of gas again measured. An electric spark is now passed through the mixture. Even if no diminution of volume should ensue, it cannot be assumed that the gas was pure nitrogen, as the combustible constituents may have existed in so small a quantity that the gas was not of itself explosive. In order to ascertain whether this was the case, about 40 volumes of electrolytic detonating gas must be added for every 100 volumes of the incombustible gas. If, after the explosion which then ensues, the volume of gas still remains unaltered, only pure nitrogen could have been present in the gas examined.

The electrolytic gas above-mentioned may be prepared by means of the apparatus represented in figure 70. The tube A is an ordinary test-tube of rather strong glass, filled to the level *s s*, with distilled water freed from air by boiling, and acidulated with a few drops of sulphuric acid. The open end of the tube is closed with a cork provided with a gas-delivery tube, and having two platinum wires passing through it, to the ends of which are attached platinum plates, serving as electrodes. When the outer extremities of the wires are connected with the poles of a voltaic battery of two of Bunsen's elements, and the portions of gas evolved in the first quarter of an hour are allowed to escape, a chemical mixture of 2 vols. hydrogen and 1 vol. oxygen is afterwards obtained, which disappears completely on explosion, so that there is no necessity to measure the amount of it mixed with any other gas. Time must, however, be allowed for it to diffuse itself through the mixture already in the eudiometer; for this purpose, half to three quarters of an hour should be allowed to elapse, after the introduction of this gas, before the explosion takes place, and the eudiometer should be well agitated.

Fig. 70.



Oxygen.—By exploding the mixture containing this gas with an excess of hydrogen, the quantity present may be very accurately determined, care being taken that the amount of explosive gas bears a proper relation to the total amount present, so that the detonation is not so violent as to endanger the safety of the tube or oxidise the nitrogen if present, and also not too feeble, as in that case oxygen may escape combustion. One-third of the total amount of contraction caused by the explosion is the quantity of oxygen which was present. The hydrogen used in these experiments may be generated in a small flask from pure zinc and dilute sulphuric acid. To remove any traces of carbonic and hydrosulphuric acids, and to prevent sulphuric acid being carried over mechanically, the gas, as it is evolved, should be made to pass through a tube containing caustic potash. The evolution of gas should always be allowed to take place for five or ten minutes before any of it is passed up into the eudiometer.

For very exact experiments, the hydrogen should be obtained by another process, which yields an absolutely pure gas, namely, from the electrolytic decomposition of water. For the generation of this gas, an apparatus similar in form to that used for obtaining the detonating gas (*fig.* 70), may be used. Instead, however, of two platinum plates, only one is used, and the positive pole consists of a platinum wire melted into the decomposing cell at the bottom, and there brought in contact with a layer of mercury amalgamated with zinc. The acid liquid is of the same degree of strength as in the former apparatus. On now passing the current of a battery through it in the proper direction, pure hydrogen is evolved, and is dried by passing through a small vessel containing sulphuric acid, or a tube containing chloride of calcium.

Hydrogen.—The method of estimating this gas is precisely the reverse of that adopted for the estimation of oxygen. The amount of hydrogen present is represented by $\frac{2}{3}$ of the contraction caused by explosion. The oxygen added is best prepared from powdered chlorate of potassium, contained in small retorts of about the capacity of eight or ten cubic centimetres.

These little retorts are easily made by blowing a bulb at the end of a piece of glass tubing, then introducing the powdered chlorate of potassium, and afterwards bending the tube a little above the bulb, so as to give it the form of a retort. The open end should also be bent upwards, in order that it may be introduced into the eudiometer. The air is, of course, first thoroughly expelled by evolving a considerable amount of gas before any is allowed to enter the eudiometer.

Carbonic Oxide.—The method of estimating this gas by absorption has already been explained; it is, however, most accurately, and in most cases most easily estimated by exploding it with oxygen, and then absorbing the carbonic acid formed by means of potash.

Light Carburetted Hydrogen (Marsh-gas).—This gas is also estimated by exploding it with oxygen, and measuring the contraction which has taken place and the amount of carbonic anhydride formed. This gas and all hydrocarbons containing their carbon and hydrogen, as they do in a condensed form, require much greater dilution with non-combustible gases, in order to modify the violence of the explosion, and prevent the oxidation of any nitrogen which may be present. Pure light carburetted hydrogen should be diluted with from 8 to 12 volumes of air and 2 of oxygen, in order that it may be exploded so as to yield accurate results. The object of using air instead of merely oxygen as the diluent is, that if the gas has afterwards be examined for nitrogen, the amount of oxygen which would be present would probably be so large that the eudiometer could not contain sufficient hydrogen to explode it.

Ethyl, Methyl, &c.—These hydrocarbons are easily estimated by simple combustion with oxygen, and measuring the amount of carbonic acid formed, care only being taken that they are sufficiently diluted with incombustible gas. To pure ethyl some 20 times its volume of air should be added, and 6 or 7 volumes of oxygen. Methyl, on the other hand, requires only about 8 volumes of air and 2 or 3 of oxygen. In operating with a mixture which may contain any of these gases, and of entirely unknown composition, the best method of proceeding is to add at first so much air and oxygen that even if the whole of the gas were ethyl, an explosion of not undue violence would take place. If the gas should not explode on passing the spark through it, then a small quantity of electrolytic gas or hydrogen must be added. In this way all danger of a violent explosion may be avoided. The solubility of the gases in strong alcohol may sometimes be examined with advantage, in order to ascertain roughly what is the composition of the gas operated on, and consequently how much diluent it is necessary to add. 1 volume of alcohol will dissolve some 18 volumes of ethyl, while of methyl and hydride of ethyl it dissolves only about its own volume. With regard to these two gases, methyl and hydride of ethyl, since they are isomeric, and in equal volumes contain the same amount of carbon and hydrogen, they cannot be distinguished by any eudiometrical process.

The methods adopted for calculating the composition of the gas from the data which have been thus obtained, are as follows:—With the gases that are estimated directly the nature of the calculation is easily understood. By taking a definite example, the method used in calculating the amount of combustible gases in a mixture will be rendered very obvious. Suppose then that the gas introduced into the long eudiometer contains hydrogen, carbonic oxide, light carburetted hydrogen, and nitrogen. Oxygen would be introduced, the mixture exploded, and the carbonic acid formed absorbed; then to determine the amount of nitrogen present, hydrogen must be added in excess, and the mixture again exploded to remove the oxygen remaining.

Let a be the amount of gas in the long eudiometer,
b „ „ after the addition of oxygen,
c „ „ after the explosion,

Let d be the amount of gas after the absorption of the carbonic acid,
e ,, ,, after the addition of hydrogen,
f ,, ,, after explosion.

From these observations the following data are deduced: —

A, the volume of combustible gas. C, the volume of carbonic acid formed.
B, ,, oxygen consumed. D, ,, nitrogen present.

$\frac{e-f}{3}$ represents the amount of oxygen which remained unconsumed by the first explosion. If this quantity be deducted from d, the remainder is evidently the amount of nitrogen present.

$$D = d - \frac{e-f}{3}$$

A, the volume of combustible gas which was present, is found by deducting the amount of nitrogen from the original volume of the gas, thus:—

$$A = a - \left(d - \frac{e-f}{3}\right)$$

By subtracting the amount of oxygen $\frac{e-f}{3}$ consumed in the second explosion from the amount originally added, we obtain B, the amount consumed by the combustible gas, thus:—

$$B = b - a - \frac{e-f}{3}$$

The amount of carbonic anhydride formed, is:

$$C = c - d.$$

The values of A, B, and C being thus known, it will be possible to calculate from them that of the three unknown quantities:

x the volume of hydrogen
y ,, ,, light carburetted hydrogen
z ,, ,, carbonic oxide

On undergoing combustion the hydrogen and carbonic oxide combine with half their volume of oxygen, whereas the marsh-gas requires twice its volume; and further, both the carbonic oxide and marsh-gas on combustion produce a volume of carbonic acid equal to their original volume. These data give, then, the three following equations:—

$$\begin{aligned} x + y + z &= A \\ \frac{x}{2} + \frac{z}{2} + 2y &= B \\ y + z &= C \end{aligned}$$

and from these may be deduced the value of x, y, and z—

$$\begin{aligned} x &= A - C \\ y &= \frac{2B - A}{3} \\ z &= C - \frac{2B - A}{3} \end{aligned}$$

Thus is obtained the quantity of these gases present in the mixture. If another combustible gas had been present, its amount might also have been determined by estimating the water produced by the explosion as well as the carbonic acid; or else it might be determined by previously removing the carbonic oxide by subchloride of copper in the manner already described. The aqueous vapour in a gas is estimated by placing the eudiometer within a larger tube, and filling the space between the two with steam, the heat from which, as the gas is under a diminished pressure, is quite sufficient to convert the whole of the water into vapour.

If two members of the olefiant gas series C^nH^{2n} should occur together, the quantity of each present may be indirectly estimated in the following way:—A complete analysis of the gas must be made in the ordinary manner, absorbing the olefiant gases by fuming sulphuric acid, and exploding the combustible gases with oxygen. A second analysis must afterwards be made; but, instead of introducing sulphuric acid to absorb the olefiant gas, oxygen is added, and the whole exploded. The difference in the amount of the carbonic acid formed, and in the contraction which has taken place after the explosion, is evidently due to the olefiant gases present.

Let volume of olefiant gases = A
" " carbonic acid formed = B
" " contraction on combustion = C

If the two gases are, for instance, believed to be ordinary olefiant gas and butylene, then, since 1 volume of olefiant gas gives 2 volumes of carbonic acid, and 2 volumes contraction, and 1 volume of butylene gives 4 volumes of carbonic anhydride and 3 volumes contraction, then, if x represent the former gas, and y the latter—

$$x + y = A$$
$$2x + 4y = B$$
$$y = \frac{B - 2A}{2}$$
$$x = A - \frac{B - 2A}{2}$$

The contraction C gives also a third formula:

$$2x + 3y = C$$

which, combined with the first equation, gives the values of x and y to be:

$$y = C - 2A$$
$$x = A - C + 2A$$

The values obtained from both these sets of equations ought to agree.

By means of the following table, it will be easy to ascertain what formulæ have to be adopted in calculating the amount of combustible gases present in any mixture.*

Name of Gas.	Volume of Gas.	Volume of Oxygen consumed.	Decrease of volume after explosion.	Vol. of carbonic anhydride produced.
Hydrogen	1	0·5	1·5	0
Carbonic oxide	1	0·5	0·5	1
Hydride of methyl	1	2·0	2·0	1
Olefiant gas	1	3·0	2·0	2
Methyl	1	3·5	2·5	2
Hydride of ethyl	1	3·5	2·5	2
Propylene	1	4·5	2·5	3
Butylene	1	6·0	3·0	4
Ethyl	1	6·5	3·5	4

If the gaseous mixture consisted, for instance, of hydrogen, carbonic oxide, and nitrogen, and if A = the volume of the gas, C the diminution after explosion, and D the amount of carbonic acid produced, then taking x = hydrogen, y = carbonic acid, and z = nitrogen, we have:

$$x + y + z = A$$
$$\frac{3}{2}x + \frac{y}{2} = C$$
$$y = D$$

which gives:

$$x = \frac{2C - D}{3}$$
$$y = D$$
$$z = A - \frac{2C + 2D}{3}$$

As another example may be taken a mixture of hydrogen, carbonic oxide, and hydride of ethyl or methyl gas; then, if x, y, and z represent the quantities of these gases present:

$$x = \frac{3A + 2C - 4D}{6}$$
$$y = \frac{3A - 2C + D}{3}$$
$$z = \frac{2C + 2D - 3A}{6}$$

---

* The Table is taken from the Handwörterbuch der Chemie.

(For further details, see Bunsen's Gasometry, translated by Roscoe, London, 1857, pp. 42—114; Regnault, "Cours élémentaire de chimie, Paris, 2^me^ éd. iv. 73—103; Handw. d. Chem. 2^te^ Aufl. i. 930—978.) W. J. R.

ANALYSIS, ZOOCHEMICAL. See ANALYSIS, ORGANIC, p. 250.

ANAMIRTIN, $C^{19}H^{36}O^2$.—The fatty matter extracted from grains of paradise or cocculus indicus (*Anamirta cocculus*), is composed of a solid glyceride, called *anamirtin* or *stearophanin*, together with a certain quantity of a free fatty acid. The seeds are first freed from picrotoxine and colouring matter by digestion in ether, then exhausted with hot ether, and the filtered ethereal solution is exposed to a low temperature. Anamirtin then separates in arborescent crystals, which are purified by two or three crystallisations from boiling absolute alcohol. It melts at 35 or 36° C., and on cooling solidifies in a wrinkled mass, but does not crystallise. It is waxy and not friable. (Francis, Ann. Ch. Pharm. xlii. 254.)

Anamirtic acid is obtained by saponifying anamirtin with caustic potash and decomposing the soap with hydrochloric acid. It then separates as a colourless oil which gradually solidifies in a white crystalline mass. When dissolved in boiling dilute alcohol, it crystallises on cooling in small needles, which have a nacreous lustre when dry. It melts at 68° C. and solidifies on cooling in very brilliant radiating masses. According to Francis (Ann. Ch. Pharm. xlii. 254) it contains $C^{35}H^{35}O^4$. Heintz, however (Lehrb. d. Zoochemie, pp. 387, and 1671), considers it to be identical with stearic acid. The *sodium-salt* separates from boiling absolute alcohol in elongated prisms. The *silver-salt* is a white precipitate, soluble in ammonia, and soon blackened by exposure to light. *Anamirtate of ethyl* is obtained by passing hydrochloric acid gas for several hours into a hot alcoholic solution of anamirtic acid. It separates at the surface of the liquid, in the form of a nearly colourless oil, which solidifies on cooling. It is but slightly volatile, and is partly decomposed by distillation. It contains 76·4 per cent. of carbon, and 12·69 of oxygen.

ANANAS, OIL OR ESSENCE OF. A solution of butyrate of ethyl in 8 or 10 times its weight of alcohol possesses the odour of the pine-apple (*Ananassa sativa*), and is employed in confectionery and perfumery, also to imitate the flavour of rum. The butyrate of ethyl thus used must be quite free from volatile fatty acids. (Hofmann Ann. Ch. Pharm. lxxxi. 87.)

ANATASE. *Octahedrite. Titane anatase.* TiO^2.—A pure or nearly pure oxide of titanium crystallised in octahedrons, belonging to the quadratic or dimetric system, with angles of terminal edges, = 136°22 and of lateral edges 97°56. The crystals are often very much elongated: hence the name, from ἀνάτασις, erection. The mineral has an adamantine lustre, exhibiting various degrees of translucency down to complete opacity; its colour by transmitted light is greenish-yellow; by reflected light yellow-grey, honey-yellow, hyacinth-red, clove-brown, and iron-black, more rarely dark sky-blue or indigo. Cleavage distinct parallel to the octahedral faces. Specific gravity 3·83—3·95, sometimes after heating, 4·11—4·16. Hardness 5·5—6. It is brittle, with sub-conchoïdal fracture, and yields a colourless powder. Streak uncoloured. Infusible before the blow-pipe. Anatase is found most abundantly at Bourg d'Oisans, in Dauphiné, with felspar, axinite, and ilmenite. It occurs with mica slate in the Grisons; in Bavaria near Hof; in the Fichtelgebirg, Norway; and in the Urals; in chlorite in Devonshire; with Brookite at Tremadoc, North Wales; in Brazil, in quartz, and in highly lustrous detached crystals. It is also said to occur in the slags from the iron furnaces of Orange County, New York. (Dana ii. 122; Handw. d. Chem. 2^te^. Aufl. i. 990). (See BROOKITE, RUTILE, TITANIC ACID.)

ANATTA. See ANNOTTO.

ANAUXITE. The name given by Breithaupt to a hydrated silicate of magnesium and aluminium found at Bilin in Bohemia. Its composition has not yet been ascertained with accuracy, but it contains 11·5 per cent. water, and 55·7 per cent. silica. It is softer than calc-spar, of a greenish-white colour, with mother-of-pearl lustre, translucent at the edges. Specific gravity 2·26. Cleavage in one direction very distinct. A doubtful species. (Handw. d. Chem. 2^te^ Aufl. i. 991.)

ANCHOIC ACID. $C^9H^{16}O^4 = C^9H^{14}O^2.H^2.O^2$. *Lepargylic acid.*—Discovered by Buckton (Chem. Soc. Qu. J. x. 166) among the products of the oxidation of Chinese wax by nitric acid; and by Wirz (Ann. Ch. Pharm. civ. 265) among the products of the action of nitric acid on the solid fatty acids of cocoa-nut oil.

Preparation.—1. When Chinese wax is heated for several hours with 4 or 5 times its volume of nitric acid, of specific gravity 1·39, the acid which distils over being continually poured back, a greenish distillate is obtained, containing caprylic, œnanthylic, and butyric acids, and a residue consisting of anchoic acid, together with suberic and pimelic acids. On boiling this residue with water, evaporating the filtrate to the crystallising point, pressing the crystalline crusts thus obtained, washing with ether, and recrystallising from hot water, anchoic acid crystallises out pure, the other acid remaining in solution. Cerotic acid also yields anchoic acid when treated with nitric acid, but not so readily as Chinese wax (Buckton).—2. Several pounds of the solid fatty acids of cocoa-nut oil (obtained by decomposing the soda soap with dilute sulphuric acid, and distilling off the volatile acid), are digested with nitric acid for several weeks till the oxidation is complete, and the mass solidifies in a white crystalline magma; this product is dissolved in twice its volume of hot water; and the granular mixture of suberic and anchoic acids which separates is redissolved and recrystallised several times, at last from weak alcohol, till the portion which first crystallises out exhibits the composition of pure anchoic acid. The mother-liquor separated from the crystalline magma of suberic and anchoic acids, contains several other acids of the series $C^nH^{2n-2}O^4$ (see ACIDS, p. 52) viz. pimelic, adipic, lipic, and succinic acid. (Wirz.)

Properties.—Anchoic acid forms snow-white aggregated nodules (Buckton); round granules resembling those of suberic acid, but harder (Wirz). Melts between 114° and 116° C. (Buckton); partially at 115°, completely at 124°, and solidifies on cooling, in a finely radiated nacreous mass (Wirz). At a stronger heat, it sublimes with partial decomposition, emitting white inodorous vapours, which produce a very suffocating effect when inhaled (Buckton): hence the name (ἄγχειν, to suffocate). It dissolves in 217·4 pts. of water at 18° C. and volatalises partially when the solution is evaporated (Wirz). Hot water dissolves it readily, the solution becoming whiter and semi-fluid on cooling (Buckton). It dissolves also in alcohol; has an acid taste and reaction.

Anchoic acid is dibasic, the formula of the neutral anchoates being $C^9H^{14}O^2.M^2.O^2$. It also forms acid salts. *Anchoate of ammonium* is an amorphous mass, which dissolves readily in water and alcohol, and gives off ammonia when heated. *Neutral anchoate of potassium* forms indistinct crystalline masses, which dissolve readily in water. The *acid* salt, $C^9H^{15}KO^4$, forms microscopic granules, which remain unaltered at 140° C. It dissolves in 3 pts. of cold water, more readily in hot water; soluble also in wood-spirit (Buckton). The *sodium*-salt crystallises more readily than the potassium-salt. *Neutral anchoate of barium*, $C^9H^{14}Ba^2O^4$, is obtained by neutralising the acid with baryta-water, or with carbonate of barium, or by precipitating a mixture of the ammonium-salt and chloride of barium with alcohol. Forms a transparent film which becomes dull at 100° C. (Buckton). After drying over sulphuric acid, it forms a white opaque mass, having the aspect of porcelain (Wirz). It is very soluble in water, insoluble in alcohol and in ether (Buckton). It does not appear possible to prepare an acid anchoate of barium (Buckton).

The ammonium-salt forms a gelatinous precipitate with chloride of *calcium*, white with acetate of *lead*, whitish with *ferrous* sulphate, light brick-red with *ferric* chloride, and bluish-green with *cupric* sulphate (Wirz). It also precipitates *zinc*-salts, *mercurous* salts and *mercuric* salts (Buckton.) *Anchoate of silver* $C^9H^{14}Ag^2O^4$, obtained by precipitation from the ammonium-salt, forms a white powder which soon decomposes when moist (Wirz): white flocks, which are permanent at 120° C., and dissolve sparingly in water. (Buckton.)

Anchoate of Ethyl. $C^{13}H^{24}O^4 = C^9H^{14}O^4.(C^2H^5)^2$.—Obtained by passing hydrochloric acid gas into the alcoholic solution of the acid. It is a yellowish viscid oil, lighter than water and having an agreeable odour. It boils at 325° C. (Buckton). Becomes brown without distilling at 260° (Wirz).

ANCHUSIN, or **ANCHUSIC ACID.** The colouring principle of the alkanet root (*Anchusa tinctoria*). It is extracted by first macerating the root in cold water, to extract the matters soluble in that liquid, then drying it in a stove, and exhausting with alcohol. The solution, at first red, becomes violet by boiling, then of a greyish-green; these changes of colour may, however, be prevented by adding a few drops of hydrochloric acid. The extract is concentrated, and agitated with ether, which then becomes charged with the colouring matter, and yields it by evaporation in the form of a resinous mass. Anchusin is an amorphous substance, having a deep red colour and resinous fracture: the colour is not altered by exposure to light. It softens at 60° C. At a higher temperature, it gives off very pungent violet vapours, similar to those of iodine; at a very high temperature, it becomes carbonised. It is insoluble in water, but dissolves in alcohol, and especially in ether; oil of turpentine, and fixed oils also dissolve it. According to Bolley and Wydler (Ann. Ch. Pharm. lii. 141) it contains $C^{35}H^{40}O^8$; 71·33 p. c. C; 7·00 H.

Nitric acid transforms anchusin into oxalic acid and a bitter substance. Concentrated sulphuric acid dissolves it, forming a solution of a beautiful amethyst colour.

The alkalis form with anchusin blue compounds, soluble in water, less soluble in alcohol and ether. With subacetate of lead it forms a bluish-grey precipitate soluble in alcohol.

The alcoholic solution of anchusin evaporated over the water-bath, leaves a blackish green residue from which water extracts a brown substance. The insoluble portion well washed with water and then treated with ether, yields a green extract containing, according to Bolley and Wydler, $C^{34}H^{44}O^{8}$, and formed from anchusin by fixation of water, and elimination of carbonic anhydride;

$$C^{35}H^{40}O^{8} + 2H^{2}O = C^{34}H^{44}O^{8} + CO^{2}.$$

ANDALUSITE. $Al^{4}O^{3}.SiO^{2}$, or $3Al^{2}O^{3}.2SiO^{3}$.—A crystallised mineral, found originally in the Spanish province of Andalusia, and occurring also in Scotland, Ireland the Pyrenees, and other localities, in mica-slate, and others of the older rocks. It forms rhombic prisms, belonging to the trimetric system, with angles of 91° 35′, and 88° 27′. Specific gravity from 3·0 to 3·2. Hardness = 7·5. It is infusible before the blowpipe: dissolves with difficulty in borax, forming a clear glass, and even less easily in phosphorus salt. It is insoluble in acids. The alumina is generally more or less replaced by the sesquioxide of iron and manganese. The minerals *chiastolite* and *cyanite* have the same composition as andalusite: cyanite, however, belongs to the triclinic (doubly oblique prismatic) system, and is found in the oldest plutonic rocks, whereas andalusite and cyanite occur in metamorphic rocks, as in mica-slate and clay-slate. Crystals are also found having the external form of andalusite, but made up of a mass of fine crystalline grains of cyanite. (Handw. d. Chem. 2te Aufl. i. 991; Gm. iii. 412; Dana, ii. 257.)

ANDAQUIES-WAX. (*Cera de los Andaquies.*)—The wax of a peculiar species of bee, found near the Oronoco and Amazon rivers, and used as a substitute for ordinary beeswax, in the manufacture of candles, &c. According to Lewy (Ann. Ch. Phys. [3] xiii. 458), it has a density of 0·917, melts at 77° C., and contains 81·6 per cent. C, 13·5 H, and 4·8 O. It is not, however, a definite compound, but, like ordinary beeswax, is a mixture of three different fats, one of which, constituting about half the entire substance, is insoluble in alcohol, melts at 72° C., and is identical with palm-wax. The solution obtained by boiling the original wax with alcohol deposits on cooling, a fat which melts at 82° C., and agrees in every respect with *cerosin* obtained from the sugar-cane; this substance exists in the Andaquies-wax to the amount of 45 per cent. Lastly, the alcoholic mother-liquor yields by evaporation about 5 per cent. of an oily fat, not yet further examined.

ANDESIN. A mineral resembling felspar in external appearance, but differing from it essentially in composition. It may be represented by the general formula $\left.\begin{matrix}M^{2}\\Al^{4}\end{matrix}\right\}4SiO^{3} = M^{2}O.SiO^{3} + Al^{4}O^{3}.3SiO^{3}$, or (regarding silicic acid as tribasic) = $3MO.2SiO^{3} + 3(Al^{2}O^{3}.2SiO^{3})$, the symbol M denoting potassium, sodium, calcium, or magnesium, which metals may replace each other in any proportions. Specific gravity 2·733. The mineral was originally obtained from the Andes, but has since been found in the Vosges and in other localities. (Handw. d. Chem. 2te Aufl. i. 993.)

ANDREASBERGOLITE and **ANDREOLITE.** See HARMOTOME.

ANEMONIN. $C^{15}H^{12}O^{6}$ (?)—A crystalline body, obtained from the leaves of several species of anemone, viz. *Anemone pulsatilla*, *A. pratensis*, and *A. nemorosa*. Water distilled off these leaves deposits, after some weeks, a white inodorous substance, which softens at 150° C., giving off water and acrid vapours. It is purified by repeated recrystallisation from boiling alcohol.

The crystals belong to the trimetric system. In the cold, they are but sparingly soluble in alcohol; ether and water dissolve but little, even at a boiling heat; the solutions are neutral. Anemonin is a poisonous substance; applied to the skin, it produces slight irritation.

By the action of alkalis, anemonin is transformed into anemonic acid. Boiled with water and oxide of lead, it yields a crystalline compound, $C^{15}H^{12}O^{11}.PbO$, soluble in boiling water. Strong sulphuric acid blackens anemonin. Hydrochloric acid dissolves it without sensible alteration. By oxidising agents, such as peroxide of manganese and sulphuric acid, it is converted into formic acid. Chlorine attacks it readily when heated, forming hydrochloric acid and an oily volatile body.

Anemonic Acid.—This name has been applied to an acid substance produced by the action of baryta-water on anemonin (Löwig and Weidmann, Pogg. Ann. xlvi. 45), and likewise to an amorphous substance, which is deposited together with anemonin, from distilled anemone water (Schwarz, Mag. Pharm. x. 193; xix. 168;

Fehling, Ann. Ch. Pharm. xxxviii. 218). Both these substances are said to consist of anemonin together with the elements of water. (Gerhardt, Traité iv. 263.)

ANGELICA BALSAM. When the root of archangel (*Angelica archangelica*) is exhausted with strong alcohol, and the residue left after distilling off the greater part of the alcohol is evaporated over the water-bath, a viscid mass is obtained, which, when washed with water and digested in ether, yields a solution from which, by evaporation, a black-brown balsam is obtained, amounting to about 6 per cent. of the root. This balsam is a mixed product, and on treating it with potash-ley and distilling off part of the water, a small quantity of an essential oil (*angelica-oil*) separates; on continuing to heat the mass with the alkaline liquid, a waxy body (*angelica-wax*), is left behind: and the liquid concentrated to a certain point yields a crystalline resin, *angelicin*. On distilling the residue with excess of sulphuric acid, butyric acid passes over with the water, and afterwards angelic acid. (Buchner, Ann. Ch. Pharm. xlii. 226.)

ANGELIC ACID. $C^5H^8O^2 = \left.\begin{matrix}C^5H^7O\\H\end{matrix}\right\}O$, [or $C^{10}H^7O^3.HO.$]—This acid exists in the root of the archangel, *Angelica archangelica* (Buchner, Ann. Ch. Pharm. xlii. 226), and in sumbul, or moschus root, a drug imported from Asia Minor, and probably also belonging to an umbelliferous plant. From *archangel root* it is prepared by boiling fifty pounds of the root, cut into small pieces, with four pounds of lime and with water, straining through a cloth, concentrating the liquid, and distilling it with dilute sulphuric acid. A complex distillate is then obtained, which is neutralised with potash, and evaporated to dryness over the water-bath. The residue, distilled with sulphuric acid diluted with twice its weight of water, yields first a distillate of water, acetic acid, and valerianic acid, and afterwards angelic acid, part of which crystallises in the neck of the retort, while the rest passes into the receiver; on leaving the distilled liquid in a cold place for some days, the angelic acid dissolved in it crystallises out. The crystals are washed with a small quantity of water, and repeatedly crystallised to free them from valerianic acid (Meyer and Zenner, Ann. Ch. Pharm. lv. 307).—From *sumbul root* the acid is obtained by exhausting the root with alcohol, evaporating the filtered solution, boiling the residual balsam with strong potash-solution, filtering to separate a volatile oil, mixing the brown-red alkaline filtrate with sulphuric acid, which separates a dark brown oil, and distilling this oil with water, added at intervals as long as the distillate continues to be mixed with drops of oil. This distillate, set aside in a cold place, deposits angelic acid, which may be purified by twice saturating it with carbonate of sodium, distilling with sulphuric acid, then distilling it alone, and lastly, boiling it for a long time to separate sumbulamic acid. (Reinsch, Jahrb. pr. Pharm. vii. 79.)

Angelic acid is also produced by heating the essential oil of chamomile (*Anthemis nobilis*)—which consists of angelic aldehyde, together with a hydrocarbon (C^5H^8)—with hydrate of potassium:

$$\underset{\substack{\text{Angelic}\\\text{aldehyde.}}}{C^5H^8O} + KHO = \underset{\substack{\text{Angelate of}\\\text{potassium.}}}{C^5H^7KO^2} + 2H$$

The oil must be gently heated with pulverised and tolerably dry potash, till the temperature of the mass rises considerably, and hydrogen begins to escape. If the source of heat be then removed, the action goes on by itself, the hydrocarbon volatilises, and angelate of potassium remains mixed with the excess of hydrate. On dissolving this residue in water, taking off the small remaining portion of oily hydrocarbon with a pipette, and treating the solution with sulphuric acid, angelic acid rises to the surface in the form of an oil, which solidifies in a crystalline mass on cooling. This mode of preparation is much more productive than the preceding, provided the application of heat be discontinued at the right time. If it be continued too long, with the view of expelling the whole of the hydrocarbon not attacked by the potash, a considerable portion of the angelic acid will be resolved into acetic and propionic acids:

$$C^5H^8O^2 + 2H^2O = C^2H^4O^2 + C^3H^6O^2 + H^2,$$

the admixture of which greatly impedes the crystallisation of the angelic acid. (Gerhardt, Traité ii. 449.)

Angelic acid is also produced, together with oreoselin, by treating peucedanin with alcoholic potash:

$$\underset{\substack{\text{Peuce-}\\\text{danin.}}}{C^{12}H^{12}O^3} + KHO = \underset{\substack{\text{Angelate}\\\text{of potassium.}}}{C^5H^7KO^2} + \underset{\text{Oreoselin.}}{C^7H^6O^2}$$

(Wagner, J. pr. Chem. lxii. 275.)

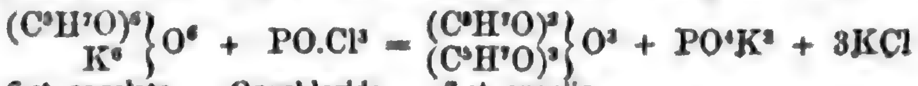
Angelic acid crystallises in large long prisms and needles, which are colourless and transparent. It melts at 45° C., boils at 190°, and distils without decomposition. It has a peculiar aromatic odour, a sour but aromatic taste, and reddens litmus. It burns with a bright and rather smoky flame. It dissolves sparingly in cold, but abundantly in hot water, whence it crystallises in needles on cooling. In alcohol, ether, oil of turpentine, and fat oils, it dissolves with great facility.

Angelic acid is monobasic, and belongs to the series of acids whose general formula is $\left.\begin{matrix} C^nH^{2n-3}O \\ H \end{matrix}\right\} O$, the other known members of which are acrylic acid (C^3), pyroterebic (C^6), hypogæic (C^{16}), and oleic (C^{18}).

The angelates of the *alkali-metals* are soluble in water and alcohol. The *calcium*-salt, $C^5H^7CaO^2 + H^2O$, forms shining laminæ, very soluble in water. The soluble angelates form with *lead*-salts, a white precipitate, $C^5H^7PbO^2$, soluble in a large quantity of water; with *ferric* salts, a flesh-coloured insoluble precipitate; with *cupric* salts, a bluish-white sparingly soluble precipitate; with *mercurous* nitrate, a white precipitate, which soon turns grey and redissolves; with *mercuric* chloride, no precipitate; and with nitrate of *silver*, a white precipitate, which dissolves in a large quantity of water, forming a solution which after a while deposits metallic silver.—A somewhat acid solution of oxide of silver in the boiling aqueous acid, yields, when evaporated at the gentlest possible heat, small greyish-white crystals of the normal silver-salt, $C^5H^7AgO^2$, sometimes also laminæ of a basic salt. (Meyer and Zenner.)

Angelate of Ethyl, Angelic Ether, is obtained by distilling angelate of sodium with a mixture of 1 pt. strong sulphuric acid, and 2 pts. of 94 per cent. alcohol. It is a colourless oily liquid, which smells like sour apples, has a sweetish, burning, aromatic taste, and excites coughing and headache when inhaled. (Reinsch and Recker, Jahrb. pr. Pharm. xvi. 12.)

ANGELIC ANHYDRIDE, or *Anhydrous Angelic Acid*, $C^{10}H^{14}O^3 = (C^5H^7O)^2O$.—Produced by the action of oxychloride of phosphorus on angelate of potassium:



$$\left.\begin{matrix}(C^5H^7O)^6 \\ K^6\end{matrix}\right\} O^6 + PO.Cl^3 = \left.\begin{matrix}(C^5H^7O)^3 \\ (C^5H^7O)^3\end{matrix}\right\} O^3 + PO^4K^3 + 3KCl$$

6 at. angelate of potassium. Oxychloride of phosphorus. 3 at. angelic anhydride.

The viscid oil resulting from the action yields, when treated with carbonate of sodium and then with ether, a solution which leaves the anhydride on evaporation. It is a perfectly neutral, limpid oil, heavier than water, and having a peculiar odour quite different from that of angelic acid. It does not crystallise, even at the temperature of a mixture of ice and salt. When distilled, it begins to boil at 240° C., but the boiling-point soon rises to 250°, and the compound is subsequently decomposed, yielding a distillate of angelic acid and a neutral oil, and leaving a carbonaceous residue.—The anhydride is but slowly rendered acid by the action of water, but dissolves readily in strong alkaline liquids. Aqueous ammonia first converts it into a buttery mass, and then dissolves it. In contact with aniline, it becomes strongly heated, and deposits crystals of *phenyl-angelamide*, $N.H,C^6H^5,C^5H^7O$. (Chiozza, Ann. Ch. Phys. [3] xxxix. 210.)

ANGELICIN. A crystalline substance obtained, according to Buchner, by treating angelica-balsam with potash (p. 287).

ANGLARITE. A variety of vivianite, found at Arglac, in the department of the Haute-Vienne, France.

ANGLESITE. Native Sulphate of Lead.

ANGUSTURINE. An organic base, said by Brande to exist in true angustura bark, *Cusparia febrifuga*. Its existence is doubtful.

ANHYDRIDES. *Secondary Negative Oxides*, or *Oxides of Acid-radicles*.—These bodies are also often called *anhydrous acids*, and are sometimes even confounded with *acids*. As regards their composition, they stand in the same relation to acids as oxide of potassium, K^2O, to potash, KHO; or, generally, as anhydrous (secondary) oxides, to hydrates (primary oxides): that is, they represent one or more atoms of water, nH^2O (the substance taken as the standard of comparison for all oxides), in which the whole of the hydrogen is replaced by one or more negative radicles; while the corresponding acids represent one or more atoms of water in which the same radicles replace one half of the hydrogen.

For example:—

Hypochlorous	anhydride	$= Cl.Cl.O$,	hypochlorous	acid	$= H.Cl.O$,
Nitric	„	$= NO^2.NO^2.O$,	nitric	„	$= H.NO^2.O$,
Acetic	„	$= C^2H^3O.C^2H^3O.O$,	acetic	„	$= H.C^2H^3O.O$,
Benzoic	„	$= C^7H^5O.C^7H^5O.O$,	benzoic	„	$= H.C^7H^5O.O$,

Aceto-benzoic anhydride = $C^2H^3O.C^7H^5O.O$,
Sulphuric „ = $SO^2.O$, sulphuric acid = $H^2.SO^2.O^2$,
Succinic „ = $C^4H^4O^2.O$, succinic „ = $H^2.C^4H^4O^2.O^2$,
Phosphoric „ = $PO.PO.O^3$, phosphoric „ = $H^3.PO.O^3$.

From these instances it is evident that there are three classes of anhydrides, namely. (*a*) those which derive from 1 at. water by the replacement of H^2 by 2 atoms of the same monatomic acid-radicle (hypochlorous, acetic, &c.), or by 2 different monatomic radicles (aceto-benzoic, &c.); (*b*) those which derive from 1 at. water by the replacement of H^2 by 1 atom of a diatomic acid-radicle (sulphuric, &c.); (*c*) those which derive from 3 at. water by the replacement of H^6 by 2 atoms of a triatomic acid-radicle (phosphoric). Anhydrides deriving from 2 at. water have not yet been shown to exist.

All anhydrides are more or less quickly converted into acids by the action of water or of hydrates; in the dry state, or when dissolved in ether or other liquids which do not change them into acids, they are without action on litmus or other vegetable colours.

Anhydrides (*a*) are obtained by the action of chlorides of monatomic acid-radicles on monatomic acids or salts:

$$Cl.Cl + \underset{\text{Hypochlorite of mercury.}}{Hg.Cl.O} = Hg.Cl + \underset{\text{Hypochlorous anhydride.}}{Cl.Cl.O.}$$

$$\underset{\text{Chloride of benzoyl.}}{C^7H^5O.Cl} + \underset{\text{Acetate of potassium.}}{K.C^2H^3O.O} = KCl + \underset{\text{Aceto-benzoic anhydride}}{C^2H^3O.C^7H^5O.O.}$$

They are liquid, or solid bodies, and those which contain only one acid-radicle, are usually volatile without decomposition: those which contain two acid-radicles are decomposed by heat into two anhydrides, each containing one radicle.

$$\underset{\text{Aceto-benzoic anhydride.}}{C^2H^3O.C^7H^5O.O} + \underset{\text{Aceto-benzoic anhydride.}}{C^2H^3O.C^7H^5O.O} = \underset{\text{Acetic anhydride.}}{C^2H^3O.C^2H^3O.O} + \underset{\text{Benzoic anhydride.}}{C^7H^5O.C^7H^5O.O.}$$

The anhydrides of this class, which correspond to organic acids, are insoluble or but slightly soluble in water; they dissolve in alcohol, but are gradually decomposed by it forming salts of ethyl (compound ethers); in ether they dissolve without alteration.

Ammonia and its derivatives convert them into amides, or alkalamides.

$$\underset{\text{Benzoic anhydride.}}{C^7H^5O.C^7H^5O.O} + 2NH^3 = H^2O + \underset{\text{2 at. benzamide.}}{2(N.C^7H^5O.H^2)}$$

$$\underset{\text{Acetic anhydride.}}{C^2H^3O.C^2H^3O.O} + \underset{\text{2 at. phenylamine (aniline).}}{2N.C^6H^5.H^2} = H^2O + \underset{\text{2 at. phenylacetamide.}}{2(N.C^2H^3O.C^6H^5.H)}$$

With perchloride of phosphorus they give chlorides of monatomic acid-radicles: with sulphide of phosphorus, sulphanhydrides (secondary negative sulphides).

The anhydrides (*b*) correspond to dibasic or diatomic acids. They are formed by the decomposition of these acids, or their salts, by heat.

$$\underset{\text{Succinic acid.}}{H^2.C^4H^4O^2.O^2} = H^2O + \underset{\text{Succinic anhydride.}}{C^4H^4O^2.O}$$

$$\underset{\text{Sesquisulphate of iron.}}{Fe^4.(SO^2)^3.O^6} = \underset{\text{Sesquioxide of iron.}}{Fe^4O^3} + \underset{\text{3 at. sulphuric anhydride.}}{3(SO^2.O)}$$

With ammonia, they give ammonium-salts of amic acids:

$$\underset{\text{Succinic anhydride.}}{C^4H^4O^2.O} + 2NH^3 = \underset{\text{Succinamate of ammonium.}}{N.C^4H^4O^2.H^2NH^4.O}$$

and, to some extent, also secondary amides (imides):

$$\underset{\text{Succinic anhydride.}}{C^4H^4O^2.O} + NH^3 = H^2O + \underset{\text{Succinimide.}}{N.C^4H^4O^2.H}$$

They react in a similar way with phenylamine (aniline) and some other primary derivatives of ammonia.

Perchloride of phosphorus converts them into chlorides of diatomic acid-radicles.

In the case of sulphuric anhydride, SO^3, or $SO^2.O$, which has been much more minutely studied than any other anhydride of this class, certain additional reactions have been observed. For instance, it has been found to combine with hydrochloric acid, forming chlorhydro-sulphuric acid:

$$SO^3 + HCl = \underset{\text{Chlorhydro-sulphuric acid.}}{HSO^3Cl}$$

as well as with other chlorides, inorganic and organic (chlorides of ammonium, barium, ethyl, phenyl, &c.), to form compounds which represent the metallic salts and ethers of this acid. It also combines with hydrocarbons, producing neutral compounds of varying constitution:

$$2SO^3 + \underset{\text{Ethylene.}}{C^2H^4} = \underset{\text{Ethionic anhydride.}}{C^2H^4S^2O^6}$$

$$SO^3 + \underset{\text{2 at. benzine.}}{2C^6H^6} = H^2O + \underset{\text{Sulphobenzide.}}{C^{12}H^{10}SO^2}$$

The comparison of these reactions with those produced by acids in similar circumstances (see pp. 43, 44), makes it clearly evident that anhydrides and acids are essentially different in their chemical characters.

Very few triatomic anhydrides (*c*) are yet known. Phosphoric anhydride, P^2O^5, or $PO.PO.O^3$, is the only well known member of this class. It is obtained by the direct combination of phosphorus and oxygen. Ammonia converts it into phosphamic acid:

$$PO.PO.O^3 + 2NH^3 = H^2O + 2(NH.PO.HO)$$

with perchloride of phosphorus it gives oxychloride of phosphorus (chloride of phosphoryl); and, like sulphuric anhydride, it combines with hydrochloric acid.—G. C. F.

ANHYDRITE. Anhydrous sulphate of calcium. There are six varieties of it: 1. *Compact.* Has various shades of white, blue, and red; massive and kidney-shaped; dull aspect; splintery or conchoïdal fracture; translucent on the edges; is scratched by fluor, but scratches calc-spar; somewhat tough: specific gravity 2·850. It contains a trace of sea-salt. It is found in the salt mines of Austria and Salzburg, and at the foot of the Harz mountains; also in the gypsum pits at Ashton-on-Trent, near Derby. —2. *Granular.* The scaly of Jameson, is found in massive concretions, of which the structure is confusedly foliated. White or bluish colour, with a pearly lustre. Composition as above, with 1 per cent. of sea-salt. It occurs in the salt mines of Halle. Specific gravity 2·957. — 3. *Fibrous.* Massive; glimmering, pearly lustre; fracture in delicate parallel fibres; scarcely translucent; easily broken. Found at Halle, Ischel, and near Brunswick.—4. *Radiated.* Blue, sometimes spotted with red; radiated, splendent fracture; partly splintery; translucent; not hard; specific gravity 2·940.—5. *Sparry* or *Cube-spar.* Milk-white colour, passing sometimes into greyish and reddish-white; short four-sided prisms, belonging to the trimetric system, having two of the opposite sides much broader than the other two; occasionally the lateral edges are truncated, whence results an eight-sided prism belonging to the trimetric system; lustre splendent, pearly; foliated fracture; threefold rectangular cleavage; cubical fragments; translucent; scratches calc-spar; brittle; specific gravity 2·9. This is the *muriacite* of some writers. It is doubly refracting. It is said to contain 1 per cent. of sea-salt. It is found at Bex in Switzerland, and Halle in the Tyrol.—6. *Siliciferous,* or *Vulpinite.* Massive concretions of a laminated structure; translucent on the edges; splendent and brittle: greyish-white, veined with bluish-grey; specific gravity 2·88. It contains 8 per cent. silica; the rest is sulphate of calcium. It is called by statuaries, *Marmo bardiglio di Bergamo,* and takes a fine polish. It derives its name from Vulpino in Italy, where it accompanies lime. U.

ANIL. A nearly obsolete synonyme of indigo. The same term is also used as a synonyme of PHENYLIMIDE (*q. v.*)

ANILAMIC ACID. Syn. of PHENYLAMIC ACID.

ANILIDES. Syn. of PHENYLAMIDES.

ANILINE. Syn. of PHENYLAMINE.

ANIMALISATION. The process or series of processes by which food is converted into the constituents of the animal body (see DIGESTION and NUTRITION). The same term is used in the arts to denote the operation by which vegetable fibres, such as cotton and flax, are made to unite with albuminous substances.

ANIMÉ RESIN, improperly called *gum-animé.*—A resinous substance used for fumigation. There are three varieties of it, the East Indian, the West Indian, and the brown American. West Indian animé, sometimes called *courbaril resin*, is the produce of the *Hymenæa Courbaril*, a tree belonging to the order *Cæsalpineæ*, growing in the West Indies and in South America; the other varieties are of unknown origin. The West Indian resin forms yellowish-white transparent, somewhat unctuous tears, or sometimes larger masses; it is brittle; of a light pleasant taste, and very agreeable odour; hence its use in fumigation and in perfumery. It softens in the mouth, melts easily in the fire, and burns with a bright flame. Specific gravity 1·028 (Bresson), 1·032 (Paoli). Insoluble in water, perfectly soluble in hot alcohol. Cold alcohol dissolves about 54 per cent. of it. The soluble portion is, according to Laurent, identical with the resin of turpentine. The insoluble portion crystallises from boiling alcohol in slender colourless needles, consisting, according to Laurent, of 83·6 per cent. C, 11·5 H, and 4·9 O, agreeing with the formula $C^{22}H^{36}O$. According to Filhol, the resin of *Hymenæa Courbaril* is nearly insoluble in cold absolute alcohol, melts at 100° C, and contains 85·3 per cent. carbon, 11·5 hydrogen, and 3·2 oxygen.

Brown American animé softens in the mouth, and dissolves completely in cold alcohol; specific gravity 1·0781 (Paoli). Oriental animé, which, according to Guiboust, is no longer met with in commerce, is likewise perfectly soluble in cold alcohol, has a density of 1·027, and appears to consist of two resins, differing in melting point (Paoli, Trommsdorff's Journ. Bd. ix. St. 1; s. 40, 61; Guiboust, Rev. Scient. xvi. 177; Laurent, Ann. Ch. Phys. [2] lxvi. 315; Gerhardt, Traité, iii. 669; Filhol, J. Pharm. [3] i. 301, 507.)

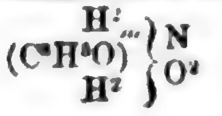
There is some confusion respecting the use of the word *animé*, the French designating copal as *résine animé;* and denoting the West Indian animé or courbaril resin, by the term *Copal* or *animé tendre*.

ANIMINE. An organic base obtained, together with three others, *odorine*, *ammoline*, and *olanine*, from bone-oil (*Oleum animale Dippelii*), by Unverdorben in 1826 (Pogg. Ann. xi. 59 and 67). None of these bases were prepared by Unverdorben in a state of purity. Odorine was afterwards obtained pure, and more exactly investigated under the name of *picoline*, by Anderson, who showed that it is isomeric with aniline, C^6H^7N. The other three bases, which were less volatile than odorine, were probably mixtures of the homologous bases *lutidine*, C^7H^9N, and *collidine*, $C^8H^{11}N$, together with other substances. (See Gm. xi. 273.)

ANION (from ἄνιον, that which goes up).—A term used by Faraday to denote the element of an electrolyte, which is eliminated at the positive pole or *anode;* the other element, which is eliminated at the negative pole or *kathode*, being called a *kation* (κατιον, that which goes down). To understand these terms, we must suppose the decomposing body to be so placed that the current (of positive electricity) passing through it, shall be parallel to, and in the same direction with, that which is supposed to exist in the earth, viz. from east to west, or in the direction of the sun's diurnal motion. The positive pole or electrode will then be towards the east. (Faraday's Experimental Researches in Electricity, vol i. p. 196.)

ANISAMIC ACID. $C^8H^9NO^3$. (Zinin, Ann. Ch. Pharm. xcii. 327.) — Obtained by passing hydrosulphuric acid into a mixture of nitranisic acid with 8 pts. of alcoholic ammonia. After twelve hours, when the acid is dissolved, the whole is boiled, with occasional addition of water, till all the alcohol is driven off; it is then filtered from the separated sulphur, and mixed with acetic acid, which precipitates anisamic acid in long brown needles: they are obtained colourless by solution in water and treatment with animal charcoal. It forms thin, brilliant, four-sided prisms, which dissolve but slightly even in boiling water, or in ether, but are readily soluble in alcohol. Hydrochloric and boiling acetic acid dissolve it unchanged; its solution in dilute nitric acid reddens on long boiling, and by cooling deposits brown flakes and a white pulverulent substance. It melts at 180°C., and is decomposed at a higher temperature.—The only anisamate that has been analysed is the *silver-salt*, $C^8H^8AgNO^3$: it is a curdy precipitate, insoluble in water, readily soluble in ammonia and acids; in the dry state, it may be heated to 120° C. without decomposition, but turns brown when boiled with water. The *ammonium-salt* is very soluble, and crystallises with difficulty in four-sided tables; its aqueous solution is partially decomposed by boiling, ammonia being evolved, and the acid crystallising out on cooling. The *lead* and *cadmium-salts* are white precipitates. An aqueous solution of anisamic acid does not precipitate lime- or baryta-water, or silver-salts. With ammoniacal sulphate of copper, it gives, in the cold, a light blue flocculent precipitate, which, on boiling, becomes pulverulent, and of a cinnamon colour.

The mode of formation of anisamic from anisic acid being analogous to that of oxybenzamic acid from benzoic acid, it should perhaps be regarded as *oxyanisamic acid*,



$$\left.\begin{matrix}H' \\ (C^8H^6O)''' \\ H^2\end{matrix}\right\}\begin{matrix}N \\ O^2\end{matrix}$$

F. T. C.

ANISAMIDE. $C^8H^9NO^2$ [or, rather, *anisamic acid*, $\left.\begin{matrix}H^2\\(C^8H^6O)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$]. (Cahours, Ann. Ch. Phys. [3] xxii. 353.)—Obtained by treating chloride of anisyl with dry ammonia, whereupon heat is evolved, and the mixture becomes a solid mass of anisamide, which is soluble in alcohol, whence it crystallises by spontaneous evaporation in large prisms. It is also formed by the action of ammonia on anisate of ethyl in a closed vessel. F. T. C.

ANISAMINES (Cannizzaro, Compt. rend. l. 1100).—These bases are produced by the action of strong alcoholic ammonia on the chlorhydrin of anisic alcohol (C^8H^9OCl):

$$C^8H^9OCl + NH^3 = \underset{\text{Anisamine.}}{C^8H^{11}ON} + HCl.$$

$$2C^8H^9OCl + NH^3 = \underset{\text{Dianisamine.}}{C^{16}H^{19}O^2N} + 2HCl.$$

The resulting mass is freed from sal-ammoniac by digestion in water, then dissolved in alcohol, and the residue obtained by evaporating the alcoholic solution to dryness, consists, after washing with ether, of a mixture of the hydrochlorates of the two bases. These hydrochlorates are separated by water, the anisamine-salt being much the more soluble of the two; and the bases are obtained in the free state by adding ammonia or potash to the solutions of the hydrochlorates, then agitating with ether, and evaporating the ethereal solution.

Anisamine crystallises in small needles, soluble in water, alcohol, and ether, and melting with colouration above 100° C. *Dianisamine* forms at first a thick oil, which, after a few days, crystallises in white laminæ. It is soluble in alcohol and in ether; less soluble in water than anisamine. It melts and solidifies between 32° and 33° C.

Both these alkaloids are strong bases. The *chloroplatinate of anisamine*, $C^8H^{11}ON.HCl.PtCl^2$, crystallises in small gold-yellow laminæ. The *chloroplatinate of dianisamine*, $C^{16}H^{19}O^2N,HCl.PtCl^2 + H^2O$ is precipitated as a brown oily liquid, gradually changing to a mass of yellow needles.

The constitution of these bases may be viewed in two different ways. If anisic alcohol be regarded as monatomic $= C^8H^9O.H.O$, the bases then appear as ordinary amines, containing the radicle C^8H^9O, viz.:

$$\text{Anisamine} = N\left\{\begin{matrix}H^2\\C^8H^9O\end{matrix}\right. ;\ \text{Dianisamine} = N\left\{\begin{matrix}H\\(C^8H^9O)^2\end{matrix}\right.$$

but if we suppose anisic alcohol to be diatomic $= (C^8H^8)''.H^2.O^2$, then the bases must be regarded as hydoramines (p. 197), viz.:

$$\text{Anisamine} = \begin{matrix}N\\O\end{matrix}\left\{\begin{matrix}(C^8H^8)''\\H^3\end{matrix}\right. ;\ \text{Dianisamine} = \begin{matrix}N\\O^2\end{matrix}\left\{\begin{matrix}(C^8\overset{''}{H^8})^2\\H^3\end{matrix}\right.$$

ANISANILIDE. See PHENYLANISAMIDE, under PHENYLAMINE.

ANISE, OIL OF. *Essence d'anis. Anisöl.*—The name given to the essential oil which is obtained by distillation with water from the seeds of the common anise (*Pimpinella anisum*), and the China or star anise (*Illicium anisatum*). (According to Hees, 20 lb. of seeds yield 5½ oz. oil.) This oil contains an oxygenated principle, which, by the action of oxidising agents, is converted into hydride of anisyl. The same principle is found in the oils extracted from fennel (*Anethum fœniculum*), and tarragon (*Artemisia Dracunculus*). All these oils may, therefore, be conveniently described in the same article, though they differ slightly in their physical properties.

1. *Oil of anise and of fennel* is a neutral, yellowish, somewhat syrupy liquid, possessing a peculiar aromatic smell and taste. Its specific gravity varies from 0·977 to 0·991. It is soluble in all proportions in cold alcohol of specific gravity 0·806, and in 2·4 pts. alcohol of specific gravity 0·84 at 25° C. It appears to consist of two distinct oils, one of which solidifies at temperatures below 10°, while the other remains fluid at all temperatures. Scarcely anything is known of the latter of these oils; according to Gerhardt (Traité, iii. 352 *et seq.*) it is isomeric with oil of turpentine. The former, which is generally known as *anethol* or *anise-camphor*, has been examined by Cahours (Ann. Ch. Phys. [3] iii. 274). The proportion of these two constituents varies in different specimens of the commercial oil; but generally the camphor composes ¾ of the whole. The crude oil absorbs oxygen when exposed to the air, becomes more syrupy, and finally loses the property of solidifying by cold. In order to obtain the camphor in a state of purity, it is freed from the liquid oil by pressure between folds of filtering paper, and repeatedly crystallised from alcohol of specific gravity 0·85. It crystallises in soft, white, lustrous laminæ, of specific gravity 1·014, having a smell similar to, but weaker and more agreeable than, that of the crude oil. It is very

friable, especially at 0° C.; melts at 18° C., and at 222° boils and volatilises completely, but not without slight coloration. Its formula is $C^{10}H^{12}O$. Its vapour-density. taken at 338° C., is 5·19; at lower temperatures, its density is higher. It is not affected by exposure to the air in the solid state; but, if kept in a state of fusion, it gradually ceases to solidify on cooling, and finally resinifies completely. *Nitric acid* converts it into hydride of anisyl, anisic or nitranisic acid, and oxalic acid; the products vary with the concentration of the acid. Generally a yellow resinous substance is also formed, to which Cahours gives the name *nitraniside*, and the formula $C^{10}H^{10}(NO^2)^2O$ (?). This is a very insoluble substance, which melts at about 100° C., and is completely decomposed by distillation; when treated with a strong solution of potash, it gives off ammonia abundantly, and is converted into a black substance, which Cahours calls *melanisic acid*. Under certain circumstances, the action of dilute nitric acid produces an acid containing 10 atoms carbon (see ANISOIC ACID). When distilled with *sulphuric acid* and *bichromate of potassium*, oil of anise yields anisic and acetic acids. (Hempel, Ann. Ch. Pharm. lix. 104.)

Strong boiling solutions of *caustic alkalis* do not attack oil of anise; but when it is heated with potash-lime in a sealed tube to the boiling point of the oil, a peculiar acid is formed, which appears to be isomeric with cuminic acid. (Gerhardt.)

Anise-camphor treated with *acid sulphite of sodium*, is resolved into methyl and hydride of anisyl, $C^{10}H^{12}O + H^2O = 2CH^3 + C^8H^8O^2$. (Städeler and Wächter Ann. Ch. Pharm. cxvi. 172.)

Anise-camphor absorbs *hydrochloric acid* gas abundantly, forming a liquid compound, $C^{10}H^{12}O.HCl$, which contains 19·8 per cent. chlorine. It absorbs *chlorine* rapidly, with evolution of heat and vapours of hydrochloric acid, forming substitution-products, in which the number of atoms of hydrogen replaced by chlorine varies with the duration of the action of the gas. The trichlorinated compound (*chloranisal*) $C^{10}H^9Cl^3O$, is a syrupy liquid, which is completely decomposed by distillation, and from which, by the further action of chlorine, aided by heat, a still higher chlorine compound may be obtained. Oil of anise treated with *pentachloride of phosphorus*, yields a liquid boiling at a high temperature, probably $C^{10}H^{12}Cl^2$. (Aelsmann and Kraut, J. pr. Chem. lxxvii. 490.)

When anhydrous *bromine* is gradually added to anise-camphor, heat and hydrobromic acid are evolved, and the whole becomes liquid, and finally, when the bromine is in excess, solidifies after a time; it is then washed with cold ether, and recrystallised from boiling ether. The *bromanisal*, $C^{10}H^9Br^3O$, thus obtained forms large lustrous crystals, insoluble in water, very slightly soluble in alcohol; it is decomposed by heat, decomposition commencing at about 100° C.; it is not further acted on by bromine.

When oil of anise is treated with *perchloride of tin* or *trichloride of antimony*, it thickens into a red pitchy mass, which, when boiled with water, deposits a white substance, apparently isomeric with anise-camphor. Cahours calls it *anisoin*. It is also formed when oil of anise is gradually mixed with $1\frac{1}{2}$ pts. strong sulphuric acid, and the resulting resinous mass treated with water. It is purified by solution in ether, and reprecipitation by dilute alcohol. Thus obtained, it is a white, inodorous solid which fuses a little above 100° C., and, when further heated, burns with a brilliant flame and an aromatic smell; it is heavier than water; insoluble in water, almost insoluble in alcohol, even on heating; more soluble in ether and volatile oils. It is soluble in strong sulphuric acid, forming a red solution, whence it is reprecipitated by water. It is not attacked by a boiling solution of caustic potash. When distilled, it partly volatilises unchanged and partly passes over as an isomeric oil. When crystallised from its ethereal solution, it forms very small white needles. The substance obtained by Will (Ann. Ch. Pharm. lxv. 230), by dropping oil of anise into a strong solution of *iodide of potassium saturated with iodine*, and treating the resulting magma with 6 or 8 times its volume of alcohol, is, according to Gerhardt, whose statement is confirmed by the recent experiments of Aelsmann and Kraut (*loc. cit.*), identical with anisoin. This substance, when treated with chlorine, yields a chlorine substitution-compound.—Anisoin is also produced by treating oil of anise with chloride of benzoyl. (Aelsmann and Kraut.)

When anise-camphor is distilled with *chloride of zinc*, a volatile oil passes over, which after a time generally deposits crystals, volatile without decomposition and not melting at 100° C. Both oil and crystals have the same composition as the original camphor; and the vapour-density of the oil is the same as that of the camphor. The oil is readily soluble in strong sulphuric acid, forming a fine crimson solution; the addition of water destroys the colour, but does not precipitate anything. By saturating the aqueous solution with carbonate of barium, a gummy salt is obtained, whose solution gives a dark violet colour with ferric salts; both acids and alkalis destroy the colour (Gerhardt). The same product is obtained when oil of anise or anise-camphor is treated with 3—4 pts. concentrated sulphuric acid, water added, the oil which separates filtered off, and the aqueous filtrate saturated with barytic carbonate. It appears to be identical with Laurent's *sulphodraconate of barium*, obtained by him from oil of tarragon.

2. *Oil of Tarragon* (Laurent, Revue Scient. x. 6) consists mainly of a camphor isomeric with that of anise, and behaving in the same manner with nitric and sulphuric acids and metallic chlorides. The proportion of liquid oil in this essence is very small: hence the crude oil does not boil below about 200° C., and the boiling point gradually rises to 206°, where it remains stationary. Its specific gravity is 0·945; vapour-density 6·157 at 230°. When treated with chlorine, it evolves heat and, acid vapours, and gradually becomes more syrupy; one of the products thus obtained (*chloride of draconyl*), of about the consistence of turpentine, gave on analysis percentages which seem to indicate the formula $C^{10}H^{16}Cl^2O.Cl^2$. When treated with alcoholic potash, this substance yielded a thick oil (*chlorodraconyl*) containing 42·5 per cent. carbon and 3·4 per cent. hydrogen.

3. *Oil of Bitter Fennel* (Cahours, *loc. cit*).—This essence is composed of two oils, the less volatile of which can readily be obtained pure by fractional distillation. Its composition is the same as that of anise-camphor; but it does not solidify at 10° C. Its specific gravity is somewhat less than that of water; it boils at 225° C. Treated with nitric acid, it behaves like anise-camphor; with bromine it gives a liquid viscous product, which is very difficult to purify. The more volatile oil appears to have the same composition as oil of turpentine. It boils about 190° C. When a stream of nitric oxide is led into it, it becomes thick and turbid, and on addition of alcohol of specific gravity 0·80, yields a white, silky precipitate, which is purified by repeated washing with alcohol. This substance, which forms fine crystalline needles, contains $3C^{10}H^{16},8NO$. It is discoloured when heated to 100° C., and at a higher temperature is entirely decomposed. It is scarcely soluble in alcohol of specific gravity 0·80, rather more in absolute alcohol, still more in ether; soluble in strong caustic potash, and reprecipitated by acids. When heated with caustic soda, it yields ammonia, an oil smelling like petroleum, and a gas which attacks the eyes. When treated with sulphydrate of ammonium in the cold, and then by an acid, it gives a precipitate which explodes slightly when heated; the filtrate gives an abundant blue precipitate with ferric salts. It dissolves in boiling sulphydrate of ammonium, forming a brown solution, and depositing sulphur, while a strong smell of oil of bitter-almonds is evolved. It is scarcely attacked by boiling hyposulphite of sodium. (Chiozza.) F. T. C.

ANISHYDRAMIDE. *Hydrure d'azoanisyl.* $C^{24}H^{24}N^2O^3$. (Cahours, Ann. Ch. Phys. [3] xiv. 487.)—The action of ammonia upon hydride of anisyl is analogous to that which it exerts upon the hydrates of benzoyl and salicyl, a hydramide being formed:

$$\underset{\text{Hydride of anisyl.}}{3C^8H^8O^2} + 2NH^3 = \underset{\text{Anishydramide.}}{C^{24}H^{24}N^2O^3} + 3H^2O$$

This substance is obtained by abandoning for some time a mixture of 1 vol. hydride of anisyl, and 4—5 vols. of a saturated aqueous solution of ammonia, in a closed vessel, when shining crystals of anishydramide gradually form, until, after some weeks, the whole becomes a semi-solid mass. The crystals are then freed from adhering liquid by pressure between folds of filtering paper, and dried. They are hard, snow-white prisms, very easily powdered; insoluble in water, soluble in boiling alcohol or ether, and in warm concentrated hydrochloric acid, whence they recrystallise on cooling. They melt at about 120° C. When anishydramide is acted on by sulphide of ammonium, a white powder is obtained, which Cahours (Compt. rend. xxv. 458) calls *thianisiol*, and Gerhardt (Traité, iii. 360) *hydride of sulphanisyl.* Its formula is C^8H^8SO.

For the probable constitution of anishydramide, see HYDRAMIDES in art. AMIDES, p. 177.

When anishydramide is kept for two hours at a temperature between 165° and 170° C., it is converted into an isomeric alkaloid, to which the name *anisine* has been given (Bertagnini, Ann. Ch. Pharm. lxxxviii. 128). In order to obtain this substance in a state of purity, it is dissolved in boiling alcohol, and hydrochloric acid added to the solution, when the hydrochlorate separates out in crystals. These are freed from the mother-liquor, decomposed by potash or ammonia, and the free base is recrystallised from alcohol. Thus obtained, anisine forms colourless transparent prisms, scarcely soluble either in hot or cold water, slightly soluble in ether, readily in alcohol. Its solution has a strong alkaline reaction and a bitter taste. Anisine forms crystallisable salts with acids. The *hydrochlorate*, $C^{24}H^{24}N^2O^3.HCl$, crystallises in colourless brilliant needles, slightly soluble in water, readily in alcohol. When dried at the ordinary temperature, they contain $4C^{24}H^{24}N^2O^3.HCl + 9H^2O$; they give off water at 100° C.

The *chloroplatinate*, $C^{24}H^{24}N^{2}O^{3},HCl,PtCl^{2}$, obtained by adding bichloride of platinum to the hydrochlorate, forms brilliant orange-coloured scales, slightly soluble in alcohol.

F. T. C.

ANISIC ACID. *Hydrate of anisyl. Draconic acid*, &c. $C^{8}H^{8}O^{3} = (C^{8}H^{6}O)''.H^{2}.O^{2}$. (Cahours, Ann. Ch. Phys. [3] ii. 287; xiv. 483; xxiii. 351; xxv. 21; xxvii. 439; Laurent, Revue Scient. x. 6, 362; Gerhardt, Ann. Ch. Phys. [3] vii. 292.)—This acid, discovered by Cahours in 1841, is a product of the oxidation of anise-camphor and of the crude oils of anise, fennel, and tarragon. The acids obtained from these several oils were at first distinguished by different names; but their identity is now clearly established. The first product of the oxidation of these substances is hydride of anisyl, which, by further oxidation, is converted into anisic acid. (See ANISYL, HYDRIDE OF.)

Cahours prepares anisic acid by boiling oil of anise with nitric acid of specific gravity 1·2 (23° Baumé), when a yellow resinous substance (*nitraniside*) is formed, together with anisic acid, which crystallises from the acid liquid on cooling. The crystals are washed with cold water, and dissolved in ammonia; the ammonium-salt is repeatedly crystallised till it is colourless, and then decomposed by acetate of lead; the difficultly soluble lead-salt is washed, and decomposed by sulphuretted hydrogen; and the anisic acid is dissolved from the sulphide of lead by boiling water, crystallised, and purified (if necessary) by sublimation.

Laurent's method of preparing it from oil of tarragon is as follows:—1 pt. oil together with a little water, is heated in a large retort, and 3 pts. common nitric acid are added gradually. The mixture thickens by degrees, and is finally converted into a brown, resinous, slightly crystalline mass. This is washed, and extracted with hot dilute ammonia, which dissolves all but a small quantity of a brown substance. The ammoniacal solution is evaporated to a syrup, when it deposits a further portion of the brown substance, which was held in solution by the free ammonia: if the evaporation be carried too far, the anisate and nitranisate of ammonium contained in the solution may be partially decomposed. The syrup is mixed with water, boiled, and filtered through animal charcoal; and the filtrate (neutralised, if acid, by ammonia) is evaporated, when anisate of ammonium crystallises in rhomboidal tables, while the nitranisate remains in the mother-liquor. The anisate is recrystallised two or three times from alcohol, dissolved in a boiling mixture of alcohol and water, and nitric acid added to the hot solution, which, on cooling, deposits crystals of anisic acid. These are further purified by recrystallisation from boiling alcohol, and, if necessary, by sublimation.

Anisic acid may also be prepared by dropping hydride of anisyl upon fused caustic potash. A soft resinous mass is obtained, which, when dissolved in water and saturated with hydrochloric acid, deposits crystals of anisic acid, which are purified as above. If hydride of anisyl be procurable, this is the most advantageous method, since the formation of nitranisic acid is entirely avoided. (Handwb.)

Anisic acid crystallises in brilliant colourless prisms, belonging to the monoclinic system, often of considerable size, with angles of 114° and 66°. The acute edges are mostly truncated; the base is replaced by two principal and three smaller faces. It has no taste or smell; is tolerably soluble in hot, but scarcely in cold, water; readily soluble in alcohol or ether, especially on boiling; its solution reddens litmus feebly. It fuses at 175° C, and solidifies on cooling to a crystalline mass; at a higher temperature it sublimes without decomposition into snow-white needles.

It is isomeric with salicylate of methyl.

It is violently attacked by chlorine and bromine (see below, SUBSTITUTION-PRODUCTS). Hot concentrated nitric acid converts it into nitranisic acid. Fuming nitric acid converts it into dinitranisol or trinitranisol (see ANISOL), the product varying with the duration of the reaction and the proportion of the reagents. If heat be applied, a third substance, chrysanisic acid, isomeric with trinitranisol, is simultaneously formed. A mixture of sulphuric and fuming nitric acids converts it into trinitranisol. Perchloride of phosphorus attacks it violently, forming chloride of anisyl, chloride phosphoryl, and hydrochloric acid. When distilled over caustic baryta, it is decomposed into carbonic anhydride and phenate of methyl (anisol).

$$C^{8}H^{8}O^{3} = CO^{2} + C^{6}H^{5}(CH^{3})O.$$

Anisates. Anisic acid is usually considered as monobasic; but it is probably diatomic, like glycollic and lactic acids. The general formula of the anisates is $C^{8}H^{7}MO^{3}$ (see ANISYL). They are mostly crystallisable: the alkaline and earthy salts are soluble, and the addition of a mineral acid separates anisic acid from their solutions.

The *aluminium-salt* crystallises slowly in fine needles, when a dilute solution of alum is added to anisate of ammonium.

The *ammonium-salt*, $C^{8}H^{7}(NH^{4})O^{3}$, is very soluble, and crystallises in large rhombic tables, the angles of whose base are 84° and 96°. Exposed to the air, they become opaque: heated to 99° C. in vacuo, they lose ammonia, pure anisic acid being left behind.

The *barium-salt*, when prepared directly by boiling anisic acid with baryta, crystallises first in needles, and then in rhomboidal scales. Chloride of barium does not precipitate anisate of ammonium immediately, but after some time, a difficultly soluble crystalline precipitate forms.

The *calcium-salt*. Chloride of calcium precipitates anisate of ammonium immediately; if the solutions are dilute, it crystallises in groups of needles.

The *copper-salt* is a bluish-white precipitate.

The *ferric-salt* is a yellow precipitate, composed of microscopic needles.

The *lead-salt* is a white precipitate, soluble in hot water, whence it crystallises on cooling in shining scales, which retain ½ atom of water after drying at 120°.

The *magnesium-salt* is soluble.

The *manganese-salt* crystallises slowly from a mixture of sulphate of manganese and anisate of ammonium.

The *mercuric*, *mercurous*, and *zinc-salts* are white precipitates; the first crystallises from hot water in microscopic needles.

The *potassium-salt* crystallises in rhomboidal or hexagonal tables; the *sodium-salt* in needles.

The *silver-salt* is a white precipitate, crystallising from hot water in fine needles, or pearly scales.

The *strontium-salt* crystallises gradually in small hexagonal or rectangular laminæ, from a mixture of chloride of strontium and anisate of ammonium.

ANISIC ETHERS. (Cahours, Ann. Ch. Phys. [3] xiv. 492.)

Anisate of Methyl, $C^9H^{10}O^3 = C^8H^7(CH^3)O^3$.—A mixture of 2 pts. anhydrous wood-spirit, 1 pt. anisic acid, and 1 pt. strong sulphuric acid, assumes an intense carmine-red colour; on the application of a gentle heat, wood-spirit first passes over, and then a heavy oil, which solidifies in the receiver. This is anisate of methyl. It is purified by washing with hot sodic carbonate, and with water, and recrystallisation from alcohol or ether. Thus prepared, it forms large, white, shining scales, which melt about 47° C., and solidify on cooling to a crystalline mass; at a higher temperature it distils undecomposed. It has a faint smell, resembling that of oil of anise, and a burning taste. It is insoluble in hot or cold water; readily soluble in alcohol or ether, especially on boiling. Unlike salicylate of methyl, it does not combine with potash or soda; but, when boiled with a strong solution of either alkali, is decomposed into methylic alcohol and an alkaline anisate. Aqueous ammonia does not dissolve it, but gradually decomposes it into methylic alcohol and anisamide, the latter of which crystallises out. Bromine, chlorine, and fuming nitric acid attack it violently, forming respectively the methyl-salts of the corresponding substitution-acid.

Anisate of Ethyl. $C^{10}H^{12}O^3 = C^8H^7(C^2H^5)O^3$.—When a solution of 1 pt. anisic acid in about 6 pts. absolute alcohol is saturated at about 60° C. with hydrochloric acid gas, a fuming liquid is obtained, whence water precipitates only anisic acid. On distilling this liquid chloride, hydrate, and finally anisate of ethyl pass over; and on adding water to the distillate, the latter product separates out as a heavy oil, which is washed with sodic carbonate, dried over chloride of calcium, and rectified over oxide of lead. It is a colourless oily liquid, heavier than water, with a smell like that of oil of anise, and a warm aromatic taste. It boils between 250° C. and 255°, is insoluble in water, readily soluble in alcohol and ether. It may be kept unchanged in closed vessels; but, when exposed to the air, it gradually becomes acid. Its decompositions are precisely analogous to those of the methyl-salt.

Substitution-derivatives of Anisic Acid.

BROMANISIC ACID. *Bromodraconesic acid* (Laurent). $C^8H^7BrO^3$.—When powdered anisic acid is treated with bromine, heat is evolved, together with abundance of hydrobromic acid; the product is washed with water, and crystallised from boiling alcohol. Bromanisic acid is thus obtained in white shining needles, slightly soluble in hot water, readily in hot alcohol or ether. It melts at 205° C., and sublimes in iridescent laminæ. When distilled with lime, it yields carbonic anhydride and bromanisol. The alkaline bromanisates are soluble; the potassium and sodium-salts yield bromanisol by dry distillation. In their solution, lead-, silver-, barium-, strontium-, and calcium-salts give white precipitates; the last three are not quite insoluble, but crystallise gradually from dilute solutions.

Bromanisate of Methyl, $C^8H^6(CH^3)BrO^3$, is obtained by dropping bromine on the anisate, and treating the yellowish-red product as in the case of bromanisic acid. Also in the same manner as the anisate, bromanisic being substituted for anisic acid. The mixture is boiled in a water-bath for a quarter of an hour, and water added, when the bromanisate separates in flakes, which are washed with dilute ammonia and crystallised from hot alcohol. It forms colourless transparent prisms, which melt at a gentle heat: it is insoluble in water; soluble, especially on heating, in alcohol and wood-spirit; less soluble in ether. By boiling potash it is decomposed like the anisate.

Bromanisate of Ethyl, $C^8H^6(C^2H^5)BrO^3$, is obtained by the same process as anisate of ethyl, anisic being replaced by bromanisic acid; or by treating anisate of ethyl with bromine. It is purified in the same way as the methyl-salt. It forms long, white, shining needles, insoluble in water, soluble in alcohol or ether: it fuses at a gentle heat, and sublimes undecomposed. It is decomposed by boiling potash, and is not attacked by excess of bromine.

CHLORANISIC ACID, $C^8H^7ClO^3$, is obtained by passing chlorine over anisic acid in fusion; the product is washed with water, and crystallised from alcohol of 95 per cent. It forms fine shining needles, scarcely soluble in water, readily in alcohol or ether. It melts at about 176° C., and may be sublimed without decomposition. It is not acted upon by chlorine, even in sunshine. Strong sulphuric acid dissolves it by aid of gentle heat; it recrystallises from the solution on cooling, or is at once precipitated by water. When heated with baryta, it is decomposed like anisic acid. The metallic chloranisates resemble the corresponding bromanisates in solubility and general properties. The *chloranisates of methyl* and *ethyl* are obtained by submitting the corresponding anisates to the action of dry chlorine; the latter may also be prepared in a similar way to anisate of ethyl. Both are crystalline compounds, insoluble in water, soluble in alcohol or ether, and decomposed by boiling potash.

NITRANISIC ACID, $C^8H^7(NO^2)O^3$, is formed by the action of strong warm nitric acid on anisic acid. It is usually prepared by boiling oil of anise with nitric acid of specific gravity 1·33 (36° Baumé), until the oily substance which first forms has completely disappeared. The addition of water then precipitates yellowish flakes of impure nitranisic acid. This is purified by washing with water, dissolving in ammonia, recrystallising the ammonium-salt till it is colourless, dissolving it in water, precipitating the acid by nitric or hydrochloric acid, and washing it repeatedly with water. It is also formed in Laurent's process for preparing anisic acid from oil of tarragon, remaining in the ammoniacal mother-liquor whence anisate of ammonium has crystallised out. It is obtained thence by adding nitric acid, washing the precipitate, and boiling it for half an hour with nitric acid; the acid solution deposits on cooling short prisms of nitranisic acid, which are washed with water, and crystallised from hot alcohol. Nitranisic acid crystallises in small shining needles, of a slight yellow tinge, without taste or smell. It is scarcely soluble even in hot water; readily in alcohol or ether. It melts between 175° and 180°. When carefully heated further, it partly sublimes, partly blackens, and is decomposed; if heated suddenly, it decomposes at once, with evolution of light. It is not attacked by chlorine, bromine, or strong nitric acid; by fuming nitric acid, it is acted on in the same way as anisic acid. When heated with perchloride of phosphorus, it yields a dark yellow oil, with a very high boiling point, which is probably chloride of nitranisyl, $C^8H^6(NO^2)O^2,Cl$ (Cahours). An alcoholic solution of sulphide of ammonium converts it into anisamic acid (p. 291). According to Laurent (*loc. cit.*) nitranisic acid combines, atom for atom, with anisic, chloranisic, and bromanisic acids, forming peculiar dibasic acids.

The alkaline *nitranisates* are soluble and crystallisable: the ammonium-salt crystallises in fine needles, grouped in spheres; it is soluble in alcohol. The alkaline-earthy nitranisates are difficultly soluble; those of the heavy metals generally insoluble.

Nitranisate of methyl is prepared by a process analogous to that described in the case of anisate of methyl; or by dissolving anisate of methyl in fuming nitric acid, adding water, and crystallising the precipitate from alcohol. It forms beautiful large shining tables of a yellowish hue. It is insoluble in water; readily soluble in hot alcohol or wood-spirit, whence it separates almost completely on cooling. It melts at about 100° C., and sublimes undecomposed.

Nitranisate of ethyl is prepared either by dissolving anisate of ethyl in an equal volume of fuming nitric acid, or by a process analogous to that described in the case of anisate of methyl. In the latter case, the mixture must be kept at a temperature of 60°—70° C., while it is saturated with hydrochloric acid. The compound is precipitated by water, washed with dilute ammonia, and crystallised from alcohol. It exactly resembles the methyl-salt in appearance, and solubility in water and alcohol, and melts between 98° and 100° C. Strong sulphuric acid dissolves it in the cold, more readily on heating; it partly recrystallises as the solution cools, and is completely precipitated by water. Bromine exerts no action upon it.

Trinitranisic Acid, $C^8H^5(NO^2)^3O^3$, is obtained by treating anisic acid in the cold with a mixture of fuming nitric and fuming sulphuric acid, and diluting the mixture with 8 to 10 times its volume of water. It forms very beautiful salts with the alkalis, especially with ammonia and potash.

SULPHANISIC ACID, $C^8H^8O^3,SO^3$. (Zervas, Ann. Ch. Pharm. ciii. 339; Limpricht, Gm. Handb. xiii. 128.)—Obtained by heating anisic acid with common sulphuric acid to 110° C. or with fuming sulphuric acid to 100°, diluting the mixture with water, adding carbonate of lead, filtering at the boiling heat, and boiling the insoluble residue with water as long as the filtered liquid yields crystals of the lead-salt on cooling. These, when decomposed by sulphuretted hydrogen, yield the acid (Zervas). Limpricht treats anisic acid with sulphuric anhydride.

Sulphanisic acid, obtained by slow evaporation of the aqueous solution, forms needles which are permanent in the air, and give off 6·9 per cent. (1 at.) water at 100° C., and suffer no further decomposition below 170°. The aqueous solution may be boiled without decomposition.

Sulphanisic acid is dibasic. The *sulphanisates* of ammonium, potassium, and sodium crystallise readily, the first in long slender needles. The *barium-salt*, $C^8H^6Ba^2O^3.SO^3 + 8H^2O$, obtained by saturating the acid with carbonate of barium, forms fine crystals, which, after drying over sulphuric acid, give off 16·9 per cent. (8 at.) water at 180° C. It dissolves easily in water, and is precipitated by alcohol. The *magnesium-salt* forms very soluble needles. The *normal lead-salt*, $C^8H^6Pb^2O^3.SO^3 + 8H^2O$, forms beautiful needles, which give off their water at 180° C. The *acid lead-salt*, $C^8H^7PbO^3.SO^3 + H^2O$, forms nodular crystals; easily soluble in water.

The *silver-salt* forms nodular crystals, sparingly soluble in water. According to Zervas, the solubility of the barium and lead-salts is diminished by repeated crystallisation. F. T. C.

ANISIC ALCOHOL. *Hydrate of Anisalyl*, $C^8H^{10}O^2 = C^8H^9O.H.O$. (Cannizzaro and Bertagnini, Ann. Ch. Pharm. xcviii. 188.)—Formed from hydride of anisyl in the same way as benzoic alcohol from hydride of benzoyl. When a solution of pure hydride of anisyl in an equal volume of alcohol is mixed with three times its bulk of alcoholic potash of about 7° Beaumé (specific gravity 1·052), a slight evolution of heat takes place, and anisic alcohol and anisate of potassium are formed, the latter in such quantity that the mixture shortly becomes a crystalline pulp. ($2C^8H^8O^2 + KHO = C^8H^7KO^3 + C^8H^{10}O^2$.) After 10 or 12 hours, the alcohol is distilled off in a water-bath, and the residue is suspended in water, and extracted with hot ether. On evaporating the ethereal solution, a brown oil is obtained, and on distilling the oil, anisic alcohol passes over at about 260°C., as a colourless liquid, which crystallises on cooling. This product generally contains some hydride of anisyl, which may be detected by agitating it with a concentrated solution of acid sulphite of sodium (see ANISYL, HYDRIDE OF). To purify it, it is treated again with a small quantity of alcoholic potash, distilled in carbonic anhydride, and the crystalline distillate pressed between filter-paper.

Anisic alcohol crystallises in hard, white, shining needles. It distils undecomposed between 248° and 250° C., and melts at 23°, when anhydrous, but at much lower temperatures when moist. It is heavier than water, has a faint spirituous, sweetish smell, and a burning taste like that of oil of anise. At ordinary temperatures, it remains unaltered in the air; but when heated nearly to its boiling point it, absorbs oxygen, and is converted into hydride of anisyl. Oxidising agents (as platinum-black, nitric acid, &c.) convert it, first into hydride of anisyl, then into anisic acid. Potassium dissolves in it with evolution of hydrogen. Sulphuric acid, even when moderately concentrated, or phosphoric anhydride, converts it into a resinous mass Heated with chloride of zinc, it yields water, and an oily liquid, which solidifies on cooling into a hard, transparent, vitreous mass, which melts at 100° C., and is insoluble in water and alcohol, but soluble in bisulphide of carbon.

When treated with hydrochloric acid gas, it forms water and a colourless liquid, having a fruity smell and a burning taste. This substance is its hydrochloric ether, or *chloride of anisalyl*, $C^8H^9O.Cl$, and is decomposed by alcoholic ammonia yielding chloride of ammonium, and the hydrochlorates of anisamine and dianisamine (p. 297).

If, as is probable from its analogy to salicylic acid, anisic acid be regarded as dibasic, anisic alcohol becomes diatomic, $(C^8H^8).H^2.O^2$; and chloride of anisalyl will be

$C^8H^8\left\{\begin{matrix}HO\\Cl\end{matrix}\right.$, analogous to glycolic chlorhydrin. F. T. C.

ANISIC ANHYDRIDE. $C^{16}H^{14}O^5 = C^8H^7O^2.C^8H^7O^2.O$. (Pisani, Ann. Ch. Pharm. cii. 284.)—Formed by the action of oxychloride of phosphorus on dry anisate of sodium; the mass is washed with water, and the insoluble residue crystallised from ether. It forms silky needles, soluble in alcohol or ether, insoluble in water or aqueous alkalis; it melts at 99°C., and distils at a higher temperature. By long boiling with water or aqueous alkalis, it is converted into anisic acid. F. T. C.

ANISIDINE (*Methylphenidine*, Gerh.) $C^7H^9NO = N.C^7H^7O.H^2$. (Cahours. Ann. Ch. Phys. [3] xxvii. 443.)—The action of sulphide of ammonium on the nitro-derivative of anisol gives rise to the formation of peculiar organic bases. Anisidine is obtained by dissolving nitranisol in an alcoholic solution of sulphide of ammonium, evaporating at a gentle heat to a quarter of its volume, adding a slight excess of hydrochloric acid to the brown residue, separating the sulphur by addition of water, and filtering. The yellow-brown filtrate deposits on evaporation, needles of hydrochlorate of anisidine, which are dried with filter paper and distilled with a strong solution of potash, when anisidine passes over with the aqueous vapour in the form of an oil, which solidifies on cooling.

The properties of anisidine but are imperfectly known. It combines with acids, forming salts. The *hydrochlorate* forms fine colourless needles, soluble in water and alcohol. When a hot concentrated solution of this salt is mixed with a concentrated solution of dichloride of platinum, the *chloroplatinate* separates on cooling in yellow needles. The *nitrate*, *sulphate*, and *oxalate* are crystallisable.

The products of the action of sulphide of ammonium on the higher nitro-derivatives of anisol may be regarded as nitro-derivatives of anisidine, though it is not known whether they can be formed by the action of nitric acid on anisidine.

NITRANISIDINE (*Methylnitrophenidine*, Gerh.) $C^7H^8N^2O^3 = C^7H^8(NO^2)NO$.—Prepared by a process similar to that described for anisidine, dinitranisol being substituted for nitranisol. The filtrate is mixed with ammonia, and the precipitate thus formed is washed with water, and crystallised from boiling alcohol. Nitranisidine forms long, garnet-red, shining needles, which are insoluble in cold, soluble in boiling, water; soluble in boiling alcohol, whence it separates almost entirely on cooling; also in ether, especially if heated. It melts at a gentle heat, and on cooling forms a radiated mass; when heated gradually to a higher temperature, it gives off yellow fumes, which condense into yellow needles. Bromine attacks it violently, forming a resinous mass, which has no alkaline properties. Fuming nitric acid decomposes it violently, yielding a viscous mass, insoluble in acids. The chlorides of benzoyl, cinnamyl, cumyl, and anisyl attack it when gently heated, forming hydrochloric acid, and compounds analogous to benzamide, which are described by Cahours under the names of *benzonitraniside*, $C^{14}H^{12}N^2O^4 = N.C^7H^5O.C^7H^6(NO^2)O.H.$, *cinnitraniside*, $C^{16}H^{14}N^2O^4$, &c. These bodies are obtained pure by successively washing the products of these reactions with water, hydrochloric acid, and dilute potash, and crystallising from boiling alcohol; they are insoluble in water or in cold alcohol.

Nitranisidine dissolves readily in acids, and with many of them forms crystalline salts. The *hydrochlorate* and *hydrobromate*, when pure, form colourless needles, slightly soluble in cold, readily in boiling, water. The *chloroplatinate* separates in orange-brown needles from a mixture of hot concentrated solution solutions of the hydrochlorate and dichloride of platinum. The *sulphate* forms concentric groups of silky needles, readily soluble in water, especially in water containing sulphuric acid. The *nitrate* forms large needles, much more soluble in hot than in cold water.

Dinitranisidine (*Methyl-dinitrophenidine*, Gerh.) $C^7H^7N^3O^5 = C^7H^4(NO^2)^2NO$.—Prepared precisely like nitranisidine, trinitranisol being substituted for dinitranisol. When dry, it is an amorphous powder, of a bright red or violet-red colour, according to the concentration of the solution from which it was precipitated. It is almost insoluble in cold water, very slightly in hot water, forming an orange solution: slightly soluble in cold, moderately in hot alcohol, and separates on cooling in violet-black crystals; slightly soluble in hot ether. It melts at a gentle heat, and solidifies on cooling into a radiated, violet-black, crystalline mass. It is much less basic in its properties than the foregoing compound: it forms crystallisable salts with hydrochloric, nitric, and sulphuric acids, if the acids be employed in excess, but these compounds are decomposed by water. When heated with fuming nitric acid, it is violently attacked, and yields a yellowish brown resinous mass, which dissolves in potash, forming an intensely brown solution. F. T. C.

ANISINE. See ANISHYDRAMIDE.

ANISOIC ACID. $C^{10}H^{10}O^6$. (Limpricht and Ritter, Ann. Ch. Pharm. xcvii. 364.)—A product of the oxidation of oil of star-anise (probably also of oil of anise, tarragon, fennel, &c.). The oil is heated with nitric acid, of specific gravity 1·2, and the oily layer which sinks to the bottom of the mixture is agitated with a warm solution of acid sulphite of sodium, whence anisoate of sodium crystallises on cooling. To the purified crystals, enough sulphuric acid is added to decompose the salt, the whole evaporated to dryness, and the acid extracted from the residue by absolute alcohol. It crystallises from its aqueous solution in small laminæ, which have a strong acid reaction, and are very soluble in water, alcohol, and ether; they melt at about 120° C., and are not volatile without decomposition.

Anisoates are mostly readily soluble. The *sodium-salt*, $C^{10}H^{11}NaO^6$, and the *barium-salt*, form white crystalline nodules. The *silver*-salt forms soluble nodules, and speedily blackens when moist. F. T. C.

Städeler and Wächter (Ann. Ch. Pharm. cxvi. 169) regard this acid as identical with *thianisoic acid*, $C^{10}H^{14}SO^4$, the product which they obtain by treating anise-camphor with nitric acid of specific gravity 1·106, then distilling and agitating the distillate with acid sulphite of sodium and alcohol. The atomic weights of the two acids are nearly equal (anisoic acid = 234; thianisoic acid = 230), so that the determinations of carbon and metal in Limpricht and Ritter's analyses of the silver and barium-salts will agree with the one formula as well as with the other. Moreover in Limpricht and Ritter's analyses of both these salts, the amount of hydrogen found was much too low for the formula of anisoic acid (in the barium-salt 5·44 per cent., by calculation 5·65; in the silver-salt 4·0 per cent., calculation 4·98), and the absence of sulphur was not established by direct experiment. (See THIANISOIC ACID.)

ANISOIN. See ANISE, OIL OF.

ANISOL. *Phenate of methyl. Dracol.* $C^7H^8O = C^6H^5(CH^3)O$. (Cahours, Ann. Ch. Phys. [3] ii. 274; x. 353; xxvii. 439.)—This compound is formed by the action of caustic baryta on anisic acid, or on its isomer, salicylate of methyl: also directly from phenic acid, by the substitution of methyl for 1 at. hydrogen. It may be obtained in various ways. Anisic acid distilled with excess of caustic baryta or lime, is decomposed, anisol passing over as a volatile oil: $C^8H^8O^3 + Ba^2O = C^7H^8O + CO^3Ba^2$. The same result follows when salicylate of methyl is dropped on finely powdered baryta, and the mixture gently distilled. A third method is to heat phenate of potassium with iodide of methyl in a sealed tube, to 100°—120° C. $C^6H^5KO + CH^3I = C^6H^5(CH^3)O. + KI$. The product of either of these reactions is washed with dilute potash and with water, and rectified over chloride of calcium.

Anisol is a colourless, very mobile liquid, with a pleasant aromatic smell. It is insoluble in water, very soluble in alcohol and ether, insoluble in potash. Its specific gravity at 15° C. is 0·991; it boils at 152° C., and distils undecomposed. It is isomeric with benzoic alcohol and taurylic acid.

It may be distilled over phosphoric anhydride without decomposition. It dissolves entirely in strong sulphuric acid, and is not precipitated by water, a copulated acid being formed. This acid, which Cahours calls *sulphanisolic*, and Gerhardt *methyl-sulphophenic* acid, has the formula $C^7H^8SO^4$. By saturating the acid liquid with carbonate of barium, a crystalline barium-salt is obtained, which contains 1 at. barium. If fuming sulphuric acid be employed, not in excess, the addition of water separates crystalline flakes of a neutral body, which Cahours calls *sulphanisolide*. Its formula is $C^{14}H^{14}SO^4$; it is to sulphanisolic acid as sulphate of ethyl is to ethyl-sulphuric acid. This body is best obtained by passing the vapour of sulphuric anhydride into artificially cooled anisol, and adding water to the mixture; sulphanisolide is then deposited in fine needles, which are recrystallised from alcohol, while sulphanisolic acid remains in solution. It forms soft silvery prisms, insoluble in water, soluble in alcohol and ether. It melts at a gentle heat, and sublimes undecomposed. Strong sulphuric acid converts it into sulphanisolic acid.

SUBSTITUTION-DERIVATIVES OF ANISOL.—Chlorine and bromine form with anisol crystalline substitution-compounds. The chlorine-compounds have not been examined; there are two bromine-compounds, *bromanisol*, C^7H^7BrO, and *dibromanisol*, $C^7H^6Br^2O$. The latter is soluble in boiling alcohol, whence it crystallises in brillant scales. It melts at 54° C., and at a higher temperature sublimes entirely in small shining tables.

Fuming nitric acid acts energetically on anisol, forming three distinct nitro-compounds, *Nitranisol*, *Dinitranisol*, and *Trinitranisol*, according to the proportions of the reagents and the duration of the reaction. *Nitranisol*, $C^7H^7(NO^2)O$, is prepared by adding fuming nitric acid by small portions to anisol, the mixture being kept cool by ice. A bluish-black oily liquid is thus obtained, which is washed with dilute potash, and rectified over chloride of calcium. Anisol distils over first, and when the boiling point remains constant at about 260° C., the receiver is changed. Nitranisol is a clear amber-coloured liquid, heavier than and insoluble in water, with an aromatic smell, something like that of bitter-almond oil. It boils between 262° and 264° C. It is not attacked by aqueous potash, even on heating. When gently heated with strong sulphuric acid, it dissolves, and separates out again on the addition of water. When heated with fuming nitric acid, it is successively converted into di- and tri-nitranisol.

Dinitranisol, $C^7H^6(NO^2)^2O$, is prepared by boiling anisol for a few minutes with excess of fuming nitric acid: on adding water, a yellow liquid is separated, which soon solidifies into a yellow mass, which is recrystallised from boiling alcohol. It is also obtained by heating anisic acid to 90°—100° C., for about half an hour, with two or three times its weight of fuming nitric acid: chrysanisic acid forms at the same time, and is removed by dilute potash. Dinitranisol crystallises in long pale yellow needles, insoluble even in boiling water, soluble in alcohol and ether. It melts at about 86° C., and sublimes undecomposed. Aqueous potash does not attack it, even on boiling, unless the solution be very strong, and even then long boiling is required: when boiled with alcoholic potash, it is speedily decomposed, dinitrophenate of potassium being formed.

Trinitranisol, $C^7H^5(NO^2)^3O$, is formed when anisol, anisic, or nitranisic acid is heated with a mixture of equal parts of strong sulphuric and fuming nitric acid. Anisic acid is generally employed for its preparation. The mixture, which at first is clear and colourless, is gently heated till it begins to become turbid, carbonic anhydride being copiously given off. The heat is then removed, when there gradually collects on the surface an oil, which solidifies on cooling. A large quantity of water is then added, and the solid product is washed with boiling water, and crystallised from a mixture of equal parts of alcohol and ether. The reaction is complete if 15 pts. of the mixed acids be employed for 1 pt. anisic acid. Trinitranisol crystallises in yellowish, very brilliant tables, insoluble in water, soluble in hot alcohol or in ether. It melts at 58°—60° C., and if carefully heated, sublimes. Warm sulphuric or nitric acid dissolves without decomposing it. Aqueous ammonia or dilute potash, does not attack it, even on boiling; but moderately strong aqueous potash gives it an intense brown-red colour, and completely decomposes it on boiling, forming a slightly soluble potassium-salt of an acid, which is isomeric with, but, according to Cahours, distinct from picric, or trinitrophenic acid, which he designates picranisic acid.

All the nitro-derivatives of anisol are readily attacked by alcoholic sulphide of ammonium, sulphur being separated, and anisidine and its nitro-derivatives being formed.
F. T. C.

ANISULMIN. The name given by Brandes and Reimann to a brown product, obtained by extracting anise-seed, after previous treatment with alcohol, water, and hydrochloric acid, with aqueous potash, and precipitating the alkaline solution by acetic acid.
F. T. C.

ANISURIC ACID. $C^{10}H^{11}NO^4$.—An acid analogous to hippuric acid, produced by the action of chloride of anisyl on the silver-compound of glycocoll ($C^2H^4AgNO^2 + C^8H^7O^2Cl = AgCl + C^{10}H^{11}NO^4$). Acids, with aid of heat, convert it into glycocoll and anisic acid. (Cahours, Ann. Ch. Pharm. ciii. 90.)

ANISYL. $C^8H^7O^2$.—A hypothetical radicle, supposed to be contained in anisic acid, hydride of anisyl, and other anisic compounds. It may be regarded as salicyl, $C^7H^5O^2$, in which 1 at. hydrogen is replaced by methyl, $C^8H^7O^2 = C^7H^4(CH^3)O^2$: and, in fact, anisic acid and salicylate of methyl are not only isomeric compounds, but are both decomposed in the same manner by caustic baryta. Anisic acid is, therefore, to salicylic acid, as acetic is to formic acid. If, as Piria's recent researches (Ann. Ch. Pharm. xciii. 262) tend to show, salicylic acid be not monobasic but dibasic, the clear analogy between it and anisic acid, would probably lead to the conclusion that the latter acid is also dibasic; in which case, all anisic compounds must be regarded as containing a diatomic radicle, C^8H^6O, rather than a monatomic radicle, $C^8H^7O^2$.

BROMIDE OF ANISYL. $C^8H^7O^2.Br$. (Cahours, Ann. Ch. Phys. [3] xiv. 486.)—Prepared by dropping dry bromine (excess of which must be avoided), upon hydride of anisyl: heat is evolved, hydrobromic acid given off, and the mixture solidifies. The solid product is rapidly washed with ether, pressed between filter-paper, and crystallised from ether. It forms white, silky crystals, which are volatile without decomposition. Strong boiling potash gradually converts it into anisate and bromide of potassium.

CHLORIDE OF ANISYL. $C^8H^7O^2.Cl$. (Cahours, Ann. Ch. Phys. [3] xxiii. 351.)—When dry anisic acid is treated in a retort with pentachloride of phosphorus, a violent action takes place, and a mixture of products passes into the receiver. These are fractionally distilled, that part which boils between 250° and 270° C. being collected apart, washed with a little water, and rectified over chloride of calcium. Chloride of anisyl also seems to be formed by the action of chlorine on the hydride. It is a colourless liquid, with a strong smell: its boiling point is 262° C.; its specific gravity it 1·261 at 15°. When exposed to moist air, it is speedily decomposed into hydrochloric and anisic acids. In contact with dry ammonia, it evolves heat, and is converted into anisamide (*q. v.*). Alcohol and wood-spirit attack it energetically, forming hydrochloric acid, and anisate of ethyl and methyl respectively.

HYDRIDE OF ANISYL, $C^8H^8O^2 = C^8H^7O^2.H$. *Anisylwasserstoff; Anisylous Acid; Anisic Aldehyde; Anisal.* (Cahours, Ann. Ch. Phys. [3] xiv. 484; xxiii. 354.) —Formed, together with anisic acid, by the oxidation of oil of anise, or of anisic alcohol; in the latter case, the action of platinum-black is sufficient to produce the effect. It is prepared by gently heating oil of anise for about an hour, with three times its volume of nitric acid of specific gravity 1·106 (14° Baumé): the heavy oil which is thus formed is washed with dilute potash, and distilled. The distillate is agitated with a warm solution of acid sulphite of sodium, of specific gravity 1·25; the crystalline compound thus formed is collected on a funnel, thoroughly washed with alcohol, dissolved in as little hot water as possible, and the solution heated with excess of strong sodic carbonate, when the hydride of anisyl separates out and floats on the surface. It is then purified by redistillation. The reaction is as follows, oxalic acid being simultaneously formed:

$$\underset{\text{Oil of anise.}}{C^{10}H^{12}O} + O^6 = \underset{\substack{\text{Hydride}\\\text{of anisyl.}}}{C^8H^8O^2} + \underset{\substack{\text{Oxalic}\\\text{acid.}}}{C^2H^2O^4} + H^2O$$

Hydride of anisyl is a yellowish liquid, with a burning taste, and an aromatic smell somewhat like that of hay: its specific gravity at 20° C. is 1·09, and its boiling-point 253°—255° C. It is almost insoluble in water, but soluble in all proportions in alcohol and ether. Strong sulphuric acid dissolves it, forming a dark-red solution, whence it is reprecipitated by water. When exposed to the air, it gradually absorbs oxygen, and is converted into anisic acid; the same change is produced more rapidly by means of oxidising agents, such as platinum-black, or dilute nitric acid. Strong nitric acid converts it into nitranisic acid. Strong aqueous potash does not dissolve it till after long boiling; fused or alcoholic potash convert it into anisate, with evolution of hydrogen, or formation of anisic alcohol. Prolonged contact with caustic ammonia converts it into anishydramide (*q. v.*). Pentachloride of phosphorus attacks it energetically, the mixture thickening, and finally becoming a black pitchy mass, and a scanty distillate is obtained, consisting of chloride of phosphoryl, together with a neutral oil having a strong smell of turpentine.

Hydride of anisyl possesses the property peculiar to aldehydes, of forming crystalline compounds with acid sulphites of alkali-metal. *Sulphite of anisyl-sodium*, $C^8H^7NaO^2,SO^3 + aq.$ (Bertagnini, Ann. Ch. Pharm. lxxxv. 268), is obtained by agitating hydride of anisyl with a strong solution of acid sulphite of sodium: the mixture assumes the consistence of butter, and finally becomes crystalline. When dried and recrystallised from boiling alcohol, it forms colourless, shining scales; but it is always partially decomposed during crystallisation. It is soluble in cold water, and is reprecipitated by acid sulphite of sodium, in which it is almost insoluble: its aqueous solution is decomposed by boiling, hydride of anisyl being formed and sulphurous anhydride evolved. Acids and alkalis decompose it also. Ammonia dissolves it, forming oily drops which gradually solidify into crystals of anishydramide. Iodine and bromine decompose it readily. The potassium- and ammonium-compounds are similar to the sodium-compound, both in mode of formation and in general properties. F. T. C.

ANKERITE. A variety of dolomite, CO^3CaMg, in which the magnesium is partly replaced by iron and manganese. According to Berthier (Pogg. Ann. xiv. 103), it fuses to a crystalline compound with carbonate of sodium.

ANNABERGITE. See NICKEL-GREEN.

ANNEALING. (*Tempering, Récuit, Anlassen.*)—Many bodies when raised to a high temperature and quickly cooled, become very hard and brittle. This is a great inconvenience in glass, and also in steel, when this metallic substance is required to be soft and flexible. These inconveniences are avoided by cooling the substance very gradually; and the process is called annealing. Glass vessels, or other articles, are carried into an oven or apartment near the great furnace, called the *leer*, where they are permitted to cool, more or less quickly, according to their thickness and bulk. The annealing or tempering of steel, or other metallic bodies, consists simply in heating them, and suffering them to cool again, either upon the hearth of the furnace, or in any other situation where the heat is moderate, or at least the temperature is not very low.—U. (See *Dictionary of Arts, Manufactures, and Mines*, i. 162.)

ANNOTTO. The pellicles of the seeds of the *Bixa orellana*, a liliaceous shrub, from 15 to 20 feet high in good ground, afford the red masses brought into Europe under the name of *annotto*, *anatto*, *arnatto*, *arnotto*, *orlean*, and *roucou*.

The annotto commonly met with in this country is moderately hard, of a brown colour on the outside and a dull red within. It is difficultly acted upon by water, and tinges the liquor of a pale brownish-yellow colour. In rectified spirit of wine, it dissolves very readily, and communicates a high orange or yellowish-red colour

Hence it is used as an ingredient in varnishes, for giving more or less of an orange cast to the simple yellows.

Ether is the best solvent of annotto. Potash and soda, either caustic or carbonated, disolve annotto in large quantity, from which solutions it is thrown down by acids in small flocks. The alkaline solutions are of a deep red colour. Chlorine decolorises the alcoholic solution of annotto, the liquid becoming speedily white and milky. If strong sulphuric acid be poured on annotto in powder, the red colour passes immediately to a very fine indigo blue: but this tint is not permanent, changing to green, and finally to violet, in the course of twenty-four hours. This property of becoming blue belongs also to saffron. Nitric acid, slightly heated on annotto, sets it on fire, and a finely divided charcoal remains. Annotto is soluble both in essential oils, as oil of turpentine, and in fixed oils. (Boussingault, Ann. Ch. Phys. xxviii. 440.)

Annotto contains a crystalline yellow colouring matter, called *bixin* (*q.v.*), which, when treated with alkalis, in contact with air, absorbs oxygen, and is converted into a red substance called *bixein*. Annotto is used in dyeing, but the colours produced by it are all fugitive; also for colouring cheese.—U. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 178.)

ANODE. Faraday's term for the positive pole or electrode in the voltaic circuit. (See ANION and ELECTRICITY.)

ANORTHITE. $Ca^2O.SiO^2 + Al^4O^6.SiO^2 = (Ca\,al^{ii})SiO^4$.—A mineral belonging to the felspar family. It occurs in small crystals belonging to the triclinic system; also massive, with granular, columnar, or coarsely lamellar structure. Cleaves perfectly in two directions, inclined to one another at 85° 48′. Specific gravity 2·66—2·78. Hardness = 6—7. Transparent to translucent, with white, greyish or reddish colour, and vitreous lustre. Streak uncoloured. Fracture conchoïdal. Brittle. Before the blowpipe it melts, and forms with soda a milk-white enamel. Strong hydrochloric acid decomposes it completely, but does not gelatinise it.

Anorthite is found on Vesuvius and Somma, in the island of Procida, in Corsica, near Bogoslowsk in the Ural, on Hecla and in other localities in Iceland, in Java, in the island of St. Eustache in the Antilles, and in the meteorite of Juvenas. The follow- are analyses:

	G. Rose. Somma.	Deville. Antilles.	Damour. Hecla.	Waltershausen. Hecla.	Potyka. Ural.
SiO^2	44·49	45·8	45·97	45·14	46·79
Al^4O^6	34·46	35·0	33·28	32·11	33·16
Fe^4O^6	0·74	—	1·12	2·03	3·04
Ca^2O	15·68	17·7	17·21	18·32	15·97
Mg^2O	5·26	0·9	—	—	—
Na^2O	—	0·8	1·85	1·06	1·28
K^2O	—	—	—	0·22	0·55
Ni^2O and Co^2O	—	—	—	0·77	—
Water	—	—	—	0·31	—
	100·63	100·2	99·43	99·96	100·79

The formula above given, which is that of an orthosilicate, requires 43·2 SiO^2, 36·8 Al^2O^6, 20·0 Ca^2O.

The following are varieties of anorthite having nearly the same composition and crystalline form:—1. *Amphodelite* has the structure and specific gravity of anorthite; found at Logi, in Finland, and Tunaberg in Sweden.—2. *Bytownite*, from Bytown in Canada.—3. *Diploite* or *Latrobite*, from the island Amitok on the coast of Labrador. Rose-red, with the form, structure, and density of anorthite.—4. *Indianite*, from Hindostan. Granular masses, having the structure of felspar.—5. *Lepolite*, from Logi and Orijarfvi in Finland. Resembles amphodelite.—6. *Lindsayite*, from the same localities, appears to be the same altered, and containing a few per cent. of water.—7. *Polyargite*, from Tunaberg. Rose-red; granular; gives off water when heated, and becomes colourless.—8. *Rosellan*, from Åker, Södermanland. Exhibits similar properties.—9. *Sundvilkite*, from Kimito, Finland. Has the form of felspar; and specific gravity = 2·70.—10. *Wilsomite*, from Canada. Rose-red; specific gravity 2·76—2·77: hardness very different in different parts; becomes colourless when heated; gives off water and melts before the blowpipe, swelling up to a white enamel. (Dana, ii. 234; Rammelsberg's Mineralchemie, 590.)

ANOTTO. See ANNOTTO.

ANOXOLUIN. According to Leconte and Goumoens (Compt. rend. xxxvi. 834), fibrin, muscular fibre, albumin, vitellin, globulin, and casein, contain two different substances, one of which, called *oxoluin*, dissolves in glacial acetic acid, while the other, *anoxoluin*, is insoluble in that acid. In fibrin and muscular fibre, the anoxoluin may also be distinguished, when examined by the microscope, by its fibrous structure, from the oxoluin, which is granular. Anoxoluin dissolves with reddish colour in dilute sulphuric acid, whereas oxoluin dissolves but sparingly and with yellowish colour. Anoxoluin is precipitated of a carmine-red colour by mercuroso-mercuric nitrate: oxoluin, light rose-red. Chromic acid dissolves anoxoluin at 100° C., forming a red-brown solution, whereas oxoluin is not affected by it. Hydrochloric acid dissolves the former readily, forming a violet solution, the latter but sparingly, with yellowish colour. A boiling saturated solution of tartaric acid dissolves anoxoluin readily, but not oxoluin.

ANTHOKIRRIN. The yellow colouring matter of the flowers of yellow toad-flax (*Linaria vulgaris* or *Antirrhinum Linaria*, L.).—It may be prepared by treating the flowers with warm alcohol, evaporating to dryness, exhausting with water to dissolve sugar, gum, &c., treating the insoluble portion with alcohol, evaporating again and digesting in ether. On evaporating the ethereal solution, the colouring matter is obtained in yellow nodules. It melts when heated, and sublimes apparently without decomposition. The fixed alkalis dissolve it with red colour; ammonia and alkaline carbonates, with dark yellow colour: from these solutions it is precipitated yellow by acids. Minerals acids dissolve it with red colour, the solutions becoming yellow on standing. The concentrated aqueous solution is precipitated reddish-yellow by acetate of lead, greenish-yellow by cupric-salts, orange-yellow by protochloride of tin. With hydrate of alumina it forms a pale yellow lake. The flowers of toad-flax are sometimes used for dyeing yellow; stuffs dyed with them have a light yellow colour, but assume a dirty yellow colour when exposed to the air. (Riegel, Pharm. Centralb. 1842, 454.)

ANTHOKYAN or **CYANIN.** The blue colouring matter of flowers. (See COLOURING MATTER.)

ANTHOLEUCIN. The white colouring matter of flowers. (See COLOURING MATTER.)

ANTHOPHYLLITE. A mineral belonging to the amphibole family. (See HORNBLENDE.)

ANTHOSIDERITE. A native silicate of iron, found at Antonio Pereira, in Minas Geraes, Brazil. It has an ochre-yellow colour inclining to yellow-brown, and a fibrous radiated structure. Its composition, according to Schnedermann's analysis, is $Si^9Fe^8O^{24} + 2H^2O = 2Fe^4O^3.9SiO^2 + 2H^2O$.

ANTHOXANTHIN. The yellow colouring matter of flowers. (See COLOURING MATTER.)

ANTHRACENE or **ANTHRACIN.** Syn. with PARANAPHTHALIN.

ANTHRACITE. *Blind coal*, *Kilkenny coal*, or *Glance coal*.—There are three varieties.—1. Massive, the conchoïdal of Jameson. Its colour is iron-black, sometimes tarnished on the surface, with a resplendent lustre. Fracture conchoïdal, with a pseudo-metallic lustre. It is brittle and light. It yields no flame, and leaves whitish ashes. It is found in the newest floetz-formations, at Meissner, in Hesse, and Walsall in Staffordshire.—2. *Slaty anthracite.* Colour black, or brownish-black. Imperfectly slaty in one direction, with a slight metallic lustre. Brittle. Specific gravity 1·4 to 1·8. Consumes without flame. It is composed of 72 carbon, 13 silica, 3·3 alumina, and 3·5 oxide of iron. It is found in both primitive and secondary rocks: at Calton Hill, Edinburgh; near Walsall, Staffordshire; in the southern parts of Brecknockshire, Carmarthenshire, and Pembrokeshire, whence it is called Welsh culm; near Cumnock and Kilmarnock, Ayrshire; and mostly abundantly at Kilkenny, Ireland.—3. *Columnar anthracite.* Small short prismatic concretions, of an iron-black colour, with a tarnished metallic lustre. It is brittle, soft, and light. It yields no flame or smoke. It forms a thick bed near Sanquhar in Dumfriesshire; at Saltcoats and New Cumnock in Ayrshire. It occurs also at Meissner in Hesse.—U. (See *Ure's Dictionary of Arts, Manufactures, and Mines.*)

ANTHRACOLITE or **ANTHRACONITE.** A variety of calc-spar or limestone, coloured black or blackish-brown, by coal and bituminous matter, occurring in certain aluminous schists, and similar formations containing vegetable and animal remains, as at Andreasberg in the Hartz, and at Christiania in Norway. When the bitumen predominates, the mineral is called *stinkstone*, from the property which it possesses of emitting, when rubbed or cracked, an odour like that of putrefying animal remains.

ANTHRACOXENE. A fossil resin which occurs in layers of great extent, and 2½ inches thick, between the strata of coal at Brandeisl, near Schlau in Bohemia. It is brownish-black in the mass, but exhibits a hyacinth-red colour in thin layers; has a shining surface, and conchoïdal fracture; is brittle, and yields a yellowish-brown powder. It melts and swells up strong when heated, and burns with a not unpleasant odour, leaving a residue of ferric oxide, lime, sulphuric acid, and silica. It appears to be a mixture of several substances. Ether dissolves a portion of it, leaving a resin, which has, according to Laurent, the composition $C^{40}H^{28}O^{18}$. The ethereal solution deposits after partial evaporation, a brown powder, containing $C^{40}H^{31}O^{7}$, and this, when exposed to the air, takes up oxygen, and becomes partially soluble in alcohol; and the alcoholic solution, precipitated with acetate of copper, yields a flocculent precipitate, containing oxide of copper, in combination with a resin, whose composition is expressed by the formula $C^{40}H^{30}O^{12}$. The portion left undissolved by the alcohol appears to contain $C^{40}H^{30}O^{8}$. (Handw. d. Chem. 2te Aufl. ii. 39.)

ANTHRANILIC ACID. See Phenylcarbamic Acid.

ANTHROPIN. Heintz, in examining human fat, obtained, besides stearic acid, an acid which melted at 52° C., and gave by analysis numbers corresponding to the formula $C^{17}H^{34}O^{2}$. This he at first supposed to be a peculiar acid (anthropic acid) existing in the fat in the form of a glyceride (anthropin); but later investigations proved that it was a mixture of stearic acid with margaric or palmitic acid. (Pogg. Ann. lxxxiv. 238; lxxxvii. 233.)

ANTIARIN, $C^{14}H^{20}O^{5} + 2H^{2}O$.—The poisonous principle of the *Upas antiar*, a kind of green resin which exudes from the upas tree (*Antiaris toxicaria*), and is employed by the Javanese for poisoning their arrows. It is extracted by exhausting the upas with boiling alcohol, evaporating to dryness after the antiar-resin (see below) has deposited, treating the extract with water, and evaporating to a syrup; the antiarin then takes the form of scales, which are purified by recrystallisation. It is without odour, dissolves at 22°·5 C. in 251 parts of water, 70 parts of alcohol, and 2·8 pts. of ether; the solution is neutral to test-papers. It likewise dissolves in dilute acids. When dried at ordinary temperatures, it contains 13·4 per cent of water of crystallisation, which it goes off at 112° C. It melts at 220° C. into a colourless liquid, which assumes a vitreous aspect on cooling, and at a higher temperature turns brown, and exhales acid vapours. Dehydrated antiarin contains $C^{14}H^{20}O^{5}$ (62·69 p.c. C and 7·45 H.) Sulphuric acid colours antiarin brown. Hydrochloric and nitric acids dissolve it without alteration; so likewise do potash and ammonia.

Antiarin applied to a wound produces vomiting, convulsions, diarrhœa, and soon afterwards death; its poisonous action is remarkably accelerated by mixture with a soluble substance, such as sugar. (Mulder, Ann. Ch. Pharm. xxviii. 304.)

ANTIAR RESIN, $C^{16}H^{24}O$.—The *upas antiar* also contains a resin which does not exhibit any poisonous action. It is extracted by treating the upas with boiling alcohol or ether, and is deposited on cooling in white, odourless, glutinous flakes, having a density of 1·032 at 20° C., melting at 60°; insoluble in water; soluble in 325 pts. of alcohol at 20°, and in 44 pts. of boiling alcohol. Boiling ether dissolves ⅝ pt. of the resin. It dissolves readily in essential oils, and is sparingly dissolved by caustic potash. Its alcholic solution is not precipitated by alcoholic acetate of lead; but on adding water to the mixture, a plastic mass is precipitated containing 23·44 per cent. oxide of lead. (Pelletier and Caventou, Ann. Ch. Phys. xxvi. 57; Mulder, Ann. Ch. Pharm. xxvii. 307.)

ANTICHLOR. The application of alkaline hypochlorites (chloride of lime, &c.) to the bleaching of cotton and linen, is attended with this inconvenience, that the fibre is apt to retain a quantity of free chlorine, which gradually rots and destroys it. Hence the necessity of removing this free chlorine, either by long continued washing, or by the application of some reagent which can unite with the chlorine, and convert it into an innocuous compound. Such reagents are called "Antichlors:" their use is especially necessary in the paper manufacture, in which long continued washing involves a considerable waste of the pulp, and on the other hand, the non-removal of the free chlorine is attended with a gradual rotting of the goods after stowage, fading of the coloured quantities, and in some instances partial obliteration of documents written upon the paper thus imperfectly prepared, besides injury of the delicate machinery of the manufactory.

The first substances used for this purpose were the neutral and acid sulphites of sodium (sulphite and bisulphite of soda). A patent for this application of the acid sulphite was granted in 1847 to Mr. Henry Donkin, a manufacturer of paper-maker's machinery, &c. at Bermondsey, and it was largely used till 1853, when it was superseded by *hyposulphite* of *sodium*, which is both cheaper to prepare and more efficacious, its practical value being just double that of the acid sulphite. (See Hyposulphites, under Sulphur.) The products formed by the action of chlorine, (or hypochlorous acid) on sulphite or hyposulphite of sodium, are sulphate and chloride of sodium, both of which are perfectly innocuous, and easily removed by washing.

To ensure the complete removal of the free chlorine, the bleached paper or other material, or the wash water which runs from it, must be tested with a mixture of iodide of potassium and starch: the slightest trace of chlorine will be indicated by a blue colour. To ascertain whether an excess of the antichlor has been used, add to the mixture of starch and iodide of potassium a few drops of the bleaching liquid, so as to produce a blue colour, and then add a portion of the liquid to be tested; if the antichlor is present in excess, the colour will be destroyed.

Sulphide of calcium, prepared by boiling sulphur with milk of lime, has also been used as an antichlor; so likewise has a solution of protochloride of tin in hydrochloric acid; in the latter case, however, it is necessary, after the completion of the bleaching process, to add carbonate of sodium, in order to neutralise the free hydrochloric acid, which would otherwise act as injuriously as the free chlorine itself. The precipitate of oxide of tin thereby produced is quite white and soft, and does not interfere with the subsequent stages of the paper manufacture.

Lastly, coal-gas has been used since 1818, as an antichlor in paper making; it does not appear, however, to be so convenient as the reagents above-mentioned. (See BLEACHING, *Ure's Dictionary of Arts, Manufactures, and Mines.*)

ANTICHLORISTIC THEORY. See CHLORINE.

ANTIGORITE. A hydrated silicate of magnesium belonging to the serpentine group, found in the valley of Antigoria in Switzerland. (See SERPENTINE.)

ANTIMONATES. See ANTIMONY, OXIDES OF.

ANTIMONIAL COPPER. Native sulphide of copper and antimony, or Wolfsbergite. (See COPPER, SULPHIDES OF.)

ANTIMONIAL COPPER GLANCE. Also called *Wolchite.*—A mineral found in the iron mines at St. Gertraud, in Carinthia. Short rhombic prisms with cleavage parallel to the brachydiagonal, imperfect; also massive. Specific gravity 5·7—5·8. Hardness = 3. Colour blackish lead-grey. Fracture conchoïdal, to uneven; brittle. Contains, according to Schrotter's analysis, 28·60 S, 16·5 Sb, 6·04 As, 29·50 Pb, 17·35 Cu, 0·40 Fe, = 95·94. (Dana, ii. 82.)

ANTIMONIAL CROCUS. See ANTIMONY, OXYSULPHIDE OF.

ANTIMONIAL LEAD ORES. See LEAD, SULPHIDES OF.

ANTIMONIAL NICKEL, and **ANTIMONIAL SILVER.** See ANTIMONY, ALLOYS OF.

ANTIMONIAL SULPHIDE of SILVER. See SILVER, SULPHIDE OF.

ANTIMONITE. Native Sulphide of Antimony.

ANTIMONITES. See ANTIMONY, OXIDES OF.

ANTIMONY. *Spiessglanzmetall, Spiessglassmetall, Antimoine, Antimonium, Stibium.* Symbol, Sb. Atomic weight (as determined by the recent experiments of Schneider) = 120·3.[*]

Some of the compounds of antimony were known to the ancients; but the method of preparing the metal itself was first described by Basilius Valentinus towards the end of the fifteenth century.

Antimony is found native, and alloyed with other metals; viz. with arsenic, nickel, and silver; also in combination with oxygen; viz. as trioxide, in the form of *antimony bloom, white antimony*, or *Valentinite*, Sb^2O^3 and as tetroxide, *antimony ochre*, or *Cervantite*, Sb^2O^4; in combination with sulphur, as *stibnite* or grey *antimony ore*, Sb^2S^3; with sulphur and oxygen, as *red antimony*, *antimony blende*, or *kermesite* $Sb^2O^3.2Sb^2S^3$; also as sulphide combined with various other metallic sulphides, chiefly those of lead and silver, *e.g. zinkenite*, $Pb^2S\ .\ Sb^2S^3$; *miargyrite*, $Ag^2S.Sb^2S^3$, &c. (See SULPHANTIMONITES.) Lastly it occurs in ferruginous water, associated with arsenic, tin, lead, and copper.

Preparation.—All the antimony of commerce is obtained from the native trisulphide, which occurs in many localities among the older rocks, gneiss, clayslate, porphyry, &c. The sulphide is first separated from its gangue by fusion (p. 329), then converted into oxide by roasting, and the oxide is subsequently reduced by coal or charcoal; or the sulphide is at once reduced to the metallic state by fusion with a mixture of charcoal and alkali, or with metallic iron. The following details are taken from Gmelin's Handbook, vol. iv. p. 318.

1. Powdered grey sulphide of antimony, mixed with about half its weight of charcoal powder to prevent caking, is roasted at a gentle heat (on the small scale, on a

---

[*] Berzelius estimated the atomic weight of antimony at 129, which number was for a long time adopted; H. Rose (J. pr. Chem. lxviii. 115, 376) obtained the number 120·7; Dexter (Pogg. Ann. c. 563) estimated it at 122·3. (See page 321.)

roasting dish; on the large scale, in a reverberatory furnace), with constant stirring, the fire being gradually increased, but not sufficiently to fuse the mass. The sulphur escapes in the form of sulphurous acid, and there remains a mixture of tetroxide of antimony with a small quantity of trioxide, amounting to about $\frac{1}{3}$ of its weight (Geiger and Reimann, Mag. Pharm. xvii. 136), and traces of undecomposed sulphide of antimony: *Antimony-ash, Calx Antimonii grisea per se*, or *Cinis Antimonii*. This residue is then mixed with half its weight of cream of tartar, or with 1 part of charcoal and $\frac{1}{2}$ pt. potash, or with charcoal powder saturated with an aqueous solution of carbonate of sodium, and fused in a covered crucible at a low red heat; the fused mass is then poured out into a hot mould partly filled with tallow, and the mould gently tapped to make the metal sink to the bottom. The slag at the top consists of a mixture of alkaline carbonate, double sulphide of antimony and potassium (or sodium) and charcoal. The charcoal separates the oxygen from the antimony, and from a portion of the alkali; and the potassium or sodium thus eliminated separates the sulphur from part of the sulphide of antimony still present, and then, in the form of sulphide, unites with the remainder.—2. A mixture of 8 parts of sulphide of antimony, and 6 parts of cream of tartar is heated in a crucible, nearly to redness, and from 2 to 3 parts of nitre are added till the mass becomes perfectly fused. Or a mixture of 8 pts. of sulphide of antimony, 6 pts. of cream of tartar, and 3 pts. of nitre, is projected by small portions at a time into a red-hot crucible placed in a furnace, and the whole is heated for a short time, till perfectly fused. The mass is then poured out as before. The lower stratum consists of metallic antimony; the upper, of double sulphide of antimony and potassium mixed with charcoal. The charcoal in the black flux withdraws oxygen from the potash; the potassium thus separated decomposes a portion of the sulphide of antimony, setting the metal free; and the resulting sulphide of potassium unites with the still undecomposed sulphide of antimony. Probably according to the following equation:

$$6Sb^2S^3 + 6K^2O + 6C = 3(2K^2S.Sb^2S^3) + 4Sb + 6CO.$$

According to this, only $\frac{2}{5}$ of the antimony contained in the sulphide should be obtained in the metallic state, or from 100 parts of the sulphide of antimony, 29·15 parts of regulus. This result accords with actual experience, 100 parts of sulphide of antimony being found to yield 27 parts of antimony. According to Liebig, however, by leaving out the nitre in this process, 100 parts of sulphide of antimony produce 45 parts of the metal.—3. An intimate mixture of 8 parts of sulphide of antimony with 1 pt. of dry carbonate of sodium and 1 pt. of charcoal, heated in an earthen crucible, and constantly stirred with a stick till it fuses quietly, and then poured out into the casting mould, yields 5·7 parts (71 per cent.) of antimony, which is afterwards purified from iron and copper by fusion with $\frac{1}{4}$ its weight of nitre (Duflos, Br. Arch. xxxvi. 277; xxxviii. 158). In this process, rather more than 3 atoms of carbonate of sodium and charcoal are used to 1 atom of trisulphide of antimony, so that a sufficient quantity of sodium is set free to separate the whole of the sulphur:

$$Sb^2S^3 + 3Na^2O + 3C = 2Sb + 3Na^2S + 3CO.$$

The fusion must be continued for a long time, during which the mass is very apt to boil over, and the antimony to burn away; the total amount obtained is only 66 per cent., and the antimony still contains the whole of the other metals which were present in the sulphide (Liebig, Mag. Pharm. xxxv. 120).—4. A mixture of 177 pts. (1 at.) of sulphide of antimony with at most 82 pts. (3 at.) of iron filings or iron nails is heated to bright redness in a closely covered crucible, and then left to cool:

$$Sb^2S^3 + 6Fe = 2Sb + 3Fe^2S.$$

The iron separates the whole of the sulphur, even at a gentle heat; but a stronger heat is required to fuse the sulphide of iron, and cause the antimony to form a distinct stratum beneath it; at this high temperature, the antimony is apt to burn away if the crucible be not well covered; hence a layer of charcoal powder over the mixture is useful.—The addition of carbonate of potassium or sodium, or of nitre, accelerates the fusion, because double sulphide of iron and potassium or sodium is thereby formed, which is more readily fusible than pure sulphide of iron. For example, 22 pts. of nitre are added to a strongly ignited mixture of 100 pts. of sulphide of antimony and 33 pts. of iron, or 6 pts. of nitre to 100 pts. of sulphide of antimony and 47 pts. of iron; —or 100 pts. of sulphide of antimony, 43 pts. of iron, from 10 to 50 pts. of dry carbonate of sodium, and 2 to 5 pts. of charcoal are melted together. Berthier, however, found it most advantageous to fuse together 100 pts. of sulphide of antimony, 55—60 pts. of smithy scales, 45 pts. of carbonate of potassium, and 10 pts. of charcoal: this mixture yielded 69 pts. of antimony; the mass, however, was found to froth up considerably. Liebig (Mag. Pharm. xxxv. 120) gives the preference to this method; but the regulus which it separates from sulphide of antimony containing lead is contaminated with that metal (Ann. Ch. Pharm. xxii. 62). A mixture of 100 pts. of sulphide of antimony, 42 pts. of iron, 10 parts of dry sulphate of sodium, and 2½ pts. of charcoal, yields between 60 and 64 pts. of antimony (Liebig).—The slag obtained in the second process likewise yields a large quantity of antimony by fusion with iron, because the double sulphide of antimony and potassium is thereby converted into double sulphide of iron and potassium.

Antimony obtained by the first, second, and third processes,—the *Regulus Antimonii simplex s. vulgaris*, which solidifies in the mould, and has a stellated structure on the upper surface, whence it has been called *Regulus Antimonii stellatus*,—may contain sulphur, potassium, arsenic, lead, iron, and copper; the antimony prepared by the fourth method, *Regulus Antimonii martialis*, may contain a large quantity of iron, especially when the iron has been used in excess. The powdered antimony may be freed from iron by fusing it with sulphide of antimony; from sulphur, by fusion with carbonate of potassium; from sulphur and potassium, by fusion with nitre; and, according to Berzelius, from sulphur, potassium, arsenic, and iron, by fusion with from ½ to 1 pt. of antimonious oxide.

By fusing sulphide of antimony, or the slag obtained in the second process, with tin, lead, copper, silver, &c., an antimony is obtained, which may contain small quantities of these metals; antimony thus prepared was formerly called *Regulus Antimonii jovialis, saturninus, venereus, lunaris*, &c.

Purification.—1. By the following method, commercial antimony and likewise that prepared on the small scale, may be perfectly freed from sulphur, arsenic, iron (when not in too large quantity), and copper, but not from lead: hence the antimony subjected to this process, should be free from lead. A mixture of 16 pts. of coarsely pounded antimony with 1 pt. of grey sulphide of antimony and 2 pts. of dry carbonate of sodium, is fused in a hessian crucible for an hour, care being taken to prevent any charcoal from falling into the mass. When cold, the crucible is broken, and the slag completely separated from the metal, which is again coarsely pulverised, fused with 1½ pt. dry carbonate of sodium for an hour, and, lastly, after cooling and removal of the slag, once more fused with 1 pt. of carbonate of sodium. In this manner 15 pts. of pure antimony are obtained (Liebig, Ann. Ch. Pharm. xix. 22). The sulphide of antimony converts the other metals, except the lead, into metallic sulphides, which pass into the slag in combination with sulphide of sodium. The remaining arsenic is separated by the carbonate of sodium, in the form of arsenate of sodium. If any charcoal falls into the crucible, it reduces arsenic from the arsenate of sodium, whereby the antimony is again rendered impure (Liebig). Hence a black-lead crucible cannot be used; such a crucible also reduces sodium, which then mixes with the antimony (Anthon, Repert. lix. 240). If the commercial antimony has been prepared with iron, and is consequently richer in iron, a larger quantity of sulphide of antimony must be added in the first fusion, that is to say, in proportion nearly corresponding to the iron (4 pts. of sulphide of antimony and 4 pts. of carbonate of sodium, to 16 parts of the antimony): in this case, the loss of antimony is greater. As long as iron is present, it is impossible to remove the arsenic by means of carbonate of sodium (Liebig, Ann. Ch. Pharm. xxix. 58; Handwörterb. 2te Aufl. ii. 45; see also Buchner, Repert. li. 267).—2. Well washed powder of algaroth is reduced with alkali and charcoal. By this means, all impurities from the heavy metals are got rid of. Artus (J. pr. Chim. viii. 127) digests 1 pt. of finely powdered grey sulphide of antimony or glass of antimony, with 2 pts. of common salt, 3 pts. of oil of vitriol and 2 pts. of water for eight hours, then boils for one hour, and afterwards mixes the liquid with water till a permanent precipitate begins to appear; then filters; precipitates the powder of algaroth by adding more water; washes it thoroughly, and fuses 100 parts of the dry compound with 80 parts of dry carbonate of sodium and 20 pts. of charcoal-powder for fifteen or twenty minutes: 61 pts. of pure antimony are thus obtained.—3. A very pure metal may be obtained by heating tartrate of antimony and potassium (tartar-emetic) to bright redness, and digesting the resulting metallic mass in water, to remove any potassium that may have been reduced at the same time. (Capitaine, J. Pharm. xxv. 516; also J. pr. Chem. xviii. 449.)

Purification from Arsenic only.—The extensive use of antimonial preparations in medicine, renders the removal of this impurity a point of particular importance.—1. Four pts. of powdered commercial antimony are mixed with five pts. of nitre and 2 pts. of dry carbonate of sodium (without the latter, insoluble arsenate of antimony would be formed), and the mixture is projected into a red-hot crucible. The mass remaining after the combustion (which takes place quietly) is then pressed together, heated for half an hour to a higher temperature, so that it may become pasty but not fused, and pressed down as often as it swells up from evolution of gas. After this, it is taken out of the crucible with the spatula, while still hot and soft, then reduced to powder, and boiled for some time in water, with frequent stirring. The water, together with the finer powder, is then poured off; the coarser powder crushed with a pestle, and boiled with a fresh quantity of water; the two liquids with their deposits are mixed; and the insoluble portion is freed by repeated subsidence and decantation, and, lastly, by washing on a filter, from the alkaline solution which contains the alkaline arsenate and but a very small quantity of antimonate. The washed acid antimonate of potassium is white; but if it contains lead, which cannot be removed by nitric acid, it has a yellow colour. It is then fused with half its weight of cream of tartar at a moderate red heat, and the resulting metallic antimony containing potassium is pulverised and thrown into water, which removes the potassium and liberates pure hydrogen gas (Wöhler, Pogg. Ann. xxvii. 628; also Ann. Ch. Pharm. v. 20.) According to C. Meyer (Ann. Ch. Pharm. lxvi. 236; Centr. Blatt. 1348, 828) the use of nitre is objectionable, because it gives rise to the formation of antimonate of potassium, which destroys the exactness of the process. Meyer recommends a mixture of nitrate and carbonate of sodium, whereby a mass is obtained which does not yield a trace of antimony to water. This method is so exact that it may be used to separate antimony from arsenic in quantitative analysis; moreover, the antimony thus obtained is not contaminated with potassium or sodium. — 2. One part of pulverised antimony, prepared by the second method (p. 312), is rapidly fused with half its weight of carbonate of potassium, and the mass is poured out; the metal obtained is then crushed, fused with one-fourth its weight of nitre, again poured out, the metal again crushed, and fused with one-third its weight of hydrated antimonic acid; and lastly, the antimony, after being repulverised, is fused with one-third its weight of carbonate of potassium, and poured into the mould. This method completely removes the arsenic (Th. Martius, Kastn. Arch. xxiv. 253). — 3. If 32 pts. of antimony, rich in arsenic, are fused with 4 pts. of nitre, the slag contains a large quantity of arsenate of potassium; and the resulting 30 pts. of metal fused with 3 pts. of nitre, still yields a small quantity of arsenate of potassium and 27 pts. of metal; this, if again fused with 2 pts. of nitre, yields a slag containing scarcely anything but antimonate of potassium, and metallic antimony perfectly free from arsenic. If carbonate of potassium be used instead of nitre, the separation of the arsenic is much more difficult (J. A. Buchner, Repert. xliv. 246). — 4. One part of antimony prepared by the third method, is heated with 1½ pt. of oil of vitriol in a porcelain basin, stirring constantly as long as sulphurous acid gas continues to be evolved, and water is carefully added by small portions at a time, till a greyish-white intumescent mass is formed. This is then mixed in a vessel made of antimony, with from 0·2 to 0·4 pt. finely powdered fluor-spar, and 0·4 to 0·8 pt. oil of vitriol (according to the quantity of arsenic present). The whole is then heated, with constant stirring, as long as hydrofluoric acid and fluoride of arsenic are given off; the residue is afterwards gradually mixed with water, and washed by decantation till the wash-water ceases to exhibit an acid reaction; and the remaining basic sulphate of antimony is reduced by fusion with half its weight of cream of tartar, in a covered crucible. If a leaden vessel were used, antimony and arsenic would be reduced together, and consequently the antimony obtained would not be free from arsenic. (Duflos, Kastn. Arch. xix. 56; also, Schw. lx. 353; further, Schw. lxii. 501; see also Buchner and Herberger, Repert. xxxviii. 381, xliv. 246.)

Tests for Impurities in Antimony. — 1. *Sulphur.* The powdered metal, when heated with strong hydrochloric acid, gives off hydrosulphuric acid. — 2. *Potassium* or *Sodium.* The antimony appears more grey than white, and loses its lustre on exposure to the air. Its powder has an alkaline taste, reddens moist tumeric paper, and evolves hydrogen gas when put under water, giving up alkali to the liquid. — 3. *Arsenic.* The metal, when fused in the air, emits a garlic colour. If its powder be detonated with about ¼ pt. of nitre, and the resulting mass treated with water, a filtrate is obtained, which contains arsenate and antimonate of potassium, so that when supersaturated with hydrochloric acid, and rapidly saturated with hydrosulphuric acid gas, it first gives a yellowish red precipitate of pentasulphide of antimony, and then, if rapidly filtered and preserved in a close vessel, gradually deposits a yellow precipitate of pentasulphide of arsenic. The antimony ignited with an equal weight of cream of tartar in a covered crucible, yields an alloy of potassium, arsenic, and antimony, which, if reduced to powder under water, evolves arseniетted hydrogen, recognisable by its depositing brown metallic arsenic on ignition (see ARSENIC). — 4. *Lead.* The powdered metal boiled with nitric acid nearly to dryness, and then treated with water, yields a filtrate which contains nitrate of lead, and is consequently precipitated by sulphuric acid. When the quantity of lead is large, a solution of antimony in aqua-regia deposits crystalline needles of chloride of lead on cooling. — If the antimony contains sulphur besides the lead, the lead remains undissolved in the form of sulphate, on treating the metal with nitric acid. If the antimonious oxide in the residue is then dissolved out by warm hydrosulphate of ammonia, black sulphide of lead remains behind, and if iron is present, black sulphide of iron also.—5. *Iron.* The finely divided metal ignited with three times its weight of nitre, and washed with boiling water, leaves a yellowish residue, from which boiling dilute hydrochloric acid separates ferric oxide, which may be detected by ferrocyanide of potassium, &c.—6. *Copper.* When the lead has been precipitated from the nitric acid solution by sulphuric acid, according to the method above given, the cupric oxide remains dissolved, and may be recognised by its behaviour with hydrosulphuric acid, ferrocyanide of potassium, ammonia, or polished iron. A solution of antimony in aqua-regia should give a yellowish-red precipitate with sulphide of ammonium, perfectly soluble in excess of the precipitant. If a black residue is left, it must consist of sulphide of lead, iron, or copper. (H. Rose.)

Properties.—Antimony is a brilliant metal, having a bluish-white colour, and highly lamellated structure. By melting it in a crucible, then leaving it to cool partially, and pouring out the still liquid portion, it may be obtained in rhombohedral crystals. Its tendency to crystallise is well shown in the cakes of metal which are met with in commerce, the surface of which often exhibits beautiful stellate or fern-like markings. Its density is from 6·702 to 6·86. It is very brittle, and easily pulverised in a mortar. It melts at 450° C. (842° Fah.), and may be distilled at a white heat in an atmosphere of hydrogen, but the distillation is very slow, in consequence of the small density of the vapour. Metallic antimony occurs native in small quantity, sometimes in rhombohedral crystals, at Andreasberg in the Harz, at Przibram in Bohemia, at Sala in Sweden, and at Allemont in France.

Amorphous Antimony.—Antimony is deposited from its solutions by electrolysis in two different states. When thus precipitated, with a positive electrode of antimony, from a solution of 5 pts. of tartar emetic and 5 pts. of tartaric acid dissolved in a mixture of 2 pts. hydrochloric acid and 30 pts. water, it has a silvery-grey colour and frosted surface, is hard in texture, has a radiating crystalline structure, and a density of 6·55. But from a solution of 1 pt. of tartar emetic in 4 pts. of the ordinary chloride of antimony (containing excess of hydrochloric acid?) it is deposited with the colour and appearance of polished steel, and a bright, metallic, amorphous fracture. Its specific gravity is then only 5·78. This amorphous antimony, when heated or struck, undergoes a rapid and intense molecular change throughout its mass, attended with great evolution of heat (from 60° to upwards of 450° F.), increasing at the same time in density, and approaching in colour and structure to the crystalline variety. At the same time, a quantity of chloride of antimony and of gas, condensed within its pores and retained with considerable force, is given off. No such change takes place in the grey crystalline metal. By carefully triturating thin pieces of the amorphous metal under water, it may be obtained in the state of a fine powder, exhibiting the molecular property above mentioned. This change of antimony from the amorphous to the crystalline state appears to be similar to that which has been observed in sulphur, selenium, and other substances. (G. Gore, Proc. Roy. Soc. ix. 70.)

In a subsequent paper (Proc. Roy. Soc. ix. 304), Mr. Gore states that the evolution of heat accompanying the change "is not limited to a particular temperature, but commences between 170° and 190° F., and increases in rapidity to some point above 212° F., when it becomes sudden. The heat may be discharged either suddenly or gradually, according to the amount to be discharged relative to the cooling influences present. The specific heat of the unchanged (amorphous) metal was found to be 0·06312; and of the same specimens, after being gradually discharged, the specific heat was not sensibly different. But the specific heat of the substance, after sudden discharge, was found to be 0·0543. The total amount of heat evolved by the substance during the change was sufficient to raise the temperature of its own weight of ordinary antimony (specific heat = 0·0508) about 650 F." An acid solution of fluoride of antimony yielded by electro-deposition, crystalline antimony not possessing the heating powers.

Antimony is not sensibly altered by exposure to the air at common temperatures, but oxidises quickly when melted. At a red heat, it takes fire, burning with a white flame, and producing white fumes of the trioxide. A lump of the pure metal heated on charcoal before the blowpipe, burns brilliantly, emitting copious white inodorous vapours, and if left to cool before it is completely burnt away, becomes covered with a white network of the crystallised oxide. If, on the contrary, the antimony is contaminated with arsenic and iron, it exhales a garlic odour, especially at the commencement; becomes covered with a slag of oxide of iron; has a dull surface; ceases to burn as soon as the blowpipe flame is withdrawn; and yields a yellow oxide. (Liebig.)

Antimony is strongly attacked and oxidised by *nitric acid*, but not dissolved. The degree of oxidation varies with the strength of the acid. If the acid be moderately dilute, the product consists of trioxide of antimony, mixed with a small quantity of pentoxide; with strong nitric acid, on the contrary, the product consists chiefly or wholly of pentoxide (H. Rose, Analyt. Chem. i. 258). The metal is not acted upon by dilute *sulphuric acid*, but when heated with the strong acid, it is converted into sulphate, with evolution of sulphurous anhydride. In the state of fine powder, it is dissolved by boiling *hydrochloric acid*, with evolution of hydrogen, but in the compact state, it resists the action of that acid, even at the boiling heat.

Antimony forms, with acid or chlorous radicles, two classes of compounds, viz.

1. *Antimonious compounds* or *tri-compounds of antimony*, containing 1 atom of the metal with 3 atoms of a monobasic acid-radicle, Cl, Br, &c. or 2 atoms of metal with 3 atoms of a dibasic acid radicle, O, S, &c., *e. g.*:

Trichloride of antimony	$SbCl^3$
Trioxide or antimonious oxide	Sb^2O^3
Trisulphide	Sb^2S^3

2. *Antimonic compounds* or *penta-compounds of antimony*, in which 1 or 2 atoms of metal are associated with 5 atoms of an acid-radicle, *e. g.*:

Pentachloride of antimony	$SbCl^5$
Pentoxide or antimonic oxide	Sb^2O^5
Pentasulphide	Sb^2S^5

In the antimonious compounds, $Sb = H^3$; in the antimonic compounds, $Sb = H^5$.

There are likewise a few compounds of antimony not included in either of these series; *e. g.* the tetroxide, SbO^2, which may, however, be regarded as a compound of the two oxides above mentioned, viz. antimonoso-antimonic oxide, $Sb^2O^3.Sb^2O^5 = 4SbO^2$.

ANTIMONY, ALLOYS OF. Antimony unites with most of the heavy metals, rendering them harder and more brittle. Most of the alloys are easily formed by fusing the two metals together; some occur native. The alkali-metals likewise form alloys with antimony.

For the compounds of arsenic and antimony see ARSENIC.

Antimonide of Copper.—Prepared by fusing the two metals together in equal quantities is pale violet, very brittle, and of laminar texture. According to Karsten, copper alloyed with 0·15 per cent. of antimony, becomes somewhat cold-short and very hot-short.

Antimonide of Gold.—The two metals unite very easily, melted gold even absorbing vapour of antimony. An alloy of 9 pts. gold to 1 pt. antimony is very brittle, white, and exhibits the fracture of porcelain. Gold loses its malleability by admixture with about $\frac{1}{2000}$ of antimony. The antimony is easily expelled from the alloy by heat.

Antimonide of Iron.—A mixture of 7 pts. of antimony, and 3 pts. of iron heated to whiteness in a crucible lined with charcoal, forms a white, very hard, slightly magnetic alloy, which gives sparks when filed. An alloy of antimony and iron is always formed when sulphide of antimony is reduced by iron in excess (*regulus antimonii martialis*). A very small quantity of antimony (0·23 per cent.) makes refined iron both hot- and cold-short.

Antimonide of Lead.—The two metals unite readily in all proportions. Lead is hardened by admixture with antimony. An alloy of equal parts of the two is brittle and ringing; 12 pts. lead and 1 pt. antimony form a malleable alloy, somewhat harder than lead. *Type-metal* is an alloy of antimony and lead, usually containing 17 to 20 per cent. of antimony. Sometimes other metals are added, *e. g.* 1 pt. bismuth to 16 pts. lead and 2 pts. tin, or, for stereotype plates, $\frac{1}{80}$ to $\frac{1}{50}$ of tin. The specific gravity of alloys of lead and antimony is always above the mean.

Antimonide of Nickel, NiSb, occurs as a metallurgic product obtained by sublimation in long hexagonal prisms. Another alloy, Ni^2Sb, occurs as a natural mineral called *antimonial nickel* or *Breithauptite*, in thin hexagonal plates of specific gravity 7·541, hardness 5·5; fracture uneven; the recent fracture exhibits a light copper colour with a tinge of violet; powder red-brown. Not magnetic. Ignited in a glass tube, it yields a small sublimate of antimony. On charcoal it forms an antimonial deposit, and cannot be fused excepting in small pieces. It is but little attacked by simple acids, but dissolves easily in aqua-regia. Analysis by Stromeyer (Pogg. Ann. xxxi. 134):

Sb	Ni	Fe	Pb^2S	
63·73	28·95	0·87	6·44	= 99·99
59·71	27·05	0·84	12·36	= 99·96

It was formerly found in the Andreasberg mountains, with calc-spar, galena, and smaltine; but the vein has long been exhausted. A similar alloy may be obtained artificially by melting 2 at. Ni with 1 at. Sb. (Dana, ii. 53.)

Antimonide of Tin. — The alloy is easily formed by fusing the two metals together, also by reducing sulphide of antimony with tin (*regulus antimonii jovialis*). Britannia metal is an alloy of 9 pts. tin and 1 pt. antimony, frequently also containing small quantities of other metals, as copper, zinc, and bismuth. Alloys of antimony with tin, or tin and lead, sometimes also containing copper, are now much used for machinery bearings in place of gun-metal. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 169.)

Antimonide of Zinc. — Antimony forms with zinc, alloys of definite crystalline character. A fused mixture of the two metals, containing from 43 to 70 per cent. of zinc, deposits by partial cooling, silver-white rhombic prisms, containing from 43 to 64 per cent. of zinc. The alloy containing exactly 43 per cent. of zinc, appears to be a definite compound, *stibiotrizincyl*, $SbZn^3$. Mixtures containing from 33 to 20 per cent. of zinc deposit rhombic crystals containing from 35 to 21 per cent. of zinc. The alloy containing exactly 33 per cent. is *stibiodizincyl*, $SbZn^2$. These alloys, especially $SbZn^3$, decompose water, with evolution of hydrogen at the boiling heat, and very rapidly under the influence of acids. (J. P. Cooke, Sill. Am. J. [2] xviii. 229; xx. 222.)

Antimonide of Potassium. — Alloys of antimony and potassium may be obtained by fusing the two metals together, or by igniting metallic antimony, or its oxide or sulphide, with an organic salt of potassium. Thus, when 5 pts. of crude tartar and 4 pts. of antimony are slowly heated in a covered crucible till the mixture becomes charred, then heated to whiteness for an hour, and left to cool, a crystalline regulus is obtained containing 12 per cent. of potassium. This alloy decomposes water rapidly, and oxidises slowly in the air when in the compact state, but becomes heated and takes fire when rubbed to powder. (Löwig and Schweizer.)

Antimonide of Silver. — Ag^4Sb and Ag^6Sb occurs native as *antimonial silver* or *discrasite*, in the form of six-sided prisms with truncated lateral edges; also in scalenohedrons, similar to those of calc-spar. Specific gravity 9·4 to 9·8; hardness 3·5 to 4; silver-white; fracture uneven. Before the blowpipe, it gives off fumes of antimony, and leaves a grey, non-malleable, metallic globule; by continuing the heat on charcoal, silver is obtained. It dissolves in nitric acid, leaving oxide of antimony. Analysis by Klaproth:

	Ag^4Sb		Ag^6Sb
	a.	*b.*	*c.*
Antimony . . .	24	24	16
Silver . . .	76	76	84
	100	100	100

a is a coarse-grained variety from Wolfach, in Baden; *b* lamino-granular, from Andreasberg, in the Hartz; *c* fine-grained, from Wolfach. The mineral occurs also at Wittichen, in Suabia; at Allemont, in Dauphiné; at Casalla, in Spain; and near Coquimbo, South America. (Gm. vi. 199; Dana, ii. 35.)

Antimonide of Sodium resembles antimonide of potassium, and is prepared in like manner.

ANTIMONY BLOOM. Native trioxide of antimony.

ANTIMONY, BROMIDE OF. $SbBr^3$.—This is the only known compound of antimony and bromine, and is formed by direct combination. Antimony takes fire in bromine vapour, or in contact with liquid bromine, running about on the surface in melted globules. To prepare the compound, bromine is put into a retort, and dry antimony powder is introduced through the tubulus, agitating each time till the combination is complete. The product is then purified by distillation. It forms on cooling a mass of colourless needles, deliquescent, melting at 90°C., volatile at 270°. Water decomposes it, forming an oxibromide.

ANTIMONY, CHLORIDES OF. Antimony and chlorine unite directly when brought in contact, and if the antimony is in a state of fine division, the combination is attended with visible combustion. The compound formed is a trichloride or a pentachloride, according as the antimony or the chlorine is in excess.

TRICHLORIDE OF ANTIMONY, $SbCl^3$, is obtained:—1. By passing chlorine gas slowly through a tube containing excess of antimony, or over heated trisulphide of antimony, the chloride of sulphur formed at the same time being afterwards volatilised by a gentle heat. - 2. By distilling 3 pts. of antimony with 8 pts. of mercuric chloride, or 2 pts. of the trisulphide of antimony with 4·6 pts. of mercuric chloride:

$$Sb + 3HgCl = SbCl^3 + 3Hg;\ \text{and}\ Sb^2S^3 + 6HgCl = 2SbCl^3 + 3Hg^2S.$$

3. By heating the trisulphide with strong hydrochloric acid, or metallic antimony with hydrochloric acid to which nitric acid is added in successive small portions: if too much nitric acid were added, a precipitate of oxide of antimony or antimonic acid would be formed. A solution of the trichloride in excess of hydrochloric acid is thus formed, and on subsequently distilling this liquid, water and hydrochloric acid pass over first, and afterwards the pure trichloride.

Trichloride of antimony is at ordinary temperatures a translucent fatty mass—thence called butter of antimony. It melts at 72° C., and boils at about 200°: fumes slightly in the air, and is very corrosive. When thrown into water, it is decomposed into hydrochloric acid and trioxide of antimony, which however remains united with a portion of the chloride, forming a white powder called *powder of algaroth*. The same decomposition takes place on adding water to the solution of the trichloride in strong hydrochloric acid. The precipitate is redissolved by excess of hydrochloric acid, and the solution, which contains hydrated trichloride of antimony, is the most convenient that can be used for exhibiting the reactions of antimony. The addition of tartaric acid to this solution, prevents its decomposition by water.

The anhydrous trichloride combines with ammonia, forming the compound $NH^3.SbCl^3$, and forms crystalline compounds with the chlorides of the alkali-metals.

PENTACHLORIDE OF ANTIMONY, $SbCl^5$, is formed, with brilliant combustion, when finely powdered antimony is thrown into chlorine gas. It may be prepared by passing dry chlorine over pulverised antimony, gently heated in a tubulated retort provided with a receiver, or over the trichloride. Hofmann (Chem. Soc. Qu. J. xiii. 65) introduces metallic antimony coarsely powdered into a combustion-tube five or six feet long, rising at an angle of 10° or 15°, one end being fitted into a tubulature of a two-necked glass globe, the other neck of which is connected with a tube supplying dry chlorine. Combination takes place in the tube, and the products flow backwards into the globe, whilst the long layer of antimony prevents the escape of any chlorine.—Pentachloride of antimony is a colourless or yellowish, very volatile liquid, which emits suffocating vapours. *Water* first converts it into a crystalline hydrate and then decomposes it, forming hydrochloric and antimonic acids. It absorbs *ammonia* and *phosphoretted hydrogen*, forming solid red-brown compounds. It absorbs *olefiant gas*, C^2H^4, as readily as chlorine, and forms Dutch liquid. By passing dry olefiant gas and dry chlorine simultaneously through boiling pentachloride of antimony, in a retort connected with an inverted condenser, large quantities of Dutch liquid may be easily obtained. The pentachloride here acts as a carrier of free chlorine, a purpose for which it may often be advantageously used (Hofmann, *loc. cit.*) It likewise absorbs *hydrosulphuric acid gas*, at ordinary temperatures, forming a white crystalline chlorosulphide of antimony, $SbCl^3S$, analogous to chlorosulphide of phosphorus, PCl^3S.—With *bisulphide of carbon*, the latter being in excess, it yields tetrachloride of carbon, trichloride of antimony, and free sulphur:

$$CS^2 + 2SbCl^5 = CCl^4 + 2SbCl^3 + S^2.$$

The mixture becomes very hot, and on cooling deposits crystals of trichloride of antimony, mixed with sulphur-crystals, the tetrachloride of carbon remaining in the liquid state (Hofmann, *loc. cit.*). The pentachloride combines with *hydrocyanic acid*, forming a white, crystalline, volatile compound, containing $SbCl^5.3HCy$: also with *chloride of cyanogen*.—A white pulverulent substance containing $2SbCl^5.3SCl^2$, is obtained by heating pentasulphide of antimony in dry chlorine gas; it is decomposed at 300° C. into chloride of sulphur, trichloride of antimony, and free chlorine.

ANTIMONY, DETECTION AND ESTIMATION OF:

1. *Blowpipe Reactions.*—Solid compounds of antimony fused upon charcoal, with dry carbonate of sodium or cyanide of potassium, yield a brittle globule of antimony, a thick white fume being at the same time given off, and the charcoal covered to some distance around with a white deposit of oxide. If the heat be continued for some time, the globule will be completely dissipated. The reduction with cyanide of potassium may be performed in a porcelain crucible without charcoal.

The antimony globule is converted by nitric acid into a white oxide, soluble in a boiling solution of cream of tartar. It is insoluble in pure hydrochloric acid, but dissolves easily on addition of a small quantity of nitric acid, forming a solution of the trichloride, which is decomposed by water, forming a white precipitate, soluble in excess of hydrochloric or tartaric acid. If tartaric acid be previously added, water produces no precipitate.

2. *Liquid Reactions.*—The acid solution of the trichloride gives with *hydrosulphuric acid gas*, a brick-red precipitate of the trisulphide, easily soluble in sulphide of ammonium, and reprecipitated by acids.—With *potash*, it forms a white precipitate of the trioxide, soluble in a large excess of the reagent.—*Ammonia* forms the same precipitate, insoluble in excess. *Carbonate of potassium* or *sodium* also gives a white precipitate of the trioxide, which dissolves in excess, especially of the potassium-salt, but reappears after a while. If, however, the solution contains *tartaric acid*, the precipitate formed by potash dissolves easily in excess of the alkali,—ammonia forms but a slight precipitate, and only after long standing,—and the precipitates formed by the alkaline carbonates are insoluble in excess of those reagents. These last mentioned characters are also exhibited by a solution of tartar-emetic (tartrate of antimony and potassium). The solution of this salt is decomposed by the stronger acids, yielding a white precipitate, consisting of acid tartrate of potassium, mixed with the oxide or a basic salt of antimony. With solutions of barium, strontium, calcium, lead, and silver, it forms white precipitates, consisting of tartar-emetic, the potassium of which is replaced by the other metal.

A solution of *trichloride of gold*, added to a solution of trichloride of antimony, or other antimonious salt, forms a yellow precipitate of metallic gold, antimonic acid being at the same time precipitated in the form of a white powder, unless the solution contains a larger excess of hydrochloric acid:

$$4AuCl^3 + 3Sb^2O^3 + 6H^2O = 4Au + 12ClH + 3Sb^2O^5.$$

The reduction is slow at ordinary temperatures, but is accelerated by heating. In a solution of the trioxide (antimonious acid), in potash, trichloride of gold produces a black precipitate, which affords a very delicate reaction for antimonious acid. *Nitrate of silver* produces in a solution of trichloride of antimony, a white precipitate, from which ammonia dissolves out chloride of silver, leaving oxide of antimony undissolved. In a solution of antimonious acid in potash, nitrate of silver produces a deep black precipitate, insoluble in ammonia. In a solution of tartar-emetic, nitrate of silver forms a white precipitate, perfectly soluble in ammonia: but if the solution be previously mixed with excess of potash, nitrate of silver produces a black precipitate insoluble in ammonia.

Zinc and *iron* precipitate antimony from its solutions, in the form of a black powder.—*Copper* precipitates it in the form of a brilliant metallic film, which may be dissolved off by a solution of permanganate of potassium, yielding a solution which will give the characteristic red precipitate with hydrosulphuric acid. (Odling, Guy's Hospital Reports [3] ii. 249.)

Antimonic Acid is distinguished from antimonious acid by the different colour of the precipitate which it forms with *hydrosulphuric acid* (p. 328); but better by its behaviour with chloride of gold and nitrate of silver. *Trichloride of gold* produces no precipitate in solutions of antimonic acid, not even when they contain excess of potash. *Nitrate of silver*, added to a solution of antimonate of potassium, forms a white precipitate of antimonate of silver, perfectly soluble in ammonia: if the solution contains excess of potash, the precipitate is brown from admixed oxide of silver, but even then it is completely soluble in ammonia. The slightest trace of antimonious acid present produces a black precipitate, insoluble in ammonia. If a small quantity of an oxide of antimony in the solid state be rubbed up with water to a milky liquid in a porcelain capsule, then dried, and moistened with *ammonio-nitrate of silver*, a black spot will be produced, if trioxide antimony is present, either in the free state or combined with antimonic acid: but if only antimonic acid is present, no blackening will take place. This is a very delicate reaction (Bunsen, Ann. Ch. Pharm. cvi. 1).—Antimonic acid may also be distinguished from the trioxide by its behaviour with *hydriodic acid*, The pure trioxide dissolves in hydrochloric acid to which iodide of potassium is added, producing a pale yellow liquid, containing tri-iodide of antimony, without separation of iodine; but antimonic acid or antimonate of antimony, forms under the same circumstances a solution coloured dark brown by free iodine:

$$Sb^2O^3 + 6HI = 2SbI^3 + 3H^2O$$

and

$$Sb^2O^5 + 10HI = 2SbI^3 + 5H^2O + 4I.$$

If the quantity of antimonic acid is considerable, the liquid gives off violet vapours on boiling; but even if it does not exceed a few hundredths of a milligramme, the free iodine in the solution may be detected by shaking it up with a few drops of bisulphide of carbon, which then exhibits a violet or amethyst colour when it rises to the surface. It is of course essential that the hydrochloric acid do not contain free chlorine, and that the iodide of potassium be free from iodate. (Bunsen.)

When the presence of antimony is suspected in liquids containing considerable quantities of organic matter, as in cases of supposed poisoning by tartar-emetic or other antimonial preparations, it is best to destroy the organic matter by oxidation with hypochlorous acid. If the matter to be examined is solid, it should be cut into small pieces; if a large quantity of liquid is present, it must be brought by evaporation to a convenient bulk. It is then mixed with strong hydrochloric acid, a gentle heat applied, and chlorate of potassium added by small portions, till the liquid acquires a light yellow colour. It is then heated till the odour of chlorine is no longer perceptible, and afterwards left to cool and filtered. From the clear liquid thus obtained, the antimony may be precipitated by hydrosulphuric acid, or by metallic copper, and the precipitates treated in the manner already described; or the liquid may be introduced into a Marsh's apparatus (see ARSENIC), with zinc and dilute sulphuric acid, and the antimony reduced, either in the escape-tube by the heat of a lamp, or on a porcelain plate held in the flame. The metallic deposit thus obtained may be dissolved in aqua-regia, and the solution treated with hydrosulphuric acid, which will produce the characteristic brick-red precipitate. Another method of testing the deposit is to moisten it with nitric acid, of specific gravity 1·42, then heat the vessel over a lamp, and blow over the surface so as to cause the acid to evaporate without boiling. The white deposit then remaining consists chiefly or wholly of trioxide of antimony, which will produce a deep black spot with ammonio-nitrate of silver. A deposit of metallic arsenic, treated in the same way, gives with ammonio-nitrate of silver, either a yellow precipitate of arsenite, or a red-brown precipitate of arsenate of silver, according to the degree of oxidation produced by the nitric acid. (Bunsen.)

3. *Quantitative Estimation.*—1. Antimony may be accurately estimated in the form of tetroxide or antimonate of antimony, SbO^2, that oxide being neither volatile nor decomposible at a red heat. The antimony being precipitated from solution by hydrosulphuric acid, the precipitate is washed and dried, then placed, together with the filter, in a porcelain basin covered with a funnel, and fuming nitric acid poured upon it. A violent action then takes place, the antimony and the greater part of the sulphur being immediately oxidised: the oxidation of the sulphur may be completed by heating the vessel over a water-bath. The resulting white mass, consisting of antimonic acid mixed with sulphuric acid, is converted by ignition into pure antimonate of antimony, containing 79·22 per cent. of the metal. The oxidation of the sulphide of antimony cannot be conveniently effected by nitric acid of ordinary strength (specific gravity 1·42), because that liquid boils at a temperature 10° C. above the melting point of sulphur, and consequently the sulphur separated at the commencement of the action collects in melted globules, which are extremely difficult to oxidise, and if left in the mass during the subsequent ignition, would reconvert a portion of the oxide of antimony into sulphide. Fuming nitric acid, on the contrary, boils below the melting point of sulphur, and the sulphur separated by its action takes the form of a fine powder, which is easily oxidised at a gentle heat. If the sulphide of antimony is mixed with a large quantity of free sulphur (which is often the case when it has been dissolved in an alkaline sulphide and reprecipitated by an acid), it is best to remove the free sulphur by washing the precipitate with bisulphide of carbon.

The oxidation of the sulphide of antimony may also be effected by igniting it with mercuric oxide (prepared by precipitating a hot solution of mercuric chloride with excess of caustic potash). When these substances are heated together in equivalent proportions, a violent explosion takes place; but if the sulphide of antimony be mixed with between thirty and fifty times its weight of mercuric oxide, the oxidation takes place quietly. The mixture is heated in a porcelain crucible, gently, so long as mercurial vapours go off, afterwards more strongly, and at last very strongly, to expel the last traces of mercury. Antimonate of antimony then remains in the form of a soft white powder. As mercuric oxide, even when prepared with the greatest care, always leaves a small residue when ignited, the amount of this residue must be determined once for all, and the proportionate amount deducted from the weight of the antimonate of antimony. As, however, this residue never exceeds a few thousandths of the whole, it is not necessary to weigh the oxide of mercury with great exactness. In this process, it is necessary, if the sulphide of antimony contains a large excess of free sulphur, to remove that substance by washing with bisulphide of carbon, before proceeding to the ignition; because free sulphur, even when ignited with a large excess of mercuric oxide, produces explosions which might occasion loss. The method just described has been lately introduced by Bunsen (Ann. Ch. Pharm. cvi. 3). It is quite exact, provided due attention be paid to the precautions above indicated.

2. The precipitated sulphide of antimony is collected on a weighed filter, dried in an oil-bath, at about 120° C., and then weighed. A known portion of it is then either decomposed by ignition in an atmosphere of hydrogen, whereby the sulphur is expelled

in the form of hydrosulphuric acid, and metallic antimony remains: or a weighed portion of the sulphide is oxidised by means of hydrochloric acid and chlorate of potassium, the action being continued till the greater part of the sulphur is converted into sulphuric acid, and the remainder collected at the bottom of the liquid in a melted globule. The liquid is then diluted with water containing tartaric acid, to prevent the precipitation of a basic salt of antimony, and decanted; the globule of sulphur washed and weighed, and the quantity of sulphur in solution estimated as sulphate of barium (see SULPHUR), the quantity thus found being added to the weight of the globule. The proportion of sulphur in the precipitated sulphide of antimony being thus found, the amount of antimony is easily calculated. Antimony cannot be accurately estimated by merely weighing the precipitated sulphide, because the precipitate almost always contains free sulphur, and sometimes pentasulphide of antimony in unknown proportion.

When antimonious and antimonic acids exist together in solution, the total quantity of antimony may be estimated by treating one portion of the liquid as above described, and the quantity existing as antimonious acid determined in another portion by means of trichloride of gold, 4 at. of precipitated gold corresponding to 3 at. of antimony (p. 313).

Atomic Weight of Antimony.—**Berzelius** (Schw. J. xxii. 69) determined the amount of tetroxide produced from a given weight of the metal by oxidation with nitric acid, and thence found, for the atomic weight of antimony, the number 129·03. The same process has more recently been followed by **Dexter** (Pogg. Ann. c. 579), who found the smaller number 122·33: but even this number is generally regarded as too high, the error being supposed to arise from incomplete oxidation and the consequent admixture of trioxide with the tetroxide.

The number at present most generally adopted is that determined by **Schneider** (Pogg. Ann. xcviii. 293) from the analysis of the native trisulphide by hydrogen. Stibnite from Arnsberg, which consists of pure trisulphide of antimony mixed with only a small quantity of quartz (about ½ per cent.), was decomposed by ignition in a stream of hydrogen, and the reduced antimony weighed, the escaping gas being passed into aqueous ammonia to absorb any sulphide of antimony that volatilised, and this quantity being afterwards precipitated by hydrochloric acid, oxidised by fuming nitric acid, and weighed as tetroxide (its quantity did not exceed 1 or 2 milligrammes). Corrections were also made for the quartz in the mineral and for the small amount of sulphide which remained unreduced and unvolatilised; for which purpose the residue in the reduction-tube was weighed,—then digested in aqua-regia, the residual quartz again weighed, the sulphur in the solution determined by precipitation as sulphate of barium, and the amount of antimony in the residue thence determined (about 0·4 per cent.) After making these corrections, the composition of the trisulphide (Sb^2S^3) was found to be 71·480 Sb + 28·520 S = 100, whence, the atomic weight of sulphur being 32, that of antimony is:

$$Sb = \frac{71{\cdot}48}{28{\cdot}52} \times 48 = 120{\cdot}30.$$

This result agrees nearly with former determinations by H. Rose, and also with that found by **Weber** (Pogg. Ann. xcviii. 455), from the analysis of trichloride of antimony, viz. 120·7. Dumas, by decomposing trichloride of antimony with a standard solution of silver, finds for the atomic weight of antimony the number 122. (Ann. Ch. Pharm. cxiii. 29.)

Valuation of Antimony Ores.—To estimate the amount of antimony in the native sulphide, the ore is carefully roasted, and then fused at a moderate heat with 1 to 3 pts. of black flux and about 25 per cent. of borax, the whole being covered with a layer of common salt. The quantity of metal which can be thus extracted from the sulphide does not exceed 54 to 64 per cent, the calculated quantity being 71·5 per cent. Or the sulphide is fused with iron filings (about 42 pts. iron to 100 of sulphide), together with three times its weight of black flux, and about 25 per cent. of borax, the whole being covered with a thick layer of common salt. This process yields 66 to 68 antimony from 100 pts. of the sulphide.

To estimate the amount of sulphide of antimony in a sample of the crude ore, the ore, in pieces of about the size of a walnut, is heated in a hessian crucible perforated at bottom, and standing on another crucible placed below the grate, and surrounded with ashes or sand to keep it cool. Care must be taken to avoid applying too much heat.

If the gangue is not attacked by hydrochloric acid, the amount of sulphide may be estimated by boiling a weighed portion of the ore with that acid and weighing the residue. (**Kerl**, Hüttenkunde, iii. 26.)

4. *Separation of Antimony from other metals.*—From the metals of the second and third groups (see ANALYSIS, p. 213) antimony is separated by precipitation

with hydrosulphuric acid; from those of the first group, whose sulphides are insoluble in alkaline sulphides, it is separated by precipitating with hydrosulphuric acid and digesting the precipitate in sulphide of ammonium. The sulphide of antimony then dissolves, the other metals remaining undissolved; and on mixing the filtrate with excess of hydrochloric or acetic acid, the sulphide of antimony is reprecipitated. When hydrochloric acid is used, care must be taken to keep the liquid dilute and not allow it to get hot, otherwise some of the antimony may be redissolved.

When antimony is combined with other metals in the form of an alloy, it may often be separated by treating the alloy with moderately strong nitric acid, which dissolves the other metals, leaving the antimony in the form of antimonic acid, which may then be converted into antimonate of antimony by ignition. This method, however, is not rigidly exact, because the nitric acid dissolves a small portion of the antimony; but it is near enough for commercial purposes. It is of course not applicable to the separation of antimony from tin, gold, or platinum.

The separation of antimony from *tin* may be effected by immersing in the solution a piece of pure tin, which precipitates the antimony in the form of a black powder. To render the separation complete, a gentle heat must be applied, and the solution should contain an excess of acid. The antimony is collected on a weighed filter, dried at a gentle heat, and weighed. If the sum of the weights of the two metals in the solution is previously known, the amount of tin is at once determined by difference; if not, the metals must be precipitated together by zinc from a known quantity of the solution, and the antimony precipitated by tin from another portion.—Another method of separation given by Levol (Ann. Ch. Phys. [3] xiii. 125) is, to precipitate the two metals by zinc, and treat the precipitate with strong hydrochloric acid, without previously decanting the solution of chloride of zinc. The tin then dissolves, while the antimony remains undissolved, the presence of the chloride of zinc diminishing its tendency to dissolve in the acid. The tin may be afterwards precipitated by hydrosulphuric acid, and the sulphide converted into stannic oxide by treating it with strong nitric acid.

For the separation of antimony from *arsenic*, *gold*, and *platinum*, see those metals. From *selenium* and *tellurium*, antimony is separated in the same manner as arsenic (*q. v.*)

ANTIMONY, FLUORIDE OF. SbF^3.—Obtained by dissolving the trioxide in hydrofluoric acid. It forms colourless crystals, which dissolve completely in water without decomposition.

ANTIMONY, GLASS OF. See ANTIMONY, OXYSULPHIDE OF.

ANTIMONY, HYDRIDE OF, or **ANTIMONIDE OF HYDROGEN,** generally called *Antimonetted* or *Antimoniuretted hydrogen* SbH^3.—When an antimony-compound, tartar-emetic for example, is introduced into an apparatus in which hydrogen is generated by the action of zinc or dilute sulphuric acid, the flame produced by the combustion of the gas at the orifice of the jet, acquires a bluish tinge from admixture of antimonide of hydrogen. This compound may be obtained in a state of greater purity by dissolving an alloy of 2 pts. of zinc and 1 pt. of antimony in hydrochloric or dilute sulphuric acid. It is always, however, more or less contaminated with free hydrogen.

It is a colourless gas, and when free from arsenic, quite inodorous; insoluble in water and in alkaline liquids. When it is passed into hot concentrated nitric acid, a white powder is deposited, consisting of antimonic acid. When passed into a solution of nitrate of silver or chloride of mercury, it forms a black precipitate, containing the whole of the silver or mercury. The silver-precipitate has been found to be $SbAg^3$, and is formed by simple substitution of silver for hydrogen. Hence the antimonide of hydrogen is inferred to be SbH^3, analogous to ammonia, and to arsenide and phosphide of hydrogen, AsH^3 and PH^3.

When antimonide of hydrogen is passed through a tube of hard glass and strongly heated by the flame of a lamp, it is decomposed, and a mirror of metallic antimony is deposited on the tube. If a funnel be held over the flame of the gas, a deposit of trioxide of antimony is formed on its inner surface. A cold porcelain dish held in the middle of the flame, becomes covered with spots of metallic antimony, which are darker in colour than those formed in a similar manner by arsenic, and are further distinguished from the latter by not dissolving in hypochlorite of sodium. The antimony deposit dissolves easily in aqua-regia and in permanganate of potassium, and the solution thus formed exhibits the characteristic reactions of antimony with hydrosulphuric acid, &c. (p. 319).

There are several compounds of antimony with alcohol-radicles, analogous to antimonetted hydrogen, viz. *stibtrimethyl*, $Sb(CH^3)^3$, *stibtriethyl*, $Sb(C^2H^5)^3$, and *stibtriamyl*, $Sb(C^5H^{11})^3$.

ANTIMONY, IODIDE OF. SbI^3.—Prepared like the bromide. It is a dark red body, decomposed by water, forming an *oxyiodide*. The *sulphiodide*, $Sb^2I^2S^3$, is obtained as a red sublimate, by heating an intimate mixture of iodine and the trisulphide in a retort. It is decomposed by water, yielding hydriodic acid and an oxysulphide.

ANTIMONY, ORES OF. See p. 311; for the valuation, p. 321.

ANTIMONY, OXIDES OF. Antimony forms with oxygen three definite compounds, viz.: the

Trioxide or Antimonious oxide	Sb^2O^3 or SbO^3
Tetroxide or Antimonoso-antimonic oxide . . .	Sb^2O^4 or SbO^4
Pentoxide or Antimonic oxide	Sb^2O^5 or SbO^5

The tetroxide is perhaps a compound of the other two, $Sb^2O^3.Sb^2O^5 = 2Sb^2O^4$. A *suboxide* Sb^2O (?) is also said to be produced, as a grey film, when antimony is used as the positive pole in the electrolysis of water. It appears, however, to be merely a mixture of the metal with the trioxide, for, when treated with hydrochloric acid, it yields solution of the trioxide and a residue of antimony. (Berzelius.)

TRIOXIDE OF ANTIMONY, or ANTIMONIOUS OXIDE, Sb^2O^3, occurs, though rarely, as a natural mineral (*Valentinite, White Antimony, Antimony-bloom, Weisspiessglanzerz*), in shining white crystals belonging to the trimetric system; specific gravity 5·566 hardness; 2·5—3. It occurs in veins of primary rocks at Przibram in Bohemia, at Bräunsdorf in Saxony, and at Malaczka in Hungary. It is found also in regular octahedrons, viz. as *Senarmontite*, a mineral from the Gued Hamimim mine, in the province of Constantine, Algeria: it is therefore dimorphous. This oxide is formed when the metal burns in the air, and may be prepared by heating antimony in a crucible imperfectly closed with its cover: it is then deposited on the sides of the crucible, a little above the melted metal, in shining prismatic crystals, known by the name of *flowers of antimony, flores antimonti argentei*. But the easiest mode of obtaining it is, to heat the trisulphide with strong hydrochloric acid as long as hydrosulphuric acid continues to escape, and pour the resulting solution of the trichloride into a boiling solution of carbonate of sodium. A crystalline powder is then deposited, consisting (according to Graham) of the anhydrous trioxide:

$$2SbCl^3 + 3Na^2CO^3 = Sb^2O^3 + 6NaCl + 3CO^2.$$

Regnault, however, states (Cours de Chimie, iii. 239) that the oxide thus obtained is a hydrate, containing $Sb^2O^3.H^2O$ or $SbHO^2$. The trioxide is likewise obtained, though mixed more or less with antimonic acid, by treating metallic antimony with nitric acid (p. 318).

The artificial as well as the native trioxide of antimony is dimorphous. The crystals produced by the rapid oxidation of the metal belong to the trimetric or right prismatic system. Sometimes, however, when the oxide is sublimed at a comparatively low temperature, as when a few ounces of antimony are heated till the metal begins to burn, and then left to cool slowly, the prismatic crystals are mixed with regular octahedrons. According to Mitscherlich (Ann. Ch. Phys. [2] xxxiii. 394) the trioxide is also deposited in regular octahedrons from a solution in boiling soda. In each of its forms, it is isomorphous with one of the forms of trioxide of arsenic (arsenious oxide): the two bodies are therefore isodimorphous. Antimonious oxide is white or greyish-white at ordinary temperatures, but turns yellow when heated. It melts below a red heat, and sublimes when raised to a higher temperature in a close vessel. When heated in the air, it is partly converted into antimonic oxide. It is not decomposed by heat alone, but is reduced to the metallic state when heated with hydrogen, charcoal, or potassium.

Trioxide of antimony dissolves sparingly in *water*, more freely in strong *hydrochloric acid;* the latter solution is quite clear, provided the oxide is free from antimonic acid, but is rendered turbid by dilution with water. It dissolves when boiled with *aqueous tartaric acid*, and very easily in a solution of *acid tartrate of potassium* (cream of tartar), forming the *tartrate of antimony and potassium*, or *tartar-emetic*, $C^4H^4KSbO^7$. (See TARTRATES.)

It is quite insoluble in *nitric acid* of ordinary strength; but dissolves in cold fuming nitric acid, forming a solution which deposits pearly scales of a nitrate, $N^2O^5.2Sb^2O^3$ (Peligot). It dissolves also in *fuming sulphuric acid*, the solution depositing shining scales of a sulphate containing $3SO^3.Sb^2O^3$. It does not absorb *carbonic acid;* indeed, no carbonate of antimony is known to exist.

Trioxide of antimony acts as a feeble acid, forming salts called **antimonites**. The precipitated trioxide dissolves easily in *alkalis*, but the resulting compounds are very unstable, being decomposed by mere evaporation. The solutions give with nitrate of silver and excess of ammonia, a black precipitate insoluble in free ammonia. They reduce trichloride of gold, precipitating the metal. More stable salts, the antimonoso-antimonates, are formed by the union of the antimonites with antimonates (*vid. inf.*). The trioxide fused with caustic alkalis or their carbonates is converted into antimonic acid, which unites with the alkali. (Fremy.)

Tetroxide of Antimony, or Antimonoso-antimonic oxide, sometimes called *Antimonious acid*, Sb^2O^4.—This oxide is found native, as *Cervantite* or *Antimony-ochre*, forming acicular crystallisations, or massive, or as a crust or powder. It is yellow, or nearly white, of a greasy, bright or earthy lustre, and specific gravity 4·084. It is found at Pereta, in Tuscany (Dana, iii. 141). The same oxide is produced by the action of heat upon antimonic oxide (Sb^2O^5), by roasting the trioxide or trisulphide, or by treating pulverised antimony with excess of nitric acid. As thus prepared, it is white, infusible, and unalterable by heat; slightly soluble in water, more soluble in hydrochloric acid. It is easily resolved into antimonious and antimonic oxides. On boiling it with acid tartrate of potassium (cream of tartar) antimonious oxide dissolves, and antimonic oxide is left behind; and when a solution of the tetroxide in hydrochloric acid is gradually dropped into a large quantity of water, a precipitate of antimonious oxide is first produced, while antimonic acid remains in solution. From these and similar reactions, it has been inferred that the tetroxide is a compound of the trioxide and pentoxide, or an antimonate of antimony ($Sb^2O^3 + Sb^2O^5 = 2Sb^2O^4$). On the other hand, it is sometimes regarded as a distinct oxide, because it dissolves in alkalis, forming salts (often called *antimonites*), which may be obtained in the solid state. By fusing the tetroxide with hydrate or carbonate of potassium, exhausting with cold water, treating the residue with boiling water, and evaporating to dryness, a yellow, uncrystalline, saline mass is obtained, composed of $K^2O.Sb^2O^4$, and by mixing the solution of this salt with a small quantity of hydrochloric acid, a more acid salt, $K^2O.2Sb^2O^4$ is precipitated. By treating the same solution with a large quantity of acid, a precipitate is formed, consisting of the hydrated tetroxide, $H^2O.Sb^2O^4$. It is, however, more in accordance with the reactions above-mentioned, to regard these salts as antimonoso-antimonates, that is to say, as compounds of *antimonates* (containing Sb^2O^5) with antimonites (containing Sb^2O^3); thus the salt, $K^2O.Sb^2O^4$, may be regarded as $(K^2O.Sb^2O^3) + (K^2O.Sb^2O^5)$, or $KSbO^2.KSbO^3$.

The antimonoso-antimonates of the earth-metals and heavy metals are insoluble in water, and may be obtained by precipitation. Two of them are known as natural minerals, viz. — 1. *Romeine*, or (so-called) *Antimonite of calcium*, found at St. Marcel, in Piedmont, in groups of minute square-based octahedrons, of hyacinth-red, or honey-yellow colour; specific gravity 4·714 (in powder 4·675), hard enough to scratch glass. It contains 62·18 per cent. antimony, 15·82 oxygen, 16·29 lime, 1·31 iron, 1·21 protoxide of manganese, and 2·86 silica. The formula, $3Ca^2O.2Sb^2O^4$, requires 61·9 per cent., Sb, 22·7 O, and 15·4 Ca (Dana, ii. 410).—2. *Ammiolite*, or (so-called) *Antimonite of mercury*, occurs, mixed with clay and hydrated sesquioxide of iron, in the quicksilver mines in Chili, and at Silberg, near Olpe in Westphalia. It is a red powder, containing, according to Domeyko (Ann. Min. [4] vi. 183), 12·5 per cent. Sb^2O^4, 14·0 Hg^2O, 22·3 Fe^4O^6, 26·5 SiO^2, and 24·7 water (and loss). Probably only a mixture. (Dana, ii. 142.)

Pentoxide of Antimony, Antimonic Oxide or Anhydride, Sb^2O^5. In the hydrated state: **Antimonic Acid.**—This compound is obtained as a hydrate: —1. By treating antimony with nitric acid, or with aqua regia containing excess of nitric acid.—2. By precipitating a solution of antimonate of potassium with an acid. —3. By decomposing pentachloride of antimony with water.

The hydrated oxide obtained by either of these methods gives off its water at a heat below redness, and yields the pentoxide or anhydrous antimonic acid, as a yellowish powder. The same body is obtained by heating pulverised antimony with mercuric oxide till the green antimonate of mercury at first produced is decomposed and all the mercury driven off. It is tasteless, insoluble in water and in acids, and has a specific gravity of 6·6 (Boullay). At a red heat, it gives off oxygen, and is converted into the tetroxide. It is dissolved by boiling potash-ley, and when fused with carbonate of potassium expels carbonic anhydride and forms a salt, from which acids separate hydrated antimonic acid.

The hydrated oxides or acids obtained by the three methods above given, are by no means identical. That obtained by the first and second method is monobasic, and according to Berzelius, contains $Sb^2O^5.H^2O$ or $SbHO^3$; according to Fremy, $Sb^2O^5.5H^2O$, or SbH^3O^4, when air-dried at mean temperature; but the acid obtained by the action of water on pentachloride of phosphorus is dibasic, and contains, according to Fremy, $Sb^2O^5.4H^2O$. The monobasic acid is called *Antimonic acid;* the dibasic acid, *Metantimonic acid.* These acids are further distinguished by the following characters. Antimonic acid is a soft white powder, sparingly soluble in water, reddens litmus, and is dissolved, even in the cold, by strong hydrochloric acid and by potash-ley. The hydrochloric solution mixed with a small quantity of water, yields after a while, a precipitate of antimonic acid, but if diluted with a large quantity of water, it remains clear. Ammonia does not dissolve it in the cold. It is converted into metantimonic acid by heating with a large excess of hydrate of potassium.—Metantimonic acid dissolves in acids more readily than antimonic acid, and is dissolved by ammonia, after a while, even at ordinary temperatures. It likewise dissolves completely in a large quantity of water, and is precipitated therefrom by acids. It is very unstable, and easily changes into antimonic acid, even in water.

ANTIMONATES and METANTIMONATES.—Antimonic acid forms neutral or normal salts, containing $M^2O.Sb^2O^5$ or $MSbO^3$, and acid salts containing $M^2O.2Sb^2O^5$, or $Sb^2O^5.2MSbO^3$. Metantimonic acid, which is dibasic, forms normal salts containing $2M^2O.Sb^2O^5$, or $M^4Sb^2O^7$, and acid salts containing $2M^2O.2Sb^2O^5$, or $M^2O.Sb^2O^5$, so that the acid metantimonates are isomeric or polymeric with the neutral antimonates.* An acid metantimonate easily changes into a neutral antimonate (Fremy, Ann. Ch. Phys. [3] xii. 316, 357; xxii. 404).—Heffter (Pogg. Ann. lxxxvi. 411) analysed a series of antimonates, which, calculating from the old atomic weight of antimony (119), he supposed to contain 12 at. Sb^2O^5 to 13 at. of a base M^2O; but on recalculating the analyses with the new atomic weight (Sb = 120·3), it is found that they agree with the general formula $M^2O.Sb^2O^5$.

The metantimonates of ammonium, potassium, and sodium, are crystalline; the antimonates of the same bases are gelatinous and uncrystallisable. The soluble acid metantimonates form a crystalline precipitate with sodium-salts; the soluble antimonates do not form any such precipitate.

The antimonates and metantimonates of the alkali-metals are the only ones that are easily soluble in water. All the rest are insoluble or sparingly soluble, and may be obtained by precipitation.

Antimonate of Aluminium.—On adding the solution of an aluminium-salt to excess of antimonate of potassium, the whole of the alumina is precipitated in combination with antimonic acid, in white flocks, somewhat soluble in excess of the aluminium-salt.

Antimonate of Ammonium, $(NH^4)^2O.Sb^2O^5 + 2H^2O$, or $(NH^4)SbO^3 + H^2O$, separates as a white powder from a solution of antimonic or metantimonic acid in warm aqueous ammonia.—Neutral *metantimonate of ammonium*, $2(NH^4)^2O.Sb^2O^5$, is obtained in solution by treating metantimonic acid with *cold* aqueous ammonia; it is not easily obtained in the solid state. The solution mixed with a drop or two of alcohol, deposits a crystalline salt, which is the *acid metantimonate of ammonium*, $(NH^4)^2O.Sb^2O^5 + 6H^2O$. This salt is soluble in water, and the solution precipitates sodium-salts. It is very unstable, being converted, with loss of water, slowly at ordinary temperatures, and immediately at the boiling heat, into the insoluble neutral antimonate, with which it is isomeric.

Antimonate of Antimony, $Sb^2O^3.Sb^2O^5$.—The tetroxide of antimony is sometimes regarded as constituted in this manner (p. 317).

Antimonate of Barium, $Ba^2O.Sb^2O^5$, or $BaSbO^3$, is obtained by double decomposition, as a flocculent precipitate which gradually becomes crystalline; it dissolves slowly in aqueous chloride of barium.

Antimonate of Calcium, $Ca^2O.Sb^2O^5$, is a crystalline precipitate, which adheres closely to the sides of the vessel, like carbonate of calcium.

Antimonate of Cobalt, $Co^2O.Sb^2O^5$.—Reddish crystalline precipitate, which, when heated, gives off water, turns violet, and then black; when heated to redness, it becomes incandescent, and on cooling appears nearly white.—By mixing a solution of sulphate of cobalt with a hot solution of antimonate of sodium, Heffter (*loc. cit.*) obtained a flocculent rose-coloured precipitate, containing $Co^2O.Sb^2O^5 + 7H^2O$, and the mother-liquor, after standing for some days, deposited six-sided prisms containing $Co^2O.Sb^2O^5 + 12H^2O$.

Antimonate of Copper, $Cu^2O.Sb^2O^5$, or $CuSbO^3$, is a greenish crystalline powder, which when heated gives off 19½ per cent. water, and turns black. At a red heat, it glows like the cobalt-salt, turns white, and is afterwards unattackable by acids or alkalis in solution. On charcoal before the blowpipe, it is reduced to antimonide of copper.

Antimonates of Iron.—The *ferrous* salt is a white powder which becomes yellowish grey when dry, red by ignition, and is sparingly soluble in water. The *ferric* salt is light yellow.

Antimonate of Lead, $Pb^2O.Sb^2O^5$, or $PbSbO^3$, is obtained as a yellow anhydrous powder by fusing pentoxide of antimony with oxide of lead, or as a white hydrate by precipitation; the hydrate gives off its water when heated, and turns yellow.

---

* If $O = 8$, the formulæ of the neutral and acid antimonates are $MO.SbO^5$ and $MO.2SbO^5$, and of the metantimonates, $2MO.SbO^5$ and $2MO.2SbO^5$ respectively.

A basic antimonate of lead, known by the name of *Naples Yellow*, is much used in oil-painting. It is obtained of the finest colour by mixing 2 pts. of chemically pure nitrate of lead with 1 pt. of the purest tartar-emetic and 4 pts. of common salt purified by repeated crystallisation, exposing the mixture for two hours to a heat just sufficient to fuse the chloride of sodium, and dissolving out the chloride of sodium with water; if the temperature has not been allowed to rise too high, the Naples yellow is then obtained in the form of a fine powder. — The same pigment is likewise obtained, but generally of a less brilliant colour, by fusing equal parts of antimony and lead with 3 pts. of nitre and 6 pts. of common salt.

Another basic antimonate of lead, $3Pb^2O.Sb^2O^5 + 4H^2O$, occurs native at Nertschinsk in Siberia, forming the mineral *Bleinierite*. It is amorphous, reniform, spheroïdal; also earthy or incrusting; sometimes with curved lamellar structure, specific gravity 3·933 (Karsten); 4·6—4·76 (Hermann). Lustre resinous, dull, or earthy. Colour grey, brownish, or yellowish. Opaque. Streak, greyish or yellowish. It is perhaps a mechanical mixture of lead and antimony ochres, and appears to result from the decomposition of other ores of antimony. (Hermann, J. pr. Chem. xxxiv. 179.)

Antimonate of Lithium. — Obtained by mixing a concentrated solution of chloride of lithium with antimonate of potassium, in flocks which soon become crystalline. It dissolves easily in hot water, and separates in grains on cooling. In dilute solutions, no precipitate is obtained.

Antimonate of Magnesium, $Mg^2O.Sb^2O^5 + 12H^2O$. — Separates by double decomposition from boiling solutions, in colourless shining hard crystals, which are isomorphous with the corresponding cobalt-salt, give off 8 per cent. water at 100° C., 10 per cent. at 200°, and 11 per cent. at 300°. (Heffter.)

Antimonate of Manganese. — White, altered by exposure to the air, sparingly soluble in water, somewhat more soluble in excess of the manganous salt. At a red heat, it becomes unattackable by acids, but does not glow.

Mercuric Antimonate, $Hg^2O.Sb^2O^5$, or $HgSbO^3$, is obtained by double decomposition as an orange-yellow precipitate. There is also an olive-green mercuric antimonate obtained by heating to low redness a mixture of 1 pt. powdered antimony, and 6 or 8 pts. mercuric oxide. At a stronger heat, this salt gives off oxygen and mercury, and leaves antimonic oxide. It is but little attacked by acids; but boiling hydrochloric acid dissolves a small quantity of it, and ammonia added to the solution throws down a light green powder.

Antimonate of Nickel. — Sulphate of nickel mixed with a boiling solution of antimonate of potassium, immediately forms a light green flocculent precipitate containing $Ni^2O.Sb^2O^5 + 6H^2O$, and the mother-liquor, after a few days, yields crystals of darker colours isomorphous with the magnesium-salt and analogous to it in constitution.

Antimonates of Potassium. — The neutral salt, $K^2O.Sb^2O^5 + 5H^2O$, is obtained by fusing 1 pt. of antimony with 4 pts. of nitre, digesting the fused mass in tepid water to remove nitrate and nitrite of potassium, and boiling the residue for an hour or two with water. The white insoluble mass of anhydrous antimonate is thereby transformed into a hydrate containing 5 at. water, which is soluble. The solution, when evaporated, leaves this hydrate in the form of a gummy uncrystallisable mass, which gives off 2 at. of water at 160° C., and the whole at a higher temperature. According to Heffter the anhydrous neutral antimonate is partly decomposed by prolonged boiling with water, an acid salt $2K^2O.Sb^2O^5$ remaining undissolved, and the liquid filtered therefrom yielding by evaporation the neutral salt with 7 at. water: $K^2O.Sb^2O^5 + 7H^2O$.

Acid Antimonate of Potassium is obtained by passing carbonic acid gas through a solution of the neutral antimonate. It is white, crystalline, perfectly insoluble in water, and is converted into the neutral salt when heated with excess of potash. This salt is the *antimonium diaphoreticum lavatum* of the pharmacopœias. (Fremy.) According to Heffter, the salt thus obtained is $2K^2O.3Sb^2O^5 + 10H^2O$.

Neutral Metantimonate of Potassium is prepared by fusing antimonic oxide or neutral antimonate of potassium with a large excess of potash. The fused mass dissolves in a small quantity of water, and the solution evaporated in vacuo yields crystals of the neutral metantimonate. This salt dissolves freely and without decomposition in warm water containing excess of potash; but cold water or alcohol decomposes it into potash and the acid matantimonate. Hence the aqueous solution of this salt gives a precipitate, after a while, with salts of soda. (Fremy.)

Acid Metantimonate of Potassium, $K^2O.Sb^2O^5 + 7H^2O$, sometimes called *granular antimonate of potassium*. — This salt is used as a test for soda. To obtain it, the neutral antimonate is first prepared and dissolved in the manner above described; the solution is filtered to separate any acid antimonate that may remain undissolved, then evaporated to a syrup in a silver vessel; and hydrate of potassium is added in lumps to convert the antimonate into metantimonate. The evaporation is then continued till the liquid begins to crystallise, which is ascertained by taking out a drop now and then upon a glass rod, and the liquid is then left to cool. A crystalline mass is thus obtained, consisting of neutral and acid metantimonate of potassium; the alkaline liquor is then decanted, and the salt dried upon filtering paper or unglazed porcelain (Fremy). This salt may also be prepared by treating trichloride of antimony with an excess of potash sufficient to redissolve the precipitate first formed, and adding permanganate of potassium till the solution acquires a faint rose colour. The liquid, filtered and evaporated, yields crystals of the granular metantimonate (Reynoso). This salt is sparingly soluble in cold water, but dissolves readily in water, between 45° and 50° C. When boiled with water for a few minutes, or kept in contact with water for some time, it is converted into the neutral antimonate. It must therefore be preserved in the solid state, and dissolved just before it is required for use. A small quantity of it is then treated with about twice its weight of cold water, to remove excess of potash, and convert any neutral metantimonate into the acid salt; the liquid is decanted; and the remaining salt is rapidly washed three or four times with cold water, then left in contact with water for a few minutes, and the liquid is filtered. On adding to the solution thus obtained a small quantity of any sodium-salt, a crystalline precipitate is formed, consisting of *acid metantimonate of sodium* (*vid. inf.*).

Antimonate of Sodium is obtained in tabular aggregates of small crystals, when the wash-water, resulting from washing a deflagrated mixture of antimony and nitre, is mixed with a sodium-salt. This salt has, according to Fremy, the composition $Na^2O.Sb^2O^5 + 7H^2O$. A salt of the same constitution is obtained, according to Heffter, in regular octahedrons, by boiling golden sulphide of antimony with caustic soda, and filtering the aqueous extract. It is nearly insoluble in cold water, soluble in about 350 pts. of boiling water. It gives off 2 at. water at 200° C., 2 at. more at 300°, and the rest at a red heat.

Acid Metantimonate of Sodium, $Na^2O.Sb^2O^5 + 7H^2O$, or $2NaHO.Sb^2O^5 + 6H^2O$.—This salt is produced when a solution of acid metantimonate of potassium, free from excess of alkali, is added to the solution of a sodium-salt. If the solution is not very dilute the precipitate is flocculent at first, but soon becomes crystalline. It is produced immediately in solutions containing not less than 1 pt. of sodium-salt in 300 pts. of liquid. In more dilute solutions, the precipitation is gradual, the metantimonate of sodium being deposited in crystals on the sides of this vessel, the effect being apparent after twelve hours, even in solutions containing not more that $\frac{1}{1000}$ pt. of sodium-salt. The precipitation is accelerated and rendered more complete by adding a little alcohol. The presence of free alkali retards it. The solution of sodium to be tested in this manner should be free from salts of lithium, ammonium, and the earth-metals, all of which, when diluted to a certain extent, yield precipitates of similar character. Acid metantimonate of sodium gives off 6 at. of water at 100°C., the seventh at about 300°.

Antimonate of Strontium.—Amorphous precipitate containing $Sr^2O.Sb^2O^5 + 6H^2O$.

Antimonate of Zinc, $Zn''O.Sb^2O^5$.—Crystalline precipitate somewhat soluble in excess of the zinc-salt. When heated, it gives off water and turns yellow, but without incandescence. On charcoal before the blowpipe it does not fuse; neither is it reduced without addition of alkali.

ANTIMONY, OXYCHLORIDE OF. *Basic Chloride of Antimony, Powder of Algaroth, Pulvis Algarothi s. angelicus, Mercurius Vitæ*, &c.—A compound formed by the action of water on trichloride of antimony. It was formerly much used in medical practice, but now serves chiefly for the preparation of pure antimonious oxide and tartar-emetic. The best way of preparing it is to boil commercial sulphide of antimony in fine powder with strong hydrochloric acid, till the liquid is saturated, sulphuretted hydrogen escaping all the while; leave the solution to cool; add to it, with agitation, small portions of water till it begins to show turbidity; then filter; mix the filtrate with five to ten times its bulk of water; and wash the resulting precipitate thoroughly with cold water by decantation or on the filter. The addition of a small quantity of water and filtration before the complete precipitation, is necessary, in order to remove a small quantity of hydrosulphuric acid, which always remains in the acid liquid, but is carried down by the first portions of oxychloride precipitated, and thereby removed: if allowed to remain, it would cause the precipitate to turn yellow.

The dried precipitate is a heavy white amorphous powder; but if left to stand in the liquid, or if boiled with it, is converted into a mass of small shining oblique rectangular prisms. It varies in composition according to the temperature of the water used for the precipitation and washing. According to Duflos and Bucholz, it is

$2SbCl^3.5Sb^2O^3$; according to Johnston, $4SbCl^3.9Sb^2O^3$; according to Schneider, $2SbOCl.Sb^2O^3$; according to Peligot, the precipitate formed in the cold is $SbCl^3.Sb^2O^3$, or SbO.Cl, (chloride of antimonyl), and after it has become crystalline by heating, $2SbCl^3.5Sb^2O^3$. Continued washing with water removes more and more of the chloride, ultimately leaving nearly pure antimonious oxide; alkaline-water removes the whole of the chloride. The oxychloride is also decomposed by heat, the chloride being volatilised and oxide remaining.

Antimonious oxide dissolves in about 15 times its weight of the boiling trichloride, and the solution on cooling solidifies into a pearly grey, perfectly crystalline mass, apparently consisting of $Sb^2OCl^4.6SbCl^3$, analogous to the sulphochloride formed in like manner (p. 338). It is decomposed by absolute alcohol, with separation of powder of algaroth. (Schneider, Pogg. Ann. cviii. 407.)

ANTIMONY, OXYIODIDE OF. Antimonious iodide is decomposed by water, yielding a white precipitate, which appears to be analogous in composition to the oxychloride. An oxyiodide, $2SbI^3.5Sb^2O^3$, is likewise obtained in gold-coloured spangles resembling iodide of lead, by adding iodine to a solution of tartar-emetic, or by treating the trichloride of antimony with solution of iodide of potassium, evaporating the solution, treating the residue with water, and repeating these operations several times. It is decomposed by heat. Hydrochloric acid dissolves it, with separation of iodine. It is slightly soluble in tartaric acid and cream of tartar. Nitric acid decomposes it, separating oxide of antimony. (Preuss, Pharm. Centr. 1839, p. 311.)

ANTIMONY, OXYSULPHIDE OF. The compound $Sb^2O^3.2Sb^2S^3$ occurs native as *Red antimony, Antimony blende, Kermesome, Rothspiessglanzerz*, in needles or tufts of capillary crystals belonging to the monoclinic system: Specific gravity = 4·5 to 4·6. Hardness = 1 to 1·5. It has a cherry-red colour and adamantine lustre, gives a brownish-red streak, and is slightly translucent, appearing scarlet by transmitted light. Melts very readily before the blowpipe, sinking into the pores of the charcoal, and volatilising in dense clouds. Ignited in a current of hydrogen, it yields hydrosulphuric acid, water, and metallic antimony (H. Rose, Pogg. Ann. iii. 452). It contains 74·5 to 74·7 Sb, 5·29 to 4·7 O, and 20·5 S. Occurs in veins in quartz, accompanying grey and white antimony, at Malaczka near Posing in Hungary, at Bräunsdorf near Freiberg, and at Allemont in Dauphiny. It appears to result from alteration of grey antimony ore. A similar compound, but of an orange-red colour and containing only 17·9 per cent. sulphur, sublimes when aqueous vapour is passed over the ignited trisulphide. (Regnault.)

Various oxysulphides of antimony may be prepared artificially. They were formerly much used in pharmacy for the preparation of tartar-emetic, but are now nearly obsolete. α. *Antimonial crocus* or *saffron* (*Crocus antimonii, s. metallorum*) is a brownish-yellow substance, prepared by fusing a mixture of 3 pts. of the trioxide and 1 pt. trisulphide of antimony, or an oxide of antimony with the proper proportion of sulphur. A similar compound, mixed however with variable quantities of antimonite of potassium, is obtained by treating the trisulphide with caustic alkalis (p. 332). β. *Glass of antimony* (*Vitrum antimonii*) is an oxysulphide prepared by roasting the grey sulphide at a moderate heat, till it is converted into the tetroxide, and fusing this *antimony ash* in an earthen crucible, with about $\frac{1}{20}$ of its weight of sulphur. It is a brilliant substance, varying in colour from yellowish-red to hyacinth-red, according to the proportions used. It gives up its oxide to acids, and evolves sulphuretted hydrogen when treated with hot hydrochloric acid. γ. A compound of trisulphide of antimony with a very small portion of oxide, called *Regulus antimonii medicinalis* or *Rubinus antimonii*, is obtained by fusing 5 pts. of the grey sulphide with 1 pt. of pearl-ash, and separating the upper stratum (consisting of sulphantimonite of potassium) from the lower. It is a black mass, having a brilliant conchoïdal fracture, and yielding a dark grey powder.

According to Liebig, mineral kermes prepared by the action of alkaline carbonates on the amorphous trisulphide, is a definite oxysulphide of antimony (see p. 328); but kermes obtained by most other modes of preparation, appears to contain the oxide merely in a state of mixture with the sulphide.

ANTIMONY, SELENIDE OF. Antimony and selenium unite when heated together, to a lead-grey crystalline mass, the combination being attended with rise of temperature, often amounting to ignition. The same compound is formed by precipitating a solution of tartar-emetic with seleniuretted hydrogen; hence its formula is probably Sb^2Se^3. Selenide of antimony is easily fusible, and oxidises when heated in the air, giving off selenious acid. Heated with trioxide of antimony, out of contact with the air, it melts into a mass resembling the fused sulphide.

ANTIMONY, SULPHIDES OF. Antimony forms two sulphides, Sb^2S^3 and Sb^2S^5, corresponding to antimonious and to antimonic oxide, and perhaps also an intermediate sulphide corresponding to the tetroxide.

TRISULPHIDE OF ANTIMONY, ANTIMONIOUS SULPHIDE, ANHYDROUS SULPHANTIMONIOUS ACID, Sb^2S^3, or SbS^3.—This compound exists in the crystalline and in the amorphous state.

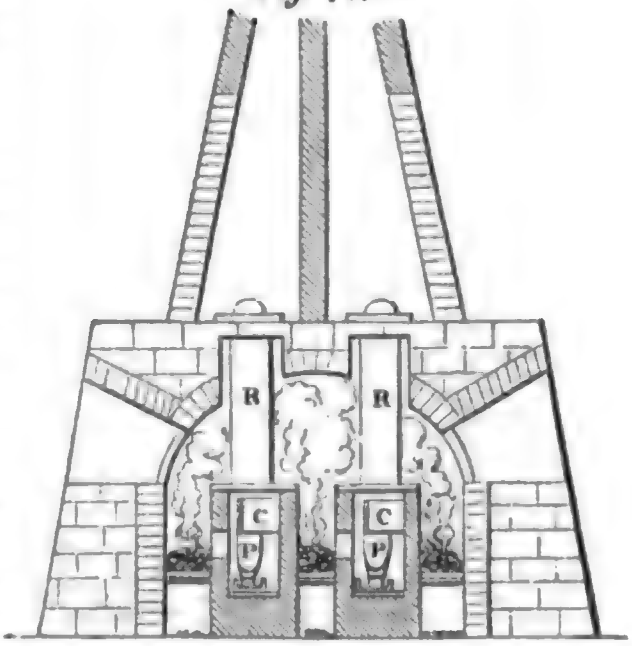
1. The *crystallised* trisulphide occurs as a natural mineral called stibnite, stibine, grey antimony, antimony-glance (*Spiessglanz*, *Grauspiessglanzerz*, *Antimoine sulfuré*, *Leo ruber*, *Plumbum nigrum*, *Lupus metallorum*). It is the source of all the antimony of commerce. It is found in various localities in Hungary, Germany, and France, also in Cornwall, in Dumfriesshire, in Maine, Maryland, and New Hampshire (U. S.), and abundantly in Borneo,—always associated with the older rocks, such as gneiss, quartz, clay-slate, mica-slate, limestone, porphyry, &c., whence it is separated by simple fusion, yielding the *crude antimony* of commerce.

The separation of the sulphide from the accompanying gangue is effected in various ways. The simplest arrangement is that which is in use at Malbosc in the department of Ardèche, in France, and at Wolfsberg in the Harz. A number of conical pots, perforated at bottom, and standing upon receivers sunk in the ground, are placed twenty-five or thirty in a row, between walls about nine inches high, the space between the pots being filled with coal, and the fire lighted with brushwood. Each pot holds about 45 kilogrammes of ore, and in forty hours four meltings are made, sufficient to fill the receivers. The advantages of this method are that it saves the expense of erecting a furnace, and may be carried on at any place to which the ore and fuel can be most easily transported. But it involves a large consumption of fuel, and is therefore advantageous only where fuel is very abundant. At Malbosc the consumption is 300 kilogrammes of coal and 40 kil. of wood, for every 100 kil. of crude antimony produced.

Another method, somewhat different from the above, consists in heating the conical pots by the flame of a reverberatory furnace, the receivers being placed below the hearth. This arrangement is also in use at Wolfsberg, and at La Lincouln in Haute Loire. At Schmöllnitz in Hungary, the pots are likewise heated by a reverberatory furnace; but the melted sulphide runs through a channel into receivers placed outside the furnace. This arrangement effects a considerable saving of time and fuel, as it enables the pots to be filled and emptied without putting out the fire.

In some localities, cylindrical tubes are used in preference to conical pots, as being more durable. An arrangement of this kind is in use at Malbosc. The ore is placed in large cylinders R R (*fig.* 71) each holding 500 pounds of ore, and four being heated in each furnace. The cylinders are perforated at bottom, and stand on plates pierced with corresponding apertures. Beneath these plates, in the chambers C C, are placed earthen pots P P, to receive the melted sulphide. The process lasts three hours, and when it is finished, the residues are taken out, either through the top of the furnace, or through apertures in the lower part of the cylinders (which are stopped with clay during the melting), and then the cylinders are refilled. With this arrangement, 64 pts. of coal are consumed for every 100 pts. of crude antimony produced.

Fig. 71.



Lastly, the ore is sometimes heated on the hearth of a reverberatory furnace, without the use of either pots or cylinders. The furnace has an inclined hearth, and the fused sulphide flows into a receiver placed outside. This arrangement, which is in use at Linz, in Prussia, and at Ramé in La Vendée, effects a great saving of fuel, and likewise does away with the expense of the containing vessels; but it involves a considerable loss of sulphide of antimony by volatilisation, and is therefore adopted only where fuel is very dear.

Whatever arrangement may be adopted, it is important that the ore be not broken into very small pieces. If it be too much divided or pulverised, the melted sulphide cakes together with the gangue, and is very difficult to separate. Too great heat must also be avoided, as at a white heat, sulphide of antimony is perfectly volatile. The residues always contain 10 or 12 per cent. of antimony, partly as sulphide, partly as oxide. [For further details, see Bruno Kerl's "Handbuch der metallurgischen Hüttenkunde," Freiberg, 1858, iii. 25.]

Native sulphide of antimony crystallises in prisms belonging to the trimetric system, with four-sided summits resting on the lateral faces. Cleavage very distinct, parallel to the shorter diagonal and the principal axis. Specific gravity 4·516 (Haüy); 4·62 (Mohr). Hardness = 2. It is sectile, and in thin laminæ slightly flexible; fracture subconchoïdal. It has a metallic lustre and lead-grey colour, inclining to steel-grey, sometimes iridescent. Produces a streak of the same colour. The fused sulphide generally forms blackish-grey, radiating, specular masses, having a steel-grey lustre. It is easily fusible, thin splinters melting even in the flame of a candle.

The native sulphide is seldom pure, being generally contaminated with lead, copper, iron and arsenic. Wittstein found in four samples of *crude antimony:*

	a	*b*.	*c*.	*d*.
Antimony	62·48	59·67	70·26	71·98
Lead	10·40	11·96		
Iron	0·70	0·63	0·31	
Arsenic	trace	trace		
Sulphur	26·42	27·74	29·43	28·02
	100·00	100·00	100·00	100·00

a. Iridescent, from Kronach in Upper Franconia; *b*. Non-iridescent, from the same locality; *c*. Hungarian; *d*. English.

The best way of detecting these impurities is to heat the finely pulverised mineral with strong hydrochloric acid, till it is completely decomposed. Lead, if present in any considerable quantity, will then separate on cooling, as crystallised chloride; water added to the solution will throw down oxychloride of antimony, while iron, copper, arsenic, and a little lead will remain in solution; copper may then be detected by ammonia, iron by ferrocyanide of potassium, lead by sulphuric acid.

To detect arsenic, the pulverised mineral is deflagrated with nitrate and carbonate of sodium; the fused mass boiled with water, the filtrate acidulated with hydrochloric acid, and sulphurous acid added to reduce the arsenic acid to arsenious acid, which may then be precipitated by sulphuretted hydrogen. The precipitate, however, may likewise contain sulphide of antimony, and must therefore be further examined.

To obtain *pure* crystallised trisulphide of antimony, it is best to prepare it artificially, by fusing pure metallic antimony with sulphur. 13 pts. of finely pulverised antimony are mixed as intimately as possible with 5 pts. of flowers of sulphur, and the mixture is thrown by small portions into a heated crucible, care being taken not to add a fresh portion till the combination of the last portion is completed, which may be known by the incandescence which accompanies the action. When the whole has been added, the crucible is covered and left to cool. If any portion of the antimony remains uncombined, it will sink to the bottom of the fused mass, and may easily be separated from the sulphide after cooling. It is sometimes recommended to remelt the product two or three times with smaller quantities of sulphur.

The *reactions* of crystallised sulphide of antimony are the same as those of the amorphous sulphide, to be presently described: but they take place less quickly, on account of the greater cohesion of the mass.

Amorphous Trisulphide of Antimony, Mineral Kermes.—Brown-red sulphide of Antimony, Pulvis Carthusianorum, Sulphur stibiatum rubrum, Stibium sulphuratum rubrum.—This substance is prepared by a great variety of processes, some of which yield the pure trisulphide, differing from the native compound only in colour and in the absence of crystalline structure, while others yield the sulphide more or less mixed with the trioxide, and sometimes with other antimonial compounds.

a. The pure amorphous sulphide may be obtained by the following processes.—1. By keeping the grey trisulphide in the fused state for a considerable time, and then cooling it very suddenly by throwing the vessel in which it has been melted into a large quantity of cold water (Fuchs).—2. By dissolving the native sulphide in potash-ley, and precipitating by an acid (Liebig).—3. By igniting 1 pt. of *crude antimony* with 2 pts. of black flax (a mixture of 1 pt. nitre, and 2 pts. cream of tartar), boiling the ignited mass with water, and mixing the clear filtrate with an alkaline carbonate, whereby the pure amorphous sulphide is precipitated (Liebig).—4. By the decomposition of alkaline sulphantimonites (livers of antimony).—5. By treating mineral kermes containing oxide of antimony, with tartaric acid, whereby the oxide is dissolved out.

b. *Mineral Kermes containing oxide* is obtained by the action of alkalis on the trisulphide. The oldest method, given by La Ligérie, consists in boiling the finely pulverised grey sulphide with the solution of an alkaline carbonate, and leaving the filtered solution to cool: the same process is given in the last edition of the Prussian Pharmacopœia. As however, crystallised sulphide of antimony dissolves but slowly in alkaline carbonate, it is better first to convert the crystallised into the amorphous sulphide, and prepare the kermes from the latter. The following is the process given by Liebig (Handw. d. Chem. 2te Aufl. ii. 121).

1 pt. of the pulverised grey sulphide is boiled for an hour with 1 part of solid caustic potash and 30 pts of water (or 1 pt. of the grey sulphide with 4 pts. potash-ley of specific gravity 2·25 and 12 pts. water, or 1 pt. sulphide, with 1 pt. carbonate of potassium, 1½ pts. slaked lime, and 15 pts. water), and the filtered liquid is mixed with dilute sulphuric acid, whereby amorphous sulphide of antimony is precipitated. The thickish mixture is then divided into three parts, and covered with water in three separate vessels; the precipitate is left to settle; the water is decanted; and fresh water added till the precipitates are well washed: they are then placed upon three separate filters. 1 pt. of anhydrous (or 2·7 pts. of crystallised) carbonate of sodium is next dissolved in 34 pts. of water; the precipitate from the first of the three filters is introduced into the filtered solution; the liquid is boiled for an hour; and the solution, which has taken up all the sulphide of antimony, is left to cool, whereupon it deposits kermes. The supernatant liquid is now brought to the boiling heat, the second precipitate is added to it and treated in the same manner, and finally the same processes are repeated with the third. The finest coloured kermes is deposited from the second boiling. The precipitates are washed with cold water: their weight after drying, amounts to nearly the half of the grey sulphide used. [For the rationale of the process, see DECOMPOSITIONS OF SULPHIDE OF ANTIMONY, p. 333.]

The solution obtained by boiling the grey sulphide with caustic potash or soda deposits kermes on cooling, provided the alkali is not in great excess; and by boiling the mother-liquors remaining after the deposition of the kermes with the undissolved portion of the grey sulphide, fresh deposits, smaller in quantity, may be obtained. According to Duflos, the solution obtained by boiling 100 pts. of grey sulphide for a quarter of an hour with a solution of 30 parts of hydrate of potassium in 300 pts. of water, deposits on cooling 25 pts. of kermes; a second boiling of the mother-liquor with the undecomposed grey sulphide yields 10 pts.; a third yields 2·3 pts. The successive deposits thus formed are continually richer in oxide of antimony.

A solution containing so much alkali as not to yield any deposit on cooling, yields a precipitate of kermes when carbonic acid gas is passed through it, and afterwards an additional quantity when treated with strong acids. The precipitate thus formed generally contains a little oxide, and always a sulphantimonate of potassium or sodium, of the form $K^2S.Sb^2S^5$, because, according to H. Rose, part of the antimony is oxidised by the air, and gives up its sulphur to the trisulphide of antimony, thereby converting it into pentasulphide.

Kermes may likewise be obtained by boiling sulphide of antimony with potash-ley and sulphur, or by boiling a solution of sulphantimonite of sodium with metallic antimony. There are also several other modes of preparation, for which we must refer to Gmelin's Handbook, vol. iv. pp. 340—349, where they are fully described. The preparations obtained by these different methods, are, however, by no means identical; they contain variable proportions of oxide of antimony, and many of them likewise contain sulphantimonite of potassium or sodium.

Properties.—The pure amorphous trisulphide obtained by Fuchs's method is a dense fissured mass, harder than the native sulphide, having a conchoïdal fracture, a grey colour, or in thin pieces, dark hyacinth-red, and yielding a red-brown powder somewhat lighter in colour than ordinary kermes; its specific gravity is 4·15. The pure amorphous sulphide prepared by other methods is a brown-red, loosely coherent powder, which makes a brown streak on paper. It is lighter than the native sulphide, and does not conduct electricity. It contains water, which it gives off below 100° C. When treated for some time with cold hydrochloric acid, or when fused and very slowly cooled, it is converted into the crystalline sulphide.

Ordinary kermes containing oxide is a brown-red loose powder, which becomes blackish-grey when washed with boiling water. By fusion and slow cooling, it is converted into a slag-like mass, totally destitute of crystalline structure, a property by which it differs essetnially from the pure amorphous sulphide.

Hydrated Trisulphide of Antimony.—The amorphous sulphide is obtained as a hydrate by passing sulphuretted hydrogen through an acid solution of the trichloride, or through a solution of tartar-emetic acidulated with acetic acid. The precipitate at first formed in a solution of the trichloride acidulated with tartaric acid, is a mixture of the hydrated sulphide with oxychloride; but on continuing the passage of the gas, it becomes darker in colour, and is completely converted into the hydrated sulphide. The precipitate obtained by decomposing a solution of sulphantimonate of potassium with sulphuric acid is probably also the hydrated sulphide.

Hydrated trisulphide of antimony when dry has a fine dark orange-colour. It gives off water when moderately heated, but to dehydrate it completely, requires a temperature of 200° C. it then turns black. At higher temperatures, it melts and solidifies in the crystalline form on cooling.

Decompositions of Trisulphide of Antimony.—The reactions of this compound are nearly the same, whether it be in the crystalline or in the amorphous state, the crystalline variety merely acting less quickly on account of its closer state of aggregation.—1. The dry amorphous sulphide touched with a red-hot body burns away in the *air* with a glimmering light, producing sulphurous anhydride, antimonious oxide, and antimonic oxide; the grey sulphide heated above its melting point, burns with a blue flame, yielding the same products.—2. The recently precipitated amorphous sulphide is decomposed by boiling for some time with a large quantity of *water*, yielding hydrosulphuric acid and antimonious oxide, which dissolve. Vapour of water passed over red-hot sulphide of antimony likewise yields hydrosulphuric acid and antimonious oxide, the latter combining with undecomposed sulphide, and an orange-yellow body subliming.

3. *Chlorine*, with the aid of heat, *decomposes* the trisulphide completely, forming trichloride of antimony and chloride of sulphur.—4. Heated in *hydrochloric acid gas* or boiled with the strong aqueous acid, it gives off hydrosulphuric acid, and forms trichloride of antimony, which in the latter case dissolves in the excess of acid.—5. With *strong sulphuric acid*, it yields sulphurous anhydride and antimonious sulphate, the sulphur being separated as a compact mass.—6. With *strong nitric acid*, it forms antimonious oxide and sulphuric acid, part of the sulphur, however, being set free and remaining mixed with the oxide.—7. *Aqua-regia* containing excess of hydrochloric acid dissolves the trisulphide, forming trichloride of antimony and sulphuric acid, and leaving a residue of sulphur often mixed with a little antimonic acid.—8. The trisulphide ignited with *nitrate of potassium or sodium*, is violently oxidised, being completely converted into sulphuric and antimonic acids, if 17 pts. or more of nitre are used to 10 of antimony; with less nitre, a compound of sulphide of potassium, sulphide of antimony and antimonic oxide is likewise formed.—9. Many metals, *e. g. iron*, *potassium*, and *sodium* (or a mixture of carbonate of potassium or sodium with charcoal), decompose sulphide of antimony at a red heat, the resulting metallic sulphide sometimes uniting with undecomposed sulphide of antimony; if, on the other hand, the reducing metal is in excess, it sometimes forms an alloy with the reduced antimony.

10. The *fixed caustic alkalis* decompose trisulphide of antimony in the same manner in the wet and in the dry way, forming trioxide of antimony and a sulphide of the alkali-metal:

$$Sb^2S^3 + 3K^2O = 3K^2S + Sb^2O^3,$$

but the final products of the action vary according to the state of aggregation of the antimonious sulphide, the temperature to which the mixture is exposed, and the proportions of the two substances present. *a.* When amorphous sulphide of antimony, prepared in the wet way, is triturated with cold potash-ley, it dissolves *completely* up to a certain point, the sulphide of potassium formed as above, taking up undecomposed sulphide of antimony, and the antimonious oxide dissolving in the potash. This solution contains sulphantimonite and antimonite of potassium. When treated with acids, it yields a precipitate of antimonious sulphide, without evolution of sulphuretted hydrogen, because the quantity of that compound evolved by the decomposition of the sulphide of potassium present, is but just sufficient to convert the trioxide of antimony into trisulphide. But if the addition of the trisulphide be continued, a point is at length reached, at which the alkaline liquid cannot take up any more antimonite of potassium, and any further quantity of antimonious oxide then formed remains undissolved, partly combined with potash, partly with antimonious sulphide, forming the mixture called *crocus antimonii* (328). The *incomplete* solution thus formed contains, however, a larger proportion of sulphide of potassium than the complete solution, the excess being proportional to the quantity of oxide left undissolved. This excess of sulphide of potassium takes up an additional quantity of sulphide of antimony, and the solution treated with acids, evolves sulphuretted hydrogen, besides giving a precipitate of antimonious sulphide. The *complete* solution mixed with carbonate of ammonium, or with acid carbonate of potassium or sodium, yields a dirty brown precipitate consisting of 3 at. antimonious sulphide with 1 at. sulphide of potassium or sodium, a portion of the alkaline sulphide also remaining in the liquid. The greater part of the alkaline antimonite is likewise precipitated, because the caustic alkali which held it in solution is converted into neutral carbonate. The precipitation of the antimonious oxide, is, however, partly caused by its affinity for the sulphide of antimony previously thrown down in combination with the alkali-metal. The *incomplete* solution is decomposed in like manner, but the precipitate contains a smaller proportion of antimonic oxide. The *complete* solution rapidly absorbs oxygen from the air; the sulphide of potassium is first decomposed, yielding oxide of potassium and sulphur, which then converts the trisulphide of antimony into pentasulphide:

$$3K^2S + Sb^2S^3 + O^2 = 2K^2O + K^2S.Sb^2S^5$$

so that the solution treated with acids yields a precipitate of pentasulphide of antimony; and subsequently the antimonite of potassium is converted into antimonate, which collects in crystals at the bottom.

b. When antimonious sulphide in excess is digested with *hot caustic alkalis*, the products formed are the same as in the cold, excepting that the sulphide of potassium then takes up a larger proportion of antimonious sulphide, the excess of which is subsequently deposited on cooling; not, however, in the pure state, but in combination, partly with alkaline sulphide, partly with antimonious oxide, the composition of the precipitate being, in fact, similar to that which is produced by alkaline bicarbonates in a cold-prepared solution of antimonious sulphide. The supernatant liquid gives with alkaline bicarbonates a precipitate of alkaline sulphantimonite free from oxide.

All the precipitates above-mentioned are altered in composition by prolonged treatment with cold water containing air, or with boiling water, antimonious oxide being dissolved out, in combination with alkali, and pure dark-coloured antimonious sulphide remaining.

c. Crystalline antimonious sulphide is acted upon by *caustic alkalis* in the same way as the amorphous sulphide, but less easily, and when the action takes place in the cold, a residue of *crocus antimonii* is always left, whatever may be the quantity of alkali present. The resulting solution exhibits the reactions of the *incomplete* solution above-mentioned.

11. *Alkaline carbonates*, fused with antimonious sulphide, either crystalline or amorphous, give off carbonic anhydride, and form antimonious oxide and a sulphide of the alkali-metal, the fused mass containing these products in combination with excess of antimonious sulphide and alkali. With 4 pts. antimonious sulphide and 1 pt. alkaline carbonate, an easily fusible mass is formed, which, after cooling, has an iron-grey colour, is perfectly homogeneous, and *is not attacked by water*. A mixture of 2 pts. carbonate to 1 pt. antimonious sulphide requires a strong red heat to melt it, and yields on cooling 12 per cent. of metallic antimony, together with a light brown liver of antimony, which deliquesces in the air, and is *perfectly soluble in water*. The separation of the metallic antimony results from decomposition of the alkaline antimonite contained in the mass, part of it being converted into antimonate. With intermediate proportions, the mixture fuses more readily, and the resulting liver of antimony is less soluble in water as the proportion of antimonious sulphide is greater. The insoluble residue contains the excess of antimonious sulphide in combination with a portion of the alkaline sulphide and with antimonious oxide; it is, in fact, similar in composition to the *crocus* prepared in the wet way, but generally contains more sulphide of antimony. Water acts upon these livers of antimony exactly in the same manner as solutions of the caustic alkalis act upon antimonious sulphide under the same circumstances.

Solutions of alkaline carbonates do not act on antimonious sulphide in the cold, but at the boiling heat, they dissolve the amorphous sulphide readily, the crystalline slowly. The hot solution, prepared out of contact with the air, contains the same products as the *complete* solution of the amorphous sulphide in cold potash-ley (p. 332). It becomes turbid on cooling, and deposits a grey-brown precipitate similar in composition to that which is produced by alkaline bicarbonates in the cold complete solution just mentioned, consisting, in fact, of two compounds, viz. an alkaline sulphantimonite and an oxysulphide of antimony. The liquid, after the separation of this precipitate, retains a certain portion of alkaline sulphide.

If the solution of antimonious sulphide in hot alkaline carbonate be boiled for some time in contact with the air, part of the alkaline sulphide becomes oxidised, and gives up part of its sulphur to the dissolved trisulphide of antimony, thereby converting it into pentasulphide, which remains in solution after cooling. The quantity of antimonious oxide in the precipitate remains the same, but the proportion of antimonious sulphide in it is diminished by the quantity thus retained in solution. The proportion of sulphide of sodium is likewise diminished by the oxidation. The quantity of antimonious oxide in the precipitate is now not only sufficient to replace all the alkaline sulphide in combination with the precipitated antimonious sulphide, but a certain quantity of alkaline antimonite likewise remains free in the liquid; and there is precipitated a *compound of trioxide and trisulphide of antimony*, which is the true **medicinal kermes**; it is generally, however, mixed with small quantities of alkaline antimonite.

Kermes prepared in this manner, contains, under all circumstances, a tolerably constant quantity of antimonious oxide, because, when alkaline carbonates are used, the portion of sulphide of antimony attacked by them passes *completely* into the solution, without leaving any residue, and consequently the entire quantity of the products thus formed is likewise contained in the liquid. (Liebig, Handwört. d. Chem. 2te. Aufl. ii. 125—130.)

12. By ignition with *baryta*, *strontia*, *lime*, and other *oxides*, antimonious sulphide is decomposed in the same manner as by caustic and carbonated alkalis: the products are insoluble in water, and consist of mixtures of metallic sulphantimonites with an oxysulphide of antimony.

Sulphantimonites.—Trisulphide of antimony is a sulphur-acid, uniting with basic metallic sulphides. Some of these compounds, containing the sulphides of the heavy metals, are natural minerals, viz.:

Zinkenite	$Pb^2S . Sb^2S^3$
Miargyrite	$Ag^2S . Sb^2S^3$
Antimonial Copper-glance	$Cu^4S . Sb^2S^3$
Plagionite	$4Pb^2S . 3Sb^2S^3$
Jamesonite	$3Pb^2S . 2Sb^2S^3$
Feather-ore	$2Pb^2S . Sb^2S^3$
Boulangerite.	$3Pb^2S . Sb^2S^3$
Pyrargyrite	$3Ag^2S . \left.\begin{matrix}Sb^2\\As^2\end{matrix}\right\}S^3$
Bournonite	$3(Cu^4S.Sb^2S^3) + 3Pb^2S.2Sb^2S^3)$
Fahl-ores	$2\begin{pmatrix}Zn^2S\\Fe^2S\end{pmatrix} + \begin{pmatrix}Sb^2S^3\\As^2S^3\end{pmatrix}$
Stephanite	$6Ag^2S . Sb^2S^3$
Polybasite	$9\begin{pmatrix}Ag^2S\\Cu^4S\end{pmatrix} + \begin{pmatrix}Sb^2S^3\\As^2S^3\end{pmatrix}$
Berthierite	$3Fe^2S . 2Sb^2S^3$
Variety of Berthierite, from Anglar . .	$Fe^2S . Sb^2S^3$
Variety of Berthierite, from Marturet . .	$3Fe^2S . 4Sb^2S^3$

In these formulæ, the elements whose symbols are written one above the other, replace one another isomorphously. [For description, see the names of the several minerals.]

The most important of the artifically prepared sulphantimonites are those which contain the protosulphides of the alkali-metals: they are called Livers of Antimony (*Hepar Antimonii*). They are obtained, mixed with oxide in various proportions, by fusing the trisulphide of antimony with alkaline carbonates, or metallic antimony with sulphate of potassium; and free from oxide, by melting sulphide of antimony with alkaline sulphates and charcoal, or with alkaline carbonates, sulphur and charcoal, or again by melting sulphantimonate of sodium with metallic antimony.

These alkaline sulphantimonites, or livers of antimony, are easily fusible, and deliquescent or unalterable in the air, according to the proportion of the alkaline sulphide and the antimonious sulphide contained in them. They are more or less soluble in water, when the ratio of the antimonious sulphide to the alkaline sulphide is less than 2 : 1; insoluble, when it is greater.

In the fused state, they are black or black-brown and crystalline. Their solutions boiled with pulverised antimonious sulphides, dissolve an additional quantity of it, which on cooling is deposited as a flocculent precipitate containing also the alkaline sulphide. Acids added to the solutions throw down the amorphous sulphide; so likewise does carbonate of ammonium. Alkaline bicarbonates immediately throw down sulphantimonite of potassium or sodium; the solution mixed with an alkaline monocarbonate, remains clear at first, but solidifies after a while to a tremulous jelly containing the same compound. The same effect is produced when the aqueous solution of a liver of antimony is diluted with a large quantity of cold water. The solution of a liver of antimony changes very quickly when exposed to the air, a sulphantimonate being formed in solution, and a portion of the trisulphide of antimony being separated in brown metallic films or as a powder.

Pentasulphide of Antimony; Antimonic Sulphide; Anhydrous Sulphantimonic Acid.—*Persulphide of Antimony; Golden Sulphuret of Antimony; Sulphur Antimonii auratum*, Sb^2S^5, or SbS^5.—This compound is not found native. It is prepared: 1. By passing sulphuretted hydrogen through a mixture of the pentachloride with water and tartaric acid, or through antimonic oxide suspended in water.—2. By decomposing the solution of the sulphantimonate of an alkali-metal with an acid, the sodium-salt, for example, whereby the sulphide of sodium is decomposed, a salt of the alkali metal being formed, with evolution of sulphuretted hydrogen, and pentasulphide is precipitated:

$$\underset{\text{Sulphantimonate of sodium.}}{3Na^2S.Sb^2S^5} + 6HCl = 6NaCl + 3H^2S + Sb^2S^5.$$

[For details see Gmelin's Handbook, iv. 355; Handwörterb. d. Chem. 2^{te} Aufl. ii. 133.]

Pentasulphide of antimony is a yellowish-red powder, or loosely agglomerated mass, without any trace of crystalline structure; it has a very feeble odour of sulphur, a sweetish sulphurous taste, and is slightly emetic. Heated in close vessels to the boiling point of sulphur, it is resolved into the trisulphide and free sulphur. It burns with flame when heated in the air. Exposed to the air in the moist state, it is partly converted, after a while, into the trioxide of antimony.—Hot *hydrochloric acid* decomposes it, giving off sulphuretted hydrogen, separating sulphur, and forming an aqueous solution of trichloride of antimony; cold hydrochloric acid imparts to it a greyish colour, perhaps in consequence of the formation of the trisulphide and liberation of 2 at. sulphur.—Triturated, out of contact of air, with aqueous *ammonia*, it dissolves completely, more easily in a warm acid than in a cold solution, and is precipitated therefrom by acids. If the pentasulphide contains trisulphide, the latter remains as a brown residue; a yellow or white residue, on the other hand, indicates the presence of sulphur or of antimonic oxide.—The pentasulphide dissolves readily in *potash* or *soda-ley*, also in *sulphide of ammonium*. With a solution of sulphate of *copper* or nitrate of *silver*, it forms sulphantimonate of copper or silver, together with antimonic oxide.

SULPHANTIMONATES.—Pentasulphide of antimony is a strong sulphur-acid, uniting readily with the more basic metallic sulphides, and forming sulphur-salts, most of which have the composition $3M^2S.Sb^2S^5$, or M^3SbS^4 [or $3MS.SbS^5$, if $S = 16$], analogous to that of the ordinary tribasic phosphates (M^3PO^4). The sulphantimonates of the alkali-metals and alkaline earth-metals, are very soluble in water, and crystallise for the most part with several atoms of water; none of them appear to be soluble in alcohol. The sulphantimonates of the heavy metals are insoluble in water.

The soluble sulphantimonates are obtained:—1. By fusing pentasulphide of antimony or a mixture of the trisulphide and sulphur, with the sulphide of an alkali-metal, or with charcoal and the carbonate or sulphate of an alkali-metal. If a strong heat is used, the addition of sulphur to the trisulphide is unnecessary, as at high temperatures that compound is resolved into metallic antimony and the pentasulphide.—2. By dissolving pentasulphide of antimony in aqueous solutions of the alkaline hydrosulphates.—3. By dissolving the pentasulphide in the solution of a caustic alkali, or of an alkaline carbonate at the boiling heat; in which process an antimonate of the alkali-metal is formed simultaneously, and deposited as a white powder.—4. By decomposing the aqueous solutions of the alkaline antimonates with hydrosulphuric acid, ⅔ of the antimony being thereby separated as pentasulphide, because the alkaline antimonates are monobasic, and the sulphantimonates tribasic:

$$\begin{array}{lllllllll} & 3(K^2O.Sb^2O^5) & + & 18H^2S & = & 3K^2S.Sb^2S^5 & + & 18H^2O & + 2Sb^2S^5. \\ \text{or:} & 3KSbO^3 & + & 9H^2S & = & K^3SbS^4 & + & 9H^2O & + Sb^2S^5. \end{array}$$

The insoluble sulphantimonates are prepared by gradually adding a solution of a metallic salt to a solution of the sulphantimonate of an alkali-metal, that of sodium being generally used, keeping the latter in excess. If, on the other hand, the solution of the other salt is in excess, and especially if the liquid be boiled, the resulting precipitate contains oxygen, and the liquid is found to contain free acid. The precipitates thus formed generally contain $3M^2S.Sb^2S^5 + 5M^2O$, or rather $8M^2S + Sb^2O^5$, being, in fact, mere mixtures of a metallic sulphide with antimonic oxide, the latter being retained in them by its insolubility. (Rammelsberg. Pogg. Ann. lii. 193.)

The soluble sulphantimonates are decomposed by all acids, even by carbonic acid, with evolution of sulphuretted hydrogen. Many of the insoluble salts are decomposed only by nitric acid and aqua-regia. The sulphantimonates of the alkali-metals are not decomposed by ignition in closed vessels; those of the heavy metals give off sulphur at a red heat, leaving sulphantimonites containing $3M^2S.Sb^2S^3$, or M^3SbS^3.

Sulphantimonate of Ammonium, $3(NH^4)^2S.Sb^2S^5$, or $(NH^4)^3SbS^4$, is produced by digesting pentasulphide of antimony in excess with pure sulphide of ammonium, free from excess of ammonia. It cannot be obtained in the solid state, being decomposed both by concentration, even out of contact with the air, and by mixture with alcohol.

Sulphantimonate of Barium, $Ba^3SbS^4 + 3H^2O$.—Obtained by dissolving recently precipitated prosulphide of antimony in sulphide of barium, and mixing the solution with alcohol, in stellate needles, which, when exposed to the air, do not deliquesce, but become covered with a brown kermes-coloured film.

Sulphantimonate of Bismuth is obtained by precipitation, but is not easily obtained free from excess either of pentasulphide of antimony or of sulphide of bismuth.

Sulphantimonate of Cadmium.—Light orange-coloured precipitate obtained by dropping a neutral cadmium-salt into a solution of sulphantimonate of sodium.

Sulphantimonate of Calcium. Sulpho stibias-calcius. Ca^3SbS^4.—Produced like the barium-salt, but cannot be crystallised. A mixture of this compound with excess of lime and saffron of antimony, constitutes the pharmaceutical preparation known as *Calx antimonii cum sulphure Hoffmanni*, *Sulphuretum stibii cum calce*, or *Calcaria sulphurata stibiata*, discovered by Hoffmann in the eighteenth century. It is prepared by igniting an intimate mixture of 3 pts. trisulphide of antimony, 4 pts. sulphur, and 16 pts. quicklime; or 8 pts. of prepared oyster shells, 1 pt. antimony, and 2 pts. sulphur. It is a whitish-yellow, yellowish, or brownish-yellow powder, which has a sharp sulphurous taste, smells of sulphuretted hydrogen when exposed to moist air, and is but partially soluble in water. The solution is colourless, and contains sulphantimonate of calcium.

Sulphantimonate of Cobalt, obtained by precipitation, is black, oxidises in the air, and is decomposed by boiling hydrochloric acid.

Sulphantimonate of Copper. Cu^3SbS^4.—Obtained by dropping a solution of cupric acetate or sulphate into a solution of sulphantimonate of sodium. The solutions must be rather dilute; the copper-solution must be dropped in slowly and with rapid stirring; and the precipitate then heated, together with the liquid, with brisk stirring all the while. Without these precautions, each drop of the copper-solution, as it enters, becomes enveloped by the precipitate; and if the precipitate be thrown on the filter in this state, the solution of sulphantimonate of sodium runs away first, and then the acetate of copper and sulphantimonate of copper decompose each other, acetic acid or sulphuric acid being set free, which then acts upon the sulphantimonate of sodium still remaining in the precipitate, setting free pentasulphide of antimony and hydrosulphuric acid. In this manner, the precipitate becomes contaminated with pentasulphide of antimony and sulphide of copper.—Sulphantimonate of copper, when pure, is a dark brown precipitate, which when heated gives off sulphur, and leaves a residue apparently consisting of cuprous sulphantimonite (Sb^2S^3 with Cu^4S). Boiling potash decomposes the sulphantimonate, separating sulphide of copper and dissolving pentasulphide of antimony, which is at the same time partially converted into antimonic acid.

If sulphantimonate of sodium be added to excess of cupric sulphate, and the precipitate boiled for some time with the liquid, a product is obtained containing 16 at. copper, 8 at. sulphur, 2 at. antimony, and 5 at. oxygen, and the liquid exhibits a strong acid reaction:

$$3Na^2S.Sb^2S^5 + 8Cu^2SO^4 + 5H^2O = (8Cu^2S + Sb^2O^5) + 3Na^2SO^4 + 5H^2SO^4.$$

The precipitate thus formed, may, as already observed (see above), be either $3Cu^2S.Sb^2S^5 + 5Cu^2O$, or $8Cu^2S + Sb^2O^5$. On boiling it with potash-ley, sulphide of copper remains behind, and a solution of antimonate of potassium is formed, which gives with acids a white precipitate of antimonic acid. On the other hand, the precipitate, when quickly and strongly heated in close vessels, gives off a large quantity of sulphurous anhydride, but no sulphur, and the residue contains sulphide of copper and pentasulphide of antimony. Moreover the same products are obtained by igniting a mixture of 8 at. pure sulphide of copper, and 1 at. pure antimonic oxide, or of 1 at. sulphantimonate of copper and 5 at. cupric oxide. So far then it is impossible to decide upon the constitution of the precipitate obtained in the manner just described. But when sulpharsenate of potassium is dropt into excess of cupric sulphate, and the mixture boiled, a precipitate is obtained consisting of pure sulphide of copper, the whole of the arsenic remaining dissolved as arsenic acid. Hence, from the analogy of the arsenic and antimony compounds, it is probable that the antimony precipitate abovementioned is a mixture of sulphide of copper and antimonic oxide.

Sulphantimonate of Iron.—Ferrous sulphate dropt into sulphantimonate of sodium forms a black precipitate, which quickly turns reddish-yellow. The sodium-salt forms with ammonio-ferric sulphate, so long as the latter is in excess, a greenish-brown precipitate, consisting merely of sulphur and pentasulphide of antimony, the whole of the iron being reduced to the ferrous state and remaining in the liquid.

Sulphantimonate of Lead. Pb^3SbS^4.—Obtained by adding acetate of lead to sulphantimonate of sodium, with the same precautions as those described for the preparation of the copper-salt. It is a dark brown precipitate, which is decomposed by heat, giving off 2 at. sulphur, and leaving sulphantimonite of lead, $3Pb^2S.Sb^2S^3$, or Pb^3SbS^3, of the same composition as the mineral Boulangerite. Boiling potash-ley decomposes it in the same manner as the copper-salt. A precipitate, containing 16Pb, 8S, 2Sb, and 5O, is likewise obtained by adding sulphantimonate of sodium to excess of acetate of lead.

Sulphantimonate of Magnesium.—Recently precipitated pentasulphide of antimony dissolves in aqueous hydrosulphuric acid, in which magnesia is suspended, the magnesia likewise dissolving; but the compound cannot be made to crystallise.

Sulphantimonate of Manganese.—Red-brown precipitate, produced by mixing the sodium-salt with sulphate of manganese; it oxidises during washing and drying.

Sulphantimonates of Mercury.—The *mercuric* salt, $3Hg^2S.Sb^2S^5$, or Hg^3SbS^4, obtained like the copper- and lead-salts, is an orange-coloured precipitate. If after washing it be immersed in solution of mercuric chloride, or a solution of sulphantimonate of sodium be added to excess of mercuric chloride, a white substance is formed, containing $3Hg^2S.Sb^2S^5 + 6HgCl + 3Hg^2O$. This substance is not a mere mixture, but a chemical compound, which is not attacked by any acid except aqua-regia. Potash decomposes it immediately, leaving mercuric sulphide, and dissolving antimonic and hydrochloric acids.—*Mercurous* nitrate, mixed with sulphantimonate of sodium, forms a black precipitate, whichever salt may be in excess.

Sulphantimonate of Nickel.—Black precipitate, which oxidises in the air, and is decomposed by hot hydrochloric acid.

Sulphantimonate of Potassium, K^3SbS^4; in the crystallised state $2K^3SbS^4 + 9H^2O$, or $3K^2S.Sb^2S^5 + 9H^2O$.—The anhydrous salt is obtained by fusing sulphide of potassium with trisulphide of antimony and sulphur, or sulphate of potassium with the trisulphide and charcoal, or by heating one of the potassium-livers of antimony, in which case metallic antimony separates out. The product is a brown mass, the aqueous solution of which yields crystals of the hydrated salt. The latter is, however, better obtained by boiling a mixture of 11 pts. of finely levigated trisulphide of antimony, 6 pts. of carbonate of potassium, 1 pt. of flowers of sulphur, and 3 pts. of lime previously burnt and slaked, with 20 pts. of water, for some hours, renewing the water as it evaporates; or by leaving the same mixture in a covered vessel for 24 hours, and stirring frequently; then filtering and evaporating. The hydrated salt forms colourless or yellowish, granular or radiating crystals, which give off their water when heated.

Sulphantimonate of potassium is likewise formed when pentasulphide of antimony is boiled with aqueous carbonate of potassium, antimonate of potassium being formed at the same time, and separating in the solid state. Hot caustic potash-ley dissolves the pentasulphide completely; but on diluting the solution, and adding carbonate of ammonium, a precipitate is formed, consisting merely of the pentasulphide mixed with a small quantity of sulphantimonate of potassium. Cold potash-ley of moderate strength acts upon pentasulphide of antimony somewhat differently; the pentasulphide loses its colour; white acid antimonate of potassium ($K^2O.2Sb^2O^5 + 6H^2O$) remains undissolved, notwithstanding the excess of potash present; free sulphide of potassium is formed; and the liquid yields by evaporation a colourless double salt, consisting of sulphantimonate and antimonate of potassium ($K^3SbS^4.KSbO^3 + 5H^2O$), crystallising in long needles, which, when exposed to the air, become covered with a kermes-coloured film. Cold water renders these crystals milk-white, dissolving a portion, and leaving a white residue of acid antimonate of potassium. Hot water dissolves the salt readily, and the solution, when mixed with acids, yields an orange-coloured precipitate, consisting of pentasulphide of antimony mixed with antimonic acid.

Sulphantimonate of Silver, Ag^3SbS^4, prepared like the lead- and copper-salts forms a black, perfectly insoluble precipitate, which gives off sulphur when heated, leaving a fused grey residue of sulphantimonate of silver, Ag^3SbS^3, which yields a red powder by trituration.—By adding sulphantimonite of sodium to excess of nitrate of silver and boiling for several hours, a precipitate is obtained containing antimonic oxide, which may be completely extracted from it by potash.

Sulphantimonate of Sodium, $Na^3SbS^4 + 9H^2O$, or $3NaS.SbS^5 + 9HO$. *Schlippe's salt.*—This salt is prepared by digesting at ordinary temperatures in a vessel that can be closed, and with frequent stirring, a mixture of 11 pts. of elutriated trisulphide of antimony, 13 pts. crystallised carbonate of sodium, 1 pt. flowers of sulphur, 5 pts. of quick lime previously slaked, and 20 pts. of water. After twenty-four hours, the liquid is strained off, the residue washed several times with water, and the solution together with the wash-water, is evaporated in a porcelain dish or clean iron pot, till a sample yields crystals on cooling. The whole is then left to cool quietly, and the resulting crystals are washed several times with cold water, and dried in the air, or better, under a bell jar, over lime or oil of vitriol. The formation of the salt is much accelerated by boiling the mixture. (Liebig, Handwört. d. Chem. 2te Aufl. ii. 139. For other modes of preparation, see Gmelin's Handbook, iv. 384.)

Sulphantimonate of sodium forms transparent, colourless, or pale yellow, regular tetrahedrons, with truncated summits, or acuminated with the faces of the rhombic dodecahedron. Its taste is bitterly metallic, and at the same time alkaline. It dissolves in 2·9 pts. of water at 15° C., and the solution is precipitated by alcohol. When heated, it melts in its water of crystallisation, and after all the water has gone off, forms a greyish-white mass, which crumbles to a bulky powder when exposed to the air. At a commencing red heat, it fuses, without decomposition, if the air be excluded. The fused mass is liver-coloured, and dissolves in water, leaving a small quantity of sulphide of antimony. The decomposition of the solution, as well as of the salt itself, by contact with the air, is due to the action of carbonic acid, but is not complete even after many months. The resulting brown precipitate contains sulphantimonate of sodium with trisulphide of antimony, and the liquid is found to contain carbonate, sulphide, and hyposulphite of sodium, but no sulphate.

When sulphantimonate of sodium is added to a solution of tartar-emetic, the liquid first turns red, and then yields an orange-coloured precipitate containing pentasulphide, trisulphide, and trioxide of antimony, while tartrate of sodium and potassium remains in solution:

$$6C^4H^4KSbO^7 + 2Na^3SbS^4 = 6C^4H^4KNaO^6 + Sb^2S^5 + Sb^2S^3 + 2Sb^2O^3$$

This precipitate melts at a high temperature, forming a black metallic-shining mass, exhibiting red translucence on the edges, and perfectly soluble in hydrochloric acid. Potash decomposes it, leaving a yellow residue consisting of sulphide of sodium, trioxide of antimony, and a compound of that oxide with potash. (Handwörterbuch.)

Sulphantimonate of Strontium.—Prepared like the calcium-salt: not crystallisable.

Sulphantimonate of Uranium.—Yellow-brown precipitate, obtained by adding ammonio-uranic chloride to sulphantimonate of sodium.

Sulphantimonate of Zinc, obtained by dropping sulphate of zinc into a solution of the sodium-salt, is an orange-coloured precipitate which dissolves in the liquid when heated, and partly runs through the filter during washing. It is decomposed and dissolved by hydrochloric acid.

The precipitate obtained with excess of the zinc-salt, has the same colour, but is not easily obtained free from the preceding, even after long boiling. Fuming nitric acid decomposes it, with ignition. (Handwörterbuch.)

ANTIMONY, SULPHOCHLORIDE OF. $SbSCl^3$. Obtained by slowly passing dry sulphuretted hydrogen into pentachloride of antimony. It is a white crystalline body, which melts at a moderate heat, is resolved at a higher temperature into sulphur and trichloride of antimony, deliquesces in moist air, and is decomposed by water into sulphur and trichloride (? oxychloride) of antimony; with aqueous tartaric acid, it yields a precipitate of sulphide of antimony mixed with oxide. (Cloez, Ann. Ch. Phys. [3] xxx. 374.)

Other sulphochlorides of antimony have been obtained by R. Schneider (Pogg. Ann. cviii. 407). Finely pulverised trisulphide of antimony dissolves in 14 or 15 times its weight of the melted trichloride, without evolution of sulphuretted hydrogen, and the light brown solution solidifies on cooling to a yellow crystalline mass. By pouring off the still remaining liquid at a certain stage of the solidification, the compound may be obtained in regular crystals (rhombic prisms bevelled at the ends with a macrodiagonal dome), containing $Sb^2SCl^4.6SbCl^3$. It is very deliquescent, and is decomposed by a large quantity of water, with separation of a yellow powder; by prolonged heating, it is resolved into volatile trichloride of antimony, and a black residue of sulphide. It is decomposed by absolute alcohol, out of contact of air, a large quantity of chloride of antimony and a little of the sulphide dissolving, and a reddish-yellow amorphous substance being left, containing $2SbClS.3Sb^2S^3$. This compound is decomposed, by heating in close vessels, into trichloride and trisulphide of of antimony, also by the action of dilute hydrochloric acid.

ANTIMONY, SULPHIODIDE OF. SbSI.—This compound is obtained by dissolving trisulphide of antimony in the melted tri-iodide. It has a brilliant metallic lustre and red-brown colour, appears red and transparent under the microscope, and yields a powder of a fine cherry-red colour. (R. Schneider, J. pr. Chem. lxxix. 422; Rép. Chim. pure, ii. 323.)

When a mixture of equal parts of iodine and trisulphide of antimony is slowly heated in a retort, an iodosulphide, probably of the same composition, rises in red vapours, which condense in the receiver. The same body is formed by subliming a mixture of 24 pts. antimony, 9 pts. sulphur, and 68 pts. iodine, or of 2 pts. iodine and 9 pts. iodide of sulphur. It forms shining transparent, blood-red needles and laminæ, which melt at a gentle heat, and sublime more easily than the iodide of antimony. It has a pungent taste and repulsive odour. It is decomposed at a strong heat, also by chlorine and by water. Henry and Garot (J. Pharm. x. 511), assigned to this product the formula SbS^2I^2; but this is doubtless incorrect.

ANTIMONY-RADICLES, ORGANIC. Antimony combines with alcohol-radicles in various proportions, forming compounds which themselves act like simple radicles, uniting with chlorine, oxygen, sulphur, &c., in the same manner as the metals. Some of these bases are formed on the type of ammonia, NH^3, containing 1 at. antimony united with 3 at. of the alcohol-radicle; others on the type NH^4; and a compound of antimony with amyl is known containing 1 at. antimony with 2 at. amyl. The names and formulæ of the antimony-radicles at present known, are given in the following table: —

Antimonides of Amyl:	
Stibdiamyl	$Sb(C^5H^{11})^2$
Stibtriamyl *or* Triamylstibine	$Sb(C^5H^{11})^3$
Antimonides of Ethyl:	
Stibtriethyl *or* Triethylstibine	$Sb(C^2H^5)^3$
Stibethylium *or* Tetrethylstibonium	$Sb(C^2H^5)^4$
Antimonides of Methyl:	
Stibtrimethyl *or* Trimethylstibine	$Sb(CH^3)^3$
Stibmethylium *or* Tetramethylstibonium	$Sb(CH^3)^4$

The existence of pentethylstibine $Sb(C^2H^5)^5$ and pentamethylstibine $Sb(CH^3)^5$, has also been rendered probable by the recent experiments of Mr. Buckton (Chem. Soc. Qu. J. xiii. 115).

The compounds containing 3 at. of alcohol-radicle are obtained by distilling the iodides of the alcohol-radicles with antimonide of potassium or sodium, or by the action of trichloride of antimony on zinc-ethyl. They are liquids which volatilise without decomposition, and rapidly absorb oxygen from the air, with great evolution of heat, sufficient in the case of the ethyl- and methyl-compounds to produce vivid combustion. The compounds containing 4 at. of alcohol-radicle are not known in the free state; but their iodides are obtained by treating the corresponding compounds containing 3 at. alcohol-radicle with the iodides of those radicles; and these iodides when treated with oxide of silver and water, yield the hydrated oxides of the same radicles, which are fixed bases, having a strong alkaline reaction, and uniting readily with acids like the hydrates of potassium and sodium. In this respect, they resemble the corresponding nitrogen-bases, hydrate of tetrethylium, $N(C^2H^5)^4.H.O$, &c.

The antimony-radicles containing 4 at. of the alcohol-radicle, are monatomic, uniting with 1 at. chlorine, iodine, &c.; but those which contain 3 at. alcohol-radicle, stibtriethyl, for example, are diatomic, uniting with 2 at. chlorine, iodine, &c., and with 1 at. oxygen, *e.g.* $Sb(C^2H^5)^3.Cl^2$, $Sb(C^2H^5)^3O$, &c. The same law holds good with respect to other organo-metallic bodies similarly constituted, arsentriethyl, for example: but it does not extend to the corresponding nitrogen-radicles, such as triethylamine, trimethylamine, &c., which, indeed, do not unite directly with oxygen, chlorine, iodine, &c., but combine with hydrated acids in the same manner as ammonia.

Antimonides of Amyl, or Stibamyls.*

These compounds are obtained by the action of iodide of amyl on antimonide of potassium, the process being conducted similarly to that for the preparation of stibethyl (p. 341). After the action has ceased, and the excess of iodide of amyl has distilled off, the residue is either distilled in an atmosphere of carbonic anhydride, whereby a distillate is obtained containing stibdiamyl; or the product is exhausted with ether, and the solution freed from ether by distillation, in which case a residue is left consisting of stibtriamyl. If the stibtriamyl thus obtained is contaminated with amylic alcohol or iodide of amyl, pure compounds may be prepared from it by dissolving it in a mixture of ether and alcohol; adding alcoholic bromine till its colour just begins to be permanent; precipitating the bromide of stibtriamyl by adding a large quantity of water; converting the bromide into oxide by means of oxide of silver suspended in

---

* F. Berlé, J. pr. Chem. lxv. 385; Gm. xi. 125.

alcohol; precipitating the oxide by water, and dissolving it in hydrochloric acid and alcohol; precipitating the pure chloride by another addition of water; and freeing it from a small quantity of water by heating it to 100° C. in contact with fused chloride of calcium.

STIBDIAMYL. $Sb(C^5H^{11})^2 = SbAm^2$. — The distillate just mentioned, after being freed from undecomposed iodide of amyl by re-distillation over antimonide of potassium, gave off at 80° C. a colourless liquid, which burnt with a white flame, diffusing a white smoke of oxide of antimony. The liquid which then remained was stibdiamyl. It was greenish-yellow, heavier than water, and tolerably mobile, with a peculiar aromatic odour and bitter taste; insoluble in water, but miscible in all proportions with alcohol and ether. It was not spontaneously inflammable, but when set on fire, burned with a very white flame, diffusing a white fume of oxide of antimony. It exploded with great violence when heated in oxygen gas, and was decomposed by nitric acid with considerable evolution of heat. Its ethereal solution exposed to the air, left an oxide which absorbed carbonic acid; and the stibdiamyl itself heated to 100° C. in a stream of dry carbonic acid, yielded a viscid liquid, which appeared to be the carbonate $(SbAm^2)^2.CO^3$. The haloïd salts of stibdiamyl are gummy liquids; the sulphate and nitrate are precipitated from their alcoholic solutions by water, in the form of gummy masses, which dry up to amorphous solids.

STIBTRIAMYL OF TRIAMYLSTIBINE. $Sb(C^5H^{11})^3 = SbAm^3$.—Transparent slightly yellowish liquid, very viscid below 20° C., more mobile at higher temperatures. It has a peculiar aromatic odour, and a bitter, somewhat metallic and very persistent taste. Specific gravity 1·333 at 17° C. (according to Cramer, Pharm. Centr. 1855, 465, it is 1·0587). In contact with the air, it does not take fire, but fumes strongly and decomposes, depositing a white powder. A drop of it placed on bibulous paper and exposed to the air, becomes so strongly heated as to char the paper. It is insoluble in water, but dissolves sparingly in alcohol, and readily in ether. It does not exhibit any tendency to unite with iodide of amyl, when heated with that compound in a sealed tube.

Stibtriamyl is a diatomic radicle, like stibtriethyl. Its *oxide*, $Sb(C^5H^{11})^3.O =$ is produced by slow evaporation of an ethereal solution of stibtriamyl in contact with the air; or by decomposing the chloride, iodide, or bromide with oxide of silver. It is a greyish-yellow viscid mass, which becomes somewhat more fluid when gently heated, but decomposes at higher temperatures. It tastes and smells like the radicle itself. It is insoluble in water, sparingly soluble in dilute alcohol and in ether, but dissolves easily in absolute alcohol. The alcoholic solution precipitates metallic oxides from their salts. Oxide of stibriamyl dissolves readily in acids, and the resulting compounds are precipitated from their solutions by water.

1. The *chloride*, $Sb(C^5H^{11})^3Cl^2$, obtained by dissolving the oxide in hydrochloric acid, is a yellowish translucent liquid, viscid at ordinary, comparatively mobile at higher temperatures, heavier than water, soluble in alcohol and ether. It tastes and smells like stibtriamyl. Decomposes at temperatures above 160° C. The *bromide* and *iodide* resemble the chloride.

Nitrate. $Sb(C^5H^{11})^3.2NO^3$.—When the chloride or iodide is mixed with an alcoholic solution of nitrate of silver, as long as a precipitate forms, and then filtered, the filtrate forms an emulsion, from which, after standing for some time in a warm place, two liquids separate, the upper being light, yellow, and mobile, and the lower a deep brown-red oil. The upper layer, when slowly evaporated, yields the nitrate in slender white crystals grouped in stars; they may be purified by recrystallisation from dilute alcohol. The dark red oil likewise dissolves on addition of a large quantity of hydrated alcohol, and the solution, after standing for some time, yields the same crystals. These crystals melt at about 20° C.: the fused mass does not dissolve in alcohol so readily as the crystals. This salt, the only crystallisable compound of stibtriamyl, is insoluble in water and ether, but dissolves in hydrated alcohol. It has a peculiar metallic taste.

The *sulphate*, $Sb(C^5H^{11})^3.SO^4$, is formed by decomposing equivalent quantities of sulphate of silver and a haloïd compound of stibtriamyl dissolved in alcohol. This salt was obtained only as an oily liquid body.

The white powder, formed by the action of the air upon stibtriamyl is insoluble in ether, alcohol, and water: it does not dissolve in hydrochloric acid, but imperfectly in fuming nitric acid; slowly in aqua-regia. It remains unaltered even when strongly heated, not decomposing below a red heat. Berlé supposes it to be *antimonite of stibtriamyl*, $SbAm^3O.Sb^2O^3$. When sulphuretted hydrogen was passed for some time through this compound suspended in alcohol, a white powder immediately separated, which gradually assumed an orange colour, and then formed a pulpy mass, which could not be filtered. After addition of a large quantity of alcohol and ether the liquid, when left to stand in a warm place, deposited an orange-red, flocculent precipitate, which, after drying, formed a brownish-yellow powder, insoluble in alcohol, ether, and water; this powder decomposed at a very high temperature, and took fire when fuming nitric acid was poured upon it. Berlé regards this compound as *sulphantimonite of stibtriamyl*, $SbAm^3S.Sb^2S^3$ (it gave 18·38 per cent. sulphur, the formula requiring 17·59). A compound, supposed to be identical with this, is formed by passing sulphuretted hydrogen for some time through an alcoholic solution of oxide of stibtriamyl.

Antimonides of Ethyl, or Stibethyls.

STIBTRIETHYL OR TRIETHYLSTIBINE, commonly called *Stibethyl*. $Sb(C^2H^5)^3 = SbE^3$. (Löwig and Schweizer, Ann. Ch. Pharm. lxxv. 315, 327; Löwig, *ibid.* lxxx. 323; Gm. ix. 79; Gerh. ii. 370.)—This compound is prepared by the action of iodide of ethyl on antimonide of potassium. The alloy is finely pulverised together with two or three times its weight of quartz-sand (if pulverised alone it is apt to take fire); the mixture is introduced into a number of small short-necked flasks, so as to fill them to about two-thirds; and iodide of ethyl is added in quantity just sufficient to moisten the mixture of alloy and sand. The action begins in a few minutes, and is accompanied with a rise of temperature sufficient to volatilise the excess of iodide of ethyl, which is collected by itself in a small receiver; as soon as this action is over, the flask is connected as quickly as possible with a condensing apparatus, through which a stream of carbonic acid gas is passed during the whole operation. This condensing apparatus consists of a tall wide cylindrical vessel closed by a cork having three apertures. Through one of these apertures, passes a tube proceeding from the carbonic acid apparatus, and reaching to the bottom of the vessel; through the second a short straight tube to carry off that gas, and through the third is inserted the distillation tube connected with the flask containing the mixture: this tube descends nearly to the bottom of the glass cylinder, and drops into the mouth of a small receiver, partly filled with antimonide of potassium. This apparatus being completely filled with carbonic acid gas, the generating flask is heated very gently at first, and afterwards more strongly as long as any liquid distils over. This flask is then removed, the distillation-tube stopped with wax, till a second flask is ready to be adapted, and the operation is then repeated. The contents of 20 to 24 flasks of 3 or 4 ounces capacity yield 4 or 5 ounces of crude product, which may thus be obtained in the course of a day. The receiver in which the distillate has been collected is then closed while still immersed in the atmosphere of carbonic acid, afterwards removed, and used as a retort in the rectification of the product, the same condensing apparatus being used as before. The first portions of the rectified product contain iodine, and deposit after a while, a number of colourless crystals consisting of iodide of stibethylium. (Löwig and Schweizer.)

2. By the action of trichloride of antimony on zinc-ethyl, similarly to the preparation of triethylphosphine. (Hofmann: See PHOSPHORUS BASES.)

Properties. Stibtriethyl is a transparent, colourless, mobile, strongly refracting liquid, having a disagreeable alliaceous odour. Specific gravity 1·3244 at 16° C. It does not solidify at 29° C. Boils at 158°·5 (bar. at 730 mm.). Vapour-density, by experiment = 7·44; by calculation 7·18, the formula $Sb(C^2H^5)^3$, representing 2 volumes of vapour. Stibtriethyl is insoluble in water, but dissolves readily in alcohol and ether.

A drop of stibtriethyl exposed to the air at the end of a glass rod, emits thick white fumes, and in a few seconds takes fire and burns with a white, strongly luminous flame. When introduced in a thin stream into oxygen gas, it burns with dazzling brightness. But if it be made to run into a glass globe containing air, in such a manner as not to take fire, it gives off dense white fumes, which collect on the sides of the vessel in the form of a powder, which is insoluble in ether, but dissolves in alcohol and water; at the same time a transparent, colourless, viscid mass is formed, which is soluble in ether. This latter substance is the *oxide of stibtriethyl*, SbE^3O; the powder is *antimonite of stibtriethyl*, $SbE^3O.Sb^2O^3$. Stibtriethyl oxidises very slowly when immersed in water; hence it is best to keep it under that liquid. *Sulphur, selenium, iodine, bromine*, and *chlorine* combine directly with stibtriethyl, the action being always attended with evolution of heat, and in the case of bromine and chlorine, with inflammation. The compounds contain 1 at. stibtriethyl, with 1 at. of a dibasic radicle, O, S, SO^4 &c., or 1 at. stibethyl with 2 at. of a monobasic radicle, Cl, Br, NO^3, &c., in which respect they resemble the compounds of stibtrimethyl, arsentriethyl (see p. 322). Stibtriethyl introduced into *hydrochloric acid gas*, yields chloride of stibtriethyl and free hydrogen:

$$SbE^3 + 2HCl = SbE^3Cl^2 + H^2.$$

The same reaction takes place with fuming hydrochloric acid. Dilute *nitric acid*, with the aid of heat, acts on stibtriethyl in the same manner as on the metals, evolving nitric oxide and forming nitrate of stibtriethyl. Neither fuming nitric acid nor aqua-regia oxidises the antimony completely.

Antimonite of Stibtriethyl, $Sb(C^2H^5)^3.Sb^2O^4$, or $SbE^3O.Sb^2O^3$, is formed, together with the oxide, by the gradual oxidation of stibtriethyl. The white fumes which stibtriethyl diffuses in the air consist almost wholly of this compound. It may be prepared by leaving an ethereal solution of stibtriethyl to evaporate spontaneously, and dissolving out the simultaneously formed oxide with ether-alcohol. The antimonite then remains as a white, pulverulent, amorphous body. It has a bitter taste, and is soluble in water and in alcohol. The aqueous solution prepared in the cold is perfectly mobile, but when heated, becomes viscid like starch-paste, and dries up to a friable mass, having the appearance of porcelain. Water poured upon this mass dissolves the greater part, but leaves a small residue of antimonious oxide. Hydrochloric acid, added to the alcoholic solution throws down chloride of stibtriethyl; the acid liquid separated from the chloride yields with sulphuretted hydrogen, a precipitate of kermes; on mixing it with water, powder of algaroth is precipitated. (Löwig.)

Bromide of Stibtriethyl. $Sb(C^2H^5)^3Br^2$. —Stibtriethyl takes fire when added by drops to bromine. The bromide is prepared by adding a recently prepared alcoholic solution of bromine to an alcoholic solution of stibtriethyl cooled by ice, as long as the colour of the bromine disappears. On mixing the solution with a large quantity of water, the bromide of stibtriethyl is precipitated, in the form of a colourless liquid which must then be washed with water and dried by contact with chloride of calcium. Transparent, colourless, strongly refracting liquid, having a density of 1·953 at 17° C. Has an unpleasant odour like that of turpentine, and excites sneezing. Solidifies in a crystalline mass at − 10° C. It is not volatile. When distilled, it yields, among other products a strongly acid liquid having an intolerable odour like that of chloral. It is decomposed by oil of vitriol, with evolution of hydrobromic acid, and by chlorine with separation of bromine. Insoluble in water, but dissolves readily in alcohol and ether. The alcoholic solution gives with metallic salts, reactions similar to those of bromide of potassium.

Chloride of Stibtriethyl. $Sb(C^2H^5)^3Cl^2$.—Stibtriethyl dropt into chlorine gas takes fire and burns with a bright but smoky flame. Introduced into dry hydrochloric acid gas, it forms chloride of stibtriethyl, and separates a quantity of hydrogen equal in volume to half the hydrochloric acid gas. The chloride is easily obtained in the pure state by decomposing a strong solution of nitrate of stibtriethyl with strong hydrochloric acid; it then separates in the form of a liquid which may be purified in the same manner as the bromide. Transparent, colourless liquid, of specific gravity 1·540 at 17° C.; it has a powerful odour like that of turpentine, and a bitter taste. Remains fluid at 12° C. When it is distilled with water, a small portion appears to volatilise undecomposed; when heated alone, it behaves like the bromide. Strong sulphuric acid decomposes it, with evolution of hydrochloric acid, while, on the other hand, hydrochloric acid added to a solution of sulphate of stibtriethyl throws down the chloride. In other respects, its relations are like those of chloride of potassium or chloride of sodium. It is insoluble in water, but dissolves readily in alcohol and ether.

Cyanide of Stibtriethyl appears to be formed when 2 at. cyanide of mercury, and 1 at. sulphide of stibtriethyl are mixed in the state of aqueous solution. Sulphide of mercury is then formed, together with a liquid which smells like prussic acid, and behaves with metallic salts like cyanide of potassium.

Iodide of Stibtriethyl. $Sb(C^2H^5)^3I^2$.—Iodine and stibtriethyl combine together under water, with rise of temperature. On adding iodine to an ethereal solution of stibtriethyl, a violent momentary ebullition takes places, and the iodine quickly disappears. The iodide is, however, most easily prepared by adding iodine in small portions to an alcoholic solution of stibtriethyl surrounded by a frigorific mixture, as long as the colour of the iodine disappears, and leaving the colourless solution to evaporate. The iodide then crystallises in colourless needles, which must be recrystallised from alcohol, and afterwards from ether, to free them from a small quantity of adhering yellow powder.

Iodide of stibtriethyl has a slight odour of stibtriethyl and a bitter taste. It dissolves in water without decomposition and readily in alcohol and ether. It melts and solidifies at 70°·5 C., sublimes in small quantity at 100°, without alteration, but is decomposed at a somewhat higher temperature, with formation of dense white fumes. In the fused state, it is instantly decomposed by *potassium*, with separation of stibtriethyl. With *sulphuric acid* and with metallic salts, it behaves like iodide of potassium. *Hydrochloric acid* immediately precipitates chloride of stibtriethyl. *Bromine* and *chlorine* separates the iodine; so likewise does nitric acid, forming nitrate of stibtriethyl. With *zinc-ethyl* it appears to form stibpentethyl, $SbE^3I^2 + ZnE = 2ZnI + SbE^5$; but this compound is decomposed by distillation into stibtriethyl, ethylene, and hydride of ethyl; $Sb(C^2H^5)^5 = Sb(C^2H^5)^3 + C^2H^4 + C^2H^6$. (**Buckton**, Chem. Soc. Qu. J. xiii. 116.)

Oxyiodide of Stibtriethyl. $(SbE^3)^2I^2O = SbE^3I^2,SbE^3O$.—Produced by the action of ammonia on iodide of stibtriethyl:

$$2SbE^3I^2 + 2NH^3 + H^2O = (SbE^3)^2I^2O + 2NH^4I$$

also by mixing the oxide and iodide of stibtrethyl in equivalent quantities. It forms octahedral crystals containing 36·9 per cent. iodine: by calculation 37·1 (**Strecker** Ann. Ch. Pharm. cvi. 306). Merck, who obtained this compound by mixing iodide of stibtriethyl with an ethereal solution of stibtriethyl in an atmosphere of carbonic anhydride, supposed it to be, not an oxyiodide, but a monoiodide of stibtriethyl SbE^3I, and explained its formation, together that with of another crystalline compound — not analysed, but supposed to be SbE^3HI,—on the hypothesis that the iodide of stibtriethyl prepared by Löwig and Schweizer, really contained 1 at. hydrogen more than those chemists supposed, its true formula being SbE^3HI^2, or $SbE^3I.HI$:

$$SbE^3HI^2 + SbE^3 = SbE^3I + SbE^3HI.$$

But the formula $SbE^3.I$ is contrary to analogy, the triethyl- and trimethyl-compounds of arsenic, bismuth, and phosphorus, all uniting with 2 at. I, Br or Cl. Moreover Merck's mode of preparation, which consisted in covering the liquid with a funnel, and passing a stream of carbonic anhydride through the beak, till all the ether was evaporated, was not very well adapted to exclude the air perfectly; hence it is probable, especially as the action took place but slowly, that oxide of stibtriethyl was first formed, and then combined with the iodide. The oxyiodide might, however, be formed without access of air, if the mixture was not perfectly dry, the compound SbE^3HI being produced at the same time: thus,

$$2SbE^3 + 2SbE^3I^2 + H^2O = (SbE^3)^2I^2O + 2SbE^3HI$$

The oxyiodide treated with hydriodic acid yields iodide of stibtriethyl and water:

$$(SbE^3)^2I^2O + 2HI = 2SbE^3I^2 + H^2O$$

With oxide of silver, it yields oxide of stibtriethyl, SbE^3O, and with chloride of mercury, an oxychloride of stibtriethyl, $(SbE^3)^2Cl^2O$. (**Strecker.**)

Merck supposed that the action of various mercury and silver-salts on his supposed iodide, SbE^3I, yielded a series of compounds of analogous constitution, viz. a chloride, SbE^3Cl, an oxide $(SbE^3)^2O$, &c.

Nitrate of Stibtriethyl. $Sb(C^2H^5)^3.2NO^3$.—Obtained by saturating dilute nitric acid with oxide of stibtriethyl, or by dissolving stibtriethyl in the dilute acid with the aid of heat. In this latter reaction, nitric oxide is evolved, and a small quantity of antimonious oxide separates. The salt may be obtained in crystals by evaporating the solution. At 62°·5 C. it melts into a transparent liquid, which solidifies to a crystalline mass at 57°; at a higher temperature, it deflagrates like a mixture of nitre and charcoal. It dissolves easily in water, less easily in alcohol, and is nearly insoluble in ether. The solutions have an acid reaction and bitter taste.

Oxide of Stibtriethyl. $Sb(C^2H^5)^3O$.—Formed by the direct oxidation of stibtriethyl, either in the free state, as above mentioned, or dissolved in alcohol or ether; as thus obtained, however, it is always more or less mixed with antimonite of stibtriethyl, especially when obtained from the ethereal solution. The alcoholic solution on the contrary yields but a small quantity of antimonite. Accordingly, the oxide may be obtained by leaving a dilute alcoholic solution to evaporate slowly in a loosely covered foot-glass, treating the residue with ether, which dissolves the oxide and leaves the antimonite, and repeating this treatment as long as the ether leaves any insoluble residue.—The oxide may also be obtained by treating an aqueous solution of sulphate of stibtriethyl with baryta-water; evaporating the filtrate over the water-bath; exhausting the residue with alcohol, which dissolves out a compound of oxide of stibtriethyl and baryta; precipitating the baryta by carbonic acid, and evaporating the filtered alcoholic solution. An alcoholic solution of stibtriethyl shaken up with finely divided red oxide of mercury, quickly reduces the mercury to the metallic state, and yields pure oxide of stibethyl.

Oxide of stibtriethyl in its purest state, is a transparent, colourless, viscid, amorphous mass, which dissolves readily in water and alcohol, somewhat less readily in ether; has a very bitter taste; does not appear to be poisonous; is not altered by exposure to the air; is not volatile; but when heated in a tube, gives off white vapours which burn with a bright flame, and leaves a residue containing antimony and charcoal. It is decomposed by *potassium*, at a gentle heat, with separation of stibtriethyl. *Fuming nitric acid* decomposes it, with evolution of light and heat; *dilute nitric* and *strong sulphuric acid* dissolve it, forming salts of stibtriethyl; *hydrochloric acid* and other hydrogen-acids dissolves it in the form of chloride of stibtriethyl and similar compounds.

Hydrosulphuric acid has no perceptible action upon it; but on evaporating a solution of the oxide saturated with the gas, crystals of sulphide of stibtriethyl are obtained; the smallest trace of antimonite of stibtriethyl mixed with the oxide is detected by the formation of a yellow precipitate.

Sulphate of Stibtriethyl, $Sb(C^2H^5)^3.SO^4$, is obtained by decomposing the aqueous solution of the sulphide with sulphate of copper. It crystallises in small white prisms, soluble in water and alcohol, inodorous, but having a bitter taste and acid reaction.

Sulphide of Stibtriethyl, $Sb(C^2H^5)^3S$, is formed, with evolution of heat, when sulphur and stibtriethyl are brought together under water. But it is most readily obtained by boiling an ethereal solution of stibtriethyl with flowers of sulphur; the liquid decanted from the sulphur soon solidifies in needle-shaped crystals, which may be purified by leaving the adhering sulphur to oxidise in the air, and crystallising several times from ether. Sulphide of stibethyl thus purified forms a bulky mass, having a silvery lustre, an unpleasant odour, and a bitter taste; it is permanent in the air when dry, melts above 100° C., and is decomposed by a stronger heat, with evolution of stibtriethyl vapour. The aqueous solution of the sulphide precipitates metals from their solutions as sulphides, and yields sulphuretted hydrogen with dilute acids.

Sulphantimonite of Stibtriethyl. $SbE^3.Sb^2S^4$, or $SbE^3S.Sb^2S^3$. — Sulphuretted hydrogen passed through a solution of the antimonite, throws down this compound in the form of a light yellow precipitate, having an extremely unpleasant, persistent odour, like that of mercaptan. The compound is also formed by adding recently precipitated trisulphide of antimony to a solution of sulphide of stibtriethyl, the latter being in excess, whereupon the brown-red colour of the kermes immediately changes to light yellow. Dried over sulphuric acid, it forms a powder of a beautiful light yellow colour, which changes to brown-red at the heat of the water-bath. When distilled over a spirit-lamp, it yields a liquid distillate having all the properties of sulphide of stibtriethyl. Dilute sulphuric acid poured upon it, separates trisulphide of antimony, with evolution of sulphuretted hydrogen, and formation of sulphate of stibtriethyl:

$$SbE^3.Sb^2S^4 + SO^4H^2 = SbE^3.SO^4 + H^2S + Sb^2S^3.$$

Fuming nitric acid decomposes it, with emission of light and heat.

STIBETHYLIUM. $Sb(C^2H^5)^4 = SbE^4$. (R. Löwig, J. p. Chem. lxiv. 415; Chem. Soc. Qu. J. viii. 261; Gm. x. 527.) — The iodide of this radicle is formed by introducing a mixture of equal parts of stibtriethyl and iodide of ethyl into a retort filled with carbonic acid gas, nearly filling the retort with water, sealing the neck, and then heating it in boiling water. The solution evaporated and cooled, yields beautiful hexagonal prisms, often an inch long, containing $2SbE^4I.3H^2O$, and other crystals, containing $4SbE^4I.3H^2O$. The salt has a very bitter taste, and 1 pt. of it dissolves in 5·26 pts. of water at 20° C. It dissolves more easily in absolute alcohol, but less in ether. The solution of this salt, mixed with chloride of mercury, forms a white precipitate, which dissolves in warm water, and yields crystals containing $3HgI.SbE^4I$. Another double iodide, $3HgI.2SbE^4I$, is obtained by adding iodide of mercury to a hot solution of iodide of stibethylium.

The iodide digested with oxide of silver, yields a strongly alkaline solution, which when evaporated, leaves the *hydrate of stibethylium* in the form of a thick colourless oily liquid, having a strong alkaline taste and reaction. It expels ammonia from its compounds, precipitates metallic oxides, and redissolves alumina and stannic oxide. It dissolves in acids, forming salts which have a bitter taste. The *carbonate* is a tough deliquescent mass. The *sulphate* and *nitrate* crystallise. The *formate* yields needle-shaped crystals, difficult to dissolve. The *acetate* forms similar crystals, but more soluble. The *oxalate* crystallises; the succinate does not. The neutral *tartrate* and *racemate* form large deliquescent crystals; the acid tartrate, fine needles.

The *sulphide*, $(SbE^4)^2S$, is obtained by treating the oxide with hydrosulphuric acid. It is a yellowish oily liquid, soluble in water and alcohol, and exhibiting the reactions of alkaline sulphides.—The *bromide* and *chloride* are crystalline compounds obtained by saturating the oxide with the corresponding acids. The chloride forms with chloride of mercury, compounds analogous to the double iodides above mentioned. It also combines with dichloride of platinum, producing the compound $3PtCl^2.2SbE^4Cl$, which forms fine yellow crystals, soluble in water and alcohol.

Antimonides of Methyl.[*]

STIBTRIMETHYL. $Sb(CH^3)^3 = SbMe^3$.—Produced, like the corresponding ethyl-compound, by the action of iodide of methyl on antimonide of potassium. It is a colourless heavy liquid, insoluble in water, sparingly soluble in alcohol, readily in ether. When exposed to the air, it gives off thick white fumes, and takes fire, burning with a white

---

[*] Landolt, Ann. Ch. Pharm. lxxviii. 91; Gm vii. 321; Gerh. i. 646.

flame and depositing metallic antimony. Its compounds are precisely analogous to those of stibtriethyl.

Stibpentamethyl, $Sb(CH^3)^5$, appears to be produced by the action of zinc-ethyl on stibtrimethyl; and to be decomposed by distillation into stibtrimethyl and hydrocarbons. (Buckton, compare page 336.)

STIBMETHYLIUM. $Sb(CH^3)^4 = SbMe^4$.—This compound is obtained as an iodide by the action of iodide of methyl on stibtrimethyl. It is not quite certain whether it has yet been isolated. The iodide distilled with excess of antimonide of potassium, in an atmosphere of carbonic anhydride, yields a spontaneously inflammable oily liquid, resembling stibtrimethyl; and the aqueous solution of the iodide subjected to the action of the electric current, yields iodine at the positive pole, while at the negative pole, the liquid becomes alkaline, and gives off a spontaneously inflammable gas containing antimony, and having the odour of stibtrimethyl; but which of these products, if either, is stibmethylium, has not yet been ascertained.

The compounds of stibmethylium closely resemble the corresponding potassium-salts, and are isomorphous with them. They have a bitter taste. They are decomposed by potash or soda, and then form white fumes, if a glass rod moistened with hydrochloric acid is held over them. They are for the most part easily soluble in water, less soluble in alcohol, and insoluble in ether. The antimony in them is scarcely recognisable by the ordinary reagents, not being precipitated by hydrosulphuric acid till after a long time. They yield a slight deposit of antimony, when treated with zinc and sulphuric acid in Marsh's apparatus. They bear a heat of about 140° C. without decomposition, but between 180° and 200° they are decomposed, and give off spontaneously inflammable vapours.

Bromide. $SbMe^4Br$.—Obtained by decomposing iodide of stibmethylium with bromide of mercury. On filtering from the iodide of mercury and evaporating, a beautiful salt is obtained, soluble in alcohol and water, but insoluble in ether, and having a saline bitter taste. This compound, when heated, evolves white vapours which take fire in the air. Oil of vitriol poured upon it liberates hydrobromic acid; nitric acid separates bromine. With metallic salts, bromide of stibmethylium behaves in the same manner as bromide of potassium.

Carbonates.—The neutral carbonate is obtained by decomposing a solution of the iodide with recently precipitated carbonate of silver. The filtered liquid evaporated over the water-bath, leaves an indistinctly crystallised, somewhat yellowish, transparent mass, which deliquesces very readily in the air, exhibits an alkaline reaction, dissolves very easily in water and in alcohol, but very slowly in ether. This compound is very unstable, beginning to smell of stibtrimethyl as soon as it is formed. When heated, it gives off white fumes, which take fire spontaneously in the air. It does not appear to contain water of crystallisation.—The *acid carbonate*, $(SbMe.H.)CO^3$, is formed by passing carbonic anhydride through a solution of the oxide or of the neutral carbonate, and evaporating. It crystallises with difficulty in small deliquescent needles, arranged in stars. In the solid form, it soon decomposes, like the neutral carbonate. The aqueous solution evolves carbonic anhydride when heated, and does not precipitate magnesium-salts.

Chloride. $SbMe^4Cl$.—Obtained by adding a hot solution of corrosive sublimate to aqueous iodide of stibmethylium, as long as a precipitate of iodide of mercury is produced. The filtered liquid evaporated over the water-bath deposits the chloride in white six-sided tables, similar to those of the iodide. These crystals are easily soluble in water and alcohol, nearly insoluble in ether: their taste is saline and bitter. This salt intumesces when heated in a tube, and at a higher temperature gradually disappears, giving off white fumes, which take fire spontaneously in the air, and deposit on the cooler part of the tube a white sublimate containing chloride of antimony.

Chloroplatinate. $SbMe^4Cl.PtCl^2$.—Obtained as a yellow crystalline precipitate, by adding dichloride of platinum to chloride of stibethylium. It may be dissolved in boiling water, and separates on cooling as an orange-yellow crystalline powder. It is the least soluble in water of all the salts of stibmethylium, and is intermediate in solubility between the chloroplatinates of potassium and sodium. It is quite insoluble in alcohol and ether, very difficult of solution in alkalis, but dissolves more easily in hot hydrochloric acid. When heated, it turns black, and soon takes fire, leaving an alloy of platinum and antimony, from which the latter metal is but imperfectly removed by aqua-regia.

Hydrate. $SbMe^4.H.O$.—Obtained by agitating an aqueous solution of the iodide with recently precipitated oxide of silver, filtering from the resulting iodide of silver, and evaporating the filtrate in vacuo over sulphuric acid. It is a white, crystalline mass which feels soapy between the fingers, is highly caustic, and dissolves rapidly in water and alcohol, but is insoluble in ether. In the state of aqueous solution, it is slightly volatile, and forms white fumes when a glass rod moistened with hydrochloric acid is held over it; but the solution, when evaporated over the water-bath, yields the original quantity with scarcely any loss. When the solid hydrate is suddenly heated in a test-tube, it gives off vapours which take fire on coming in contact with the air, and deposit metallic antimony; but when carefully heated, it sublimes undecomposed.

The aqueous solution has an alkaline taste and odour, and instantly turns reddened litmus paper blue. In all its chemical relations, it exhibits the closest resemblance to caustic potash. When evaporated in an open vessel, it absorbs carbonic acid, and then effervesces strongly with acids; but on the addition of lime-water, carbonate of calcium is precipitated, and the pure base is again found in the solution. It expels *ammonia* from ammoniacal salts, even in the cold, and separates *baryta* from iodide of barium. *Lime* and *oxide of lead* are immediately precipitated by the solution of this base. With *zinc-salts* it forms a white precipitate, soluble in excess; with *copper-salts* a precipitate insoluble in excess; with *mercurous*, *mercuric*, and *silver-salts*, it gives the same reactions as potash; with *chloride of platinum*, it forms a yellow precipitate, resembling the chloroplatinate of potassium. The aqueous solution, boiled with *sulphur*, forms a yellow liquid, which, when mixed with dilute acids, yields a precipitate of sulphur, and gives off sulphuretted hydrogen.

Iodide of Stibmethylium, $SbMe^4I$, is formed by the action of iodide of methyl on stibtrimethyl. If, in the preparation of stibtrimethyl, the iodide of methyl which distils over at first, and the stibtrimethyl which passes over when the temperature is raised, are collected in the same receiver, a slight ebullition takes place, and the liquid mixture solidifies after a while into a perfectly white, crystalline mass. This is dissolved in warm water, the excess of iodide of methyl separated, and the solution set aside to evaporate slowly over the water-bath. The iodide of stibmethylium then separates in crystals belonging to the hexagonal system. They are remarkably beautiful, large, six-sided tables, usually scalariform, and from 10 to 15 millimetres in diameter; the terminal faces are plane, and the lateral edges intersect one another at angles of 120°. The crystals contain water mechanically enclosed, and consequently decrepitate when heated. They dissolves in 3·3 pts. of water at 23° C., and are likewise easily soluble in alcohol, but dissolve very slowly in ether.—Iodide of stibmethylium heated in a test-tube first falls to powder, and at 200° C. begins to decompose, disappearing gradually, and evolving thick white fumes, which have the odour of stibtrimethyl. The vapour thus evolved is partly deposited as a coating on the inside of the tube; but the greater portion reaches the mouth, where it takes fire spontaneously, forming rings of smoke like phosphoretted hydrogen. Boiling water dissolves but a small portion of the deposit in the tube. The solution treated with *nitrate of silver*, yields a precipitate consisting of iodide of silver and metallic silver, the latter being doubtless produced by pure stibtrimethyl or stibmethylium, the former by undecomposed iodide. The aqueous solution of iodide of stibmethylium is gradually decomposed by repeated *evaporation*, a small quantity of a yellow insoluble substance (not yet examined) being formed, and the odour of stibtrimethyl evolved. The yellow substance likewise appears, though not constantly, when the solution is exposed to sunshine. [For the decomposition by electrolysis, see page 345.] Filtering paper, covered with strong starch-paste, to which iodide of stibmethylium has been added, behaves towards *ozone*, exactly in the same manner as paper prepared with iodide of potassium, but is even more sensitive. *Sulphuric acid*, *bromine*, *chlorine*, and *nitric acid*, act upon iodide of stibmethylium exactly as upon iodide of potassium; *hydrochloric acid* decomposes it, with formation of chloride of stibmethylium. Aqueous solution of iodide of stibmethylium poured upon *amalgam of sodium*, produces a succession of little explosions, accompanied by appearance of fire, metallic antimony being also separated. The iodide distilled with excess of *antimonide of potassium*, yields a yellow oily liquid, which is perhaps stibmethylium. The aqueous solution dissolves a considerable quantity of the yellow modification of *mercuric iodide*. The red iodide boiled in the solution changes into the yellow modification before it dissolves; and as the liquid cools, a considerable portion of the mercuric iodide separates out, but always in the yellow modification.

Nitrate of Stibmethylium, $SbMe^4.NO^3$.—Formed by adding nitrate of silver to an aqueous solution of iodide of stibmethylium as long as any precipitate is formed, then filtering and evaporating till the salt crystallises. The crystals are anhydrous. The salt dissolves readily in water, slowly in alcohol or ether. Its taste is harsh and bitter, not cooling like that of nitre. When heated, it gives off white fumes, which immediately take fire; the entire mass then explodes with a large white flame, just like a mixture of nitre and charcoal. The salt is very stable, not being decomposed, even by boiling with strong sulphuric acid.

Sulphates of Stibmethylium.—The neutral sulphate, $(SbMe^4)^2.SO^4$, is obtained by adding a hot solution of sulphate of silver to aqueous iodide of stibmethylium, as long as any precipitate of iodide of silver is formed. On evaporating the filtered liquid over the water-bath, colourless crystals are obtained, which may be pressed between paper and dried in the air; also, by saturating a concentrated solution of the acid salt with oxide of stibmethylium, and mixing the aqueous solution with alcohol and ether; the neutral salt then separates in oily drops, which after a while assume the solid form. The crystals, which appear to be rhombic, contain 15·42 per cent. (5 at.) water of crystallisation, which they give off at 100° C. Placed over sulphuric acid, they lose part of their water, and fall to a white powder. The crystals dissolve very readily in water; the anhydrous salt becomes strongly heated when water is poured upon it. The salt is also soluble in alcohol, but insoluble in ether. Its taste is saline and bitter.

Acid Sulphate, $(SbMe^4).H.SO^4$.—Obtained by adding 1 at. sulphuric acid to an aqueous solution of 1 at. of the neutral sulphate. After several crystallisations, beautiful, hard, transparent crystals are obtained, some of which are four-sided tablets with obliquely truncated edges. It has a strongly acid taste, leaving a bitter taste in the mouth. When heated, it behaves exactly like the neutral sulphate. On dissolving it in a small quantity of water, then adding alcohol, precipitating by ether, and repeating these operations several times, the neutral sulphate is at length obtained. In this respect, the acid salt behaves exactly like acid sulphate of potassium. The salt contains no water of crystallisation. The basic water (or hydrogen), like that of acid sulphate of potassium, is not driven off at 120° C.

Sulphide, $(SbMe^4)^2S$.—Prepared, like monosulphide of potassium, by dividing an aqueous solution of oxide of stibmethylium into two parts, saturating the one with hydrosulphuric acid, and then adding the other. The resulting solution, quickly evaporated in a retort, leaves the sulphide in the form of an amorphous green powder, which smells like mercaptan, dissolves readily in water and alcohol, but is insoluble in ether. The solutions give black precipitates with lead- and silver-salts. Heated in a tube, it melts and decomposes, giving off spontaneously inflammable vapours, and leaving sulphide of antimony. In contact with the air, it oxidises rapidly.

A solution of hydrate of stibmethylium boiled with sulphur, yields milk of sulphur on the addition of an acid: hence it is probable that higher sulphides of stibmethylium may be formed.

STIBTRIMETHYLETHYLIUM, $Sb(CH^3)^3(C^2H^5)$, is obtained as an iodide by the action of iodide of ethyl on stibtrimethyl. It closely resembles the iodide of stibmethylium.

STIBMETHYLTRIETHYLIUM, $Sb(CH^3)(C^2H^5)^3 = SbMeE^3$. (Friedländer, J. pr. Chem. lxx. 443; Gm. xiii. 500).—The *iodide* of this radicle, obtained by the action of iodide of methyl on stibtriethyl, forms beautiful crystals, apparently having the form of rhombic prisms, with a glassy lustre when fresh, changing after a while to nacreous; they crumble to pieces when dry, but are otherwise permanent in the air. The iodide has an intensely bitter taste, is inodorous when cold, but at 100° C. gives off a peculiar odour, without sensible decomposition. It dissolves in twice its weight of water at 20° C., is soluble also in alcohol, but insoluble in ether. The solutions turns the plane of polarisation to the left.

Iodide of stibmethyltriethylium forms two double salts with *mercuric iodide*, viz. $SbMeE^3I.2HgI$, obtained by adding recently precipitated mercuric iodide to a solution of iodide of stibmethyltriethylium; and $SbMeE^3I.3HgI$, which is precipitated on adding a hot solution of mercuric chloride to a boiling solution of iodide of stibmethyltriethylium, the chloride of the antimony-radicle then remaining in solution:

$$4SbMeE^3I + 3HgCl = SbMeE^3I.3HgI + 3SbMeE^3Cl.$$

This double iodide is insoluble in water, and sparingly soluble in alcohol and ether, crystallising from the alcoholic solution in yellow needles which melt below 100° C.

Chloride, $SbMeE^3Cl$.—Produced as above, or by dissolving the hydrate or carbonate in hydrochloric acid, and may be obtained by evaporation in small crystalline needles.

Hydrate.—Produced (1), by decomposing the iodide with moist oxide of silver (when thus prepared, however, it always contains silver); or (2), by decomposing the sulphate with an exactly equivalent quantity of hydrate of barium, and concentrating the filtrate in vacuo. It is a thick, oily, non-volatile liquid, which has a strong bitter taste and alkaline reaction, decomposes ammonia-salts, and precipitates metallic oxides from their solutions, the zinc and alumina precipitates being soluble in excess.

Hydrate of stibmethyltriethylium dissolves in acids, forming neutral and acid salts, which may likewise be prepared by double decomposition from the iodide, chloride, or sulphate. The salts are more or less soluble in water and alcohol; some are deliquescent, others permanent. Those which crystallise do not contain water. There are no basic salts of stibmethyltriethylium.

The *carbonate*, $(SbMeE^3)^2.CO^3$, is a white resinous mass which reacts like carbonate of ammonium. The *sulphate*, $(SbMeE^3)^2.SO^4$ is produced by dissolving the hydrate in sulphuric acid, or by decomposing the iodide with sulphide of silver, and may be obtained, by evaporation in vacuo, in white, shining, bitter crystals, which melt at 100° C. and are extremely deliquescent.

The *acetate*, *formate*, and *butyrate* are crystalline. The *neutral oxalate*, $(SbMeE^3)^2.C^2O^4$, forms anhydrous glassy needles, moderately soluble in water. The *acid oxalate*, $SbMeE^3.H.C^2O^4$, forms needles very soluble in water. The *tartrate* is obtained by evaporation as a syrupy liquid which rapidly absorbs water, but does not crystallise.

The *cyanide* is obtained by dissolving the hydrate in hydrocyanic acid. The clear watery solution boiled with potash-ley gives off ammonia and forms an antimonetted acid, which yields insoluble or sparingly soluble salts with all bases, except potash, soda, and ammonia.

ANTIPHLOGISTIC THEORY. See Combustion.

ANTIRRHIN. See Anthokirrin.

ANTIRRHINIC ACID. An acid of unknown composition, obtained by Morin from the leaves of the fox-glove (*Digitalis purpurea*). It is prepared by distilling the leaves with water, saturating the distillate with baryta, evaporating, distilling the residue with excess of sulphuric or oxalic acid, and rectifying over chloride of calcium. The acid then floats on the top of the liquid in oily drops, having an unpleasant odour like that of the plant, and producing headache and giddiness. It reddens litmus strongly, dissolves readily in alcohol, and in contact with water forms white films, which gradually dissolve. (J. Pharm. April 1845, p. 299.)

ANTISEPTICS. Substances which prevent the spontaneous decomposition of vegetable and animal substances. They are chiefly: the mineral acids, the alkaline hypochlorites, common salt, nitre, spices, sugar, creosote and yeast. (See Fermentation and Putrefaction.)

ANTITARTARIC ACID, also called *Lævotartaric* and *Lævoracemic* acid. Pasteur has shown that racemic acid, which has no action on polarised light, is a compound of two acids in equal proportions, one of which turns the plane of polarisation of a ray of light to the right, and the other to the left. Hence he calls these acids respectively, *dextro-* and *lævoracemic acids*, or *dextro-* and *lævo-tartaric*. The dextro-acid is identical with ordinary tartaric acid. Gmelin (Handb. x. 365) retains the name *tartaric* for the ordinary dextro-rotatory acid, and distinguishes the lævo-rotating acid as antitartaric acid. (See Tartaric and Racemic Acids.)

ANTRIMOLITE. A hydrated silicate of aluminium, found in white stalactitic masses on the north coast of Antrim. According to Th. Thompson's analysis (J. pr. Chem. viii. 489) it contains 43·47 per cent. of silica, 30·26 alumina, and 15·32 water, together with 7·50 per cent. lime, 4·10 potash, 0·19 protoxide of iron, and 0·098 chlorine. It appears to be related to mestoype.

ANTS, OIL OF. The red ant (*Formica rufa*) contains a volatile oil, which may be extracted by distilling the insects with water: to the amount of 0·12 per cent., according to Nölle; 1 per cent. according to Hermbstadt. It is transparent and colourless, and has an agreeable odour; its taste is not burning. It is slightly soluble in absolute alcohol. (Gm. xiv. 358.)

ANTYRRHINIC ACID. The name given by Walz to a volatile acid, obtained by distilling toad-flax (*Antirrhinum Linaria*, L., *Linaria vulgaris*, Dec.) with water. It forms a deliquescent barium-salt, the analysis of which gives for the atomic weight of the acid the number 212.

ANYLAMIDE. Syn. with Nitrosalicylamide. See Salicylamide.

APATELITE. A native basic sesquisulphate of iron = $2(Fe^4O^3.3SO^3) + 3H^2O$, found, in egg-shaped, earthy, yellow masses, in the clay, at Meudon and Auteuil, near Paris.

APATITE. *Phosphate of calcium.*—This mineral occurs both massive and crystallised. The crystals are six-sided prisms, belonging to the rhombohedral system, sometimes passing into the six-sided table; often hemihedral. Lustre vitreous, inclining to subresinous. Translucent, rarely transparent. Scratches fluor-spar, but is scratched by felspar. Brittle. Colours, white, wine-yellow, green, and red. Specific gravity 3·17 to 3·25. Phosphoresces on coals. Electric by heat and friction. It occurs in primitive rocks; in the tin veins of the granite of St. Michael's Mount, Cornwall; near Chudleigh in Devonshire; at Nantes in France; on the St. Gothard; and with molybdenum in granite, near Colbeck, Cumberland; also at Ehrenfriedersdorf, in Saxony, in the Tyrol, in Bavaria, in Bohemia, and in Spain. Large crystals are found near New York — one crystal from Robinson's farm being nearly a foot in length, and weighing 18 pounds — also in New Hampshire, in Maine, Massachusets, and Delaware. A massive variety called *Phosphorite*, because it becomes phosphorescent by friction, is found in veins of tin-stone, and likewise in secondary formations. A very large vein of this mineral is found at Estremadura in Spain. It has a botryoïdal and kidney-shaped surface, and a radiating fibrous texture.

The chemical composition of apatite may be expressed, according to Gustav Rose (Pogg. Ann. ix. 185), by the general formula, $3PO^4Ca^3 + \begin{matrix} Ca\,F \\ Ca\,Cl \end{matrix}$, the chlorine and fluorine, which are isomorphous, being capable of replacing one another in any proportion whatever. If the chlorine is altogether absent, the mineral becomes a *Fluor-apatite*, or *Francolite*, $3PO^4Ca^3 + CaF$, containing 7·9 per cent. fluoride of calcium, and 92·31 tribasic phosphate. An analysis of Francolite by Dr. Henry gives in 100 pts. 41·34 phosphoric anhydride (P^2O^5), 53·38 lime (Ca^2O), 2·96 protoxide of iron (Fe^2O), 2·32 fluorine, and a trace of chlorine; whence we may calculate that the proportion of tribasic phosphate of calcium is 93·3, and that of the fluoride 4·91; part of the theoretical quantity of calcium is, however, replaced by the iron. The apatites of the St. Gothard, of Ehrenfriedersdorf in Saxony, and of Faldigl and Greiner in the Tyrol, are fluor-apatites. Apatites free from fluorine have not yet been found. The greater number contain chlorine and fluorine together. The largest amount of chloride of calcium is found in the apatite of Snarum in Norway, which contains 4·28 CaCl, 1·59 CaF, and 91·13 PO^4Ca^3. An apatite in which the fluorine was wholly replaced by chlorine would contain 10·62 per cent. of chloride of calcium.

The composition of apatite is only a particular case of the general formula $3\left(\begin{matrix} P \\ As \end{matrix} O^4M^3\right) + \begin{matrix} MCl \\ MF \end{matrix}$ in which M denotes a metal, which, in the species hitherto examined, may be either calcium or lead, and in which phosphorus and arsenic may replace each other in any proportion, as well as chlorine and fluorine. This formula likewise includes the pyromorphites, or green lead-ores, which are isomorphous with apatite. Apatite was so named by Werner from ἀπατεῖν, to deceive, on account of the mistakes of the earlier mineralogists respecting its nature. Even Berzelius was not aware of the presence of phosphorus in it. (Handw. d. Chem. 2^te^ Aufl. ii. 147.)

APATOID. A mineral free from phosphoric acid, found in certain American meteorites.

APELAIC ACID. See Azelaic Acid.

APHANESITE. See Abichite (p. 6).

APHANITE. See Diorite.

APHLOGISTIC LAMP. Lamp without flame, or glow-lamp. (See Alcohol, p. 74.)

APHRITE. *Schieferspar. Chaux carbonatée nacrée.* — A slaty carbonate of calcium, having a mother-of-pearl lustre, found rarely in beds and veins in the older rocks, as in Cornwall, at Kongsberg, &c. A soft friable variety of it, called *earth-foam* (*Schaumkalk*, *Schaumerde*), containing silica and oxide of iron, is found at Gera, and at Eisleben in Thuringia.

APHRIZITE. See Tourmaline.

APHRODITE. A hydrated silicate of magnesium, resembling meerschaum, found at Longbanshytta, in Sweden. Its formula is $16Mg^2O.15SiO^2 + 12H^2O$. Now in the magnesia-silicates, 3 at. water may be supposed to replace 1 at. magnesia (see Silicates) hence the preceding formula may be reduced to $4M^2O.3SiO^2$, or $2MO.SiO^3$ [M denoting a monatomic metal].

APHRONITRUM, (ἄφρος froth and νίτρον soda.) — An old name for the saline efflorescences formed on walls, commonly called *wall-nitre*, but consisting for the most part of carbonate and sulphate of sodium, sometimes with sulphate of magnesium.

APHROSIDERITE. A silicate of iron and aluminium, containing, according to Sandberger, 26·4 per cent. silica, 21·2 alumina, 1·1 magnesia, 44·2 protoxide of iron, and 7·7 water. Sandberger represents it by the formula $3(3FeO.SiO^3) + 3Al^2O^3.SiO^3 + 6HO$. It is doubtful, however, whether all the iron exists as protoxide.

APHTALOSE. See Arcanite.

APHTONITE. The name given by Svanberg to a mineral from Wärmkog, in Wärmeland, resembling fahl-ore (*q. v.*), but distinguished by a peculiarly large amount of basic metallic sulphides. According to Svanberg's analysis (Ofversigt af Kongl.

Vätenskaps Acad. Vörhandlingar, iv. 85), its general formula is $7M^2S.Sb^2S^3$; perhaps a mixture of $6M^2S.Sb^2S^3$ with M^2S. It consists chiefly of copper, zinc, silver, iron, and antimony, with only a trace of arsenic. Specific gravity 4·87.

APIIN.—A gelatinous substance extracted by Braconnot (Ann. Ch. Phys. [3] ix. 250), from common parsley (*Apium petroselinum*) by boiling with water. The boiling liquor passed through a cloth becomes on cooling a transparent jelly, like pectic acid. It is washed in cold water, and after drying over the water-bath, is treated with boiling alcohol and ether, which extract from it a certain quantity of chlorophyll.

Pure apiin is a colourless powder, without odour or taste. It melts at 180°C. into a yellow liquid, which forms a vitreous mass on cooling. It begins to decompose between 200° and 210° C. It is very sparingly soluble in cold water, but dissolves readily in boiling water, which deposits it on cooling in the form of a jelly. It is soluble in boiling alcohol and insoluble in ether. According to Planta and Wallace (Ann. Ch. Pharm. lxxiv. 262) it contains $C^{24}H^{28}O^{13}$. Its solution in boiling water produces a blood-red colour with ferrous salts: this reaction is extremely delicate, sufficing to indicate the smallest traces of apiin. The aqueous solution, after boiling for a long time, no longer gelatinises on cooling, but deposits nearly white flakes, which appear to consist of $C^{24}H^{28}O^{13}.H^2O$. When apiin is boiled with dilute sulphuric or hydrochloric acid, the liquor deposits on cooling, white flakes, which appear to contain $C^{24}H^{20}O^9$, that is to say, apiin *minus* 4 atoms of water. Apiin is dissolved by alkalis and reprecipitated in its original state by acids. When boiled with sulphuric acid and peroxide of manganese, it yields carbonic, acetic, and formic acids.

APIOS TUBEROSA or *Glycine apios* (*L.*)—A leguminous plant from North America, the roots of which have been proposed as a substitute for the potato, and the young seeds for peas. The roots are eaten in Virginia, and are said to have been used by the aborigines of the country. Payen (Compt. rend. xxviii. 189) gives the following statement of the composition of the roots, compared with that of the variety of potato called *patraque jaune:*

	Apios.	Potato.
Nitrogenous matter	4·5	1·7
Fatty matter	0·8	0·1
Starch, sugar, pectin, &c.	33·55	21·2
Cellulose and epidermis	1·3	1·5
Inorganic matter	2·25	1·1
Water	57·8	74·4

APIRIN or **APYRIN.** An alkaline substance said to be contained in the nut of *Cocos nucifera* and *Cocos lapidea*. (Bizio, J. Chim. méd. 1833, 495.)

APJOHNITE. See MANGANESE-ALUM.

APLITE. A name inappropriately given to a kind of granite, consisting chiefly of a fine-ground mixture of quartz and felspar with only a trace of mica.

APLOME. See GARNET.—**APOGLUCIC ACID.** See GLUCIC ACID.

APROCRENIC ACID. See HUMIC ACID.

APOPHYLLIC ACID, $C^8H^7NO^4$.—A nitrogenous acid obtained by the decomposition of cotarnine; first prepared by Wöhler (Ann. Ch. Pharm. i. 24), afterwards more fully examined by Anderson (Edinb. Phil. Trans. xxiii. 347; Chem. Soc. Qu. J. v. 257).

Preparation.—1. Cotarnine is dissolved in nitric acid diluted with twice its volume of water; strong nitric acid is added; and the whole is heated to boiling, whereupon abundance of red vapours are evolved. As soon as a small portion of the solution, on being mixed with alcohol and ether, quickly deposits crystals (if no crystals appear the heating must be continued), the whole of the solution is treated in the same way, and the crystals which are deposited after 24 hours, are filtered off and purified by boiling their solution which animal charcoal, and recrystallising. A great excess of nitric acid hinders the precipitation of the apophyllic acid (Anderson).—2. On decomposing chloroplatinate of cotarnine with sulphuretted hydrogen, filtering off the platinum and evaporating the filtrate with hydrate of barium, apophyllate of barium was found in the residue; and after extracting the cotarnine with alcohol, and boiling the residue with dilute sulphuric acid, a yellow solution was obtained which deposited crystals of apophyllic acid after the lapse of several weeks. (Wöhler.)

Apophyllic acid crystallises from a boiling saturated solution on cooling, in rather long anhydrous prisms, which do not effloresce when heated. It reddens litmus strongly and has a weak acid taste (Wöhler). Melts at 205° C., and solidifies on cooling, into a crystalline mass. (Anderson.)

a. *Hydrated apophyllic acid*, $C^8H^7NO^4 . H^2O$, crystallises from a saturated and not boiling solution, in colourless, very sharp rhombic octahedrons the form of which approaches to that of a square-based octahedron. Angles of the base about 88° and 92°; of the lateral edges, about 106° 28′, 105° 24′, and 190°. The crystals cleave very readily in a direction parallel to the base, forming faces of pearly lustre, like the crystals of apophyllite (hence the name). These give off their water, amounting to about 9 per cent., at a temperature much below 100° C. (Wöhler.)

Aqueous Apophyllic Acid.—Apophyllic acid dissolves slowly and with great difficulty in cold water. It is soluble in sulphuric acid (Anderson); insoluble in alcohol and ether.

When heated, it melts, chars, and evolves an oily, strongly alkaline liquid, which smells like chinoline (Wöhler). By distillation it yields a neutral oil, as well as a base, which does not become coloured when treated with chloride of lime (Anderson).—2. Nitric acid converts it into oxalic acid (Anderson).

Apophyllates.—Nearly all the apophyllates are soluble in water.

Apophyllate of Ammonium forms small prismatic needles. It is readily soluble in water.

Apophyllate of Barium is obtained in nodular crystals by digesting the acid with carbonate of barium and adding alcohol to the solution. (Anderson.)

Apophyllate of Ammonium does not precipitate *lead-salts.* (Wöhler.)

Apophyllate of Silver, $C^8H^6AgNO^4$, is obtained by digesting apophyllic acid with moist carbonate of silver and precipitating the solution with alcohol and ether. It forms a crystalline powder, which burns slowly when heated, leaving a residue of metallic silver. It is easily soluble in water, insoluble in alcohol and ether (Anderson). On mixing a solution of apophyllate of ammonium with nitrate of silver, a double salt, consisting of apophyllate and nitrate of silver, $C^8H^6AgNO^4 . NO^3Ag$, is deposited after a while in small crystalline stars, which soon increase to zeolitic groups of fine needles. The salt explodes violently when heated, like oxalate of silver. It is slightly soluble in water.

APOPHYLLITE. *Ichthyophthalmite, Fish-eye stone.*—A silicate of calcium and potassium, also containing fluorine, which is found both massive and crystallised. The crystals belong to the dimetric system. The most usual form is $\infty P \infty . P$, also with $0P$. Cleavage perfect, parallel to $0P$, imperfect parallel to $\infty P \infty$. The massive variety has a laminated structure. Specific gravity 2·3 to 2·4. Hardness about that of apatite, or generally rather less. The finest varieties are transparent and colourless, or sometimes tinged with rose colour; translucent crystals are also found, or opaque in the mass, translucent only at the edges, and white, reddish-white, or flesh-coloured. External lustre splendent and peculiar; internal lustre glistening and pearly. The transparent crystals exhibit, according to Brewster, a peculiar optical character, which shows that each individual crystal is an aggregate of several pieces symmetrically arranged. In some places (especially at Aussig in Bohemia) a variety called *albin* is found, consisting of opaque crystals of peculiar form. Apophyllite, heated before the blowpipe, exfoliates (hence its name, from ἀποφυλλίζειν), then froths, and melts into an opaque bead. It is easily decomposed by strong hydrochloric acid, with separation of gelatinous silica. The filtrate, supersaturated with ammonia, yields a precipitate of fluoride of calcium.

The composition of apophyllite, as determined by analysis, is as follows:—

	Berzelius.	Stromeyer.	C. Gmelin.
Silica	52·13	51·86	53·90
Potash	5·27	5·31	6·13
Lime (including CaF) . .	25·53	25·22	25·00
Water	16·20	16·91	15·70
	99·13	99·30	100·73

From these results, L. Gmelin (Handb. iii. 394) deduces the formula $KO.2SiO^2 + 6(CaO.2SiO^2) + CaO.SiO^2 + CaF + 16HO$[*], or $15SiO^2.7Ca^2O.K^2O + 2CaF + 16H^2O$.[†] Simpler formulæ may be obtained, if we suppose the fluorine to take the place of part of the oxygen in equivalent proportion. Berzelius gives the formula $KO.2\not{S}iO^2 - 8(CaO.\not{S}iO^2)$[‡] $+ 16HO$, which, if M denote a monatomic radicle, may be reduced to $10\not{S}iO^2.9MO.16HO$. The analytical results may, however, be equally well represented by the general formula $9\not{S}iO^2.8MO.15HO$; and, assuming that $3HO$ may replace $1MO$ (see ISOMORPHISM, POLYMERIC), this formula may be reduced to $9\not{S}iO^2.13MO$,[‡] or $27SiO^2.26M^2O$.

---

[*] $Si = 14$; $O = 8$.

[†] $Si = 28$; $O = 16$.

[‡] $\not{S}i = 21{\cdot}5$; $O = 8$.

APORETIN. A resin obtained by dissolving in alcohol that portion of the alcoholic extract of rhubarb which is insoluble in water, precipitating by ether, and again treating the precipitate with alcohol, the aporetin then remaining undissolved (Schlossberger and Döpping, Ann. Ch. Pharm. i. 219). Treated with concentrated nitric acid, it yields a yellow substance, which appears to be chrysammic acid, together with oxalic acid and an acid which produces a brown-red colouring with alkalis. (De la Rue and Müller, Chem. Soc. Qu. J. x. 298.)

APOSEPIDIN. *Käsoxyd.*—A product of the putrefaction of the so-called protein-compounds, discovered by Proust, but since shown by Mulder and others to be merely impure leucine.

APOTHEM. A term applied by Berzelius to the insoluble brown deposit which forms in vegetable extracts when exposed to the air. It is not a definite compound, but a mixture of several substances in a state of decomposition, and therefore of very variable constitution. (See Decay and Putrefaction.)

APPLES. A comparison of various sorts of apples and pears, with regard to specific gravity and amount of water and acid in the juice, has been made by Schulze (J. pr. Chem. lxii. 207). The results vary greatly according to season, climate, and soil; but the general conclusions are as follows:—The specific gravity of the fresh fruit varies from 0·72 to 0·91. The fruits contain between 13 and 21 per cent. of dry substance, of specific gravity above 1·4. The juice of 20 kinds of apples had a specific gravity between 1·020 and 1·027; in two varieties only, it was found to be between 1·033 and 1·037. The acid in the juice, estimated as tartaric acid, amounted to between 0·48 and 1·13 per cent. In Wurtemberg, the specific gravity of the juice of apples and pears rises in warm seasons above 1·080, and even approaches 1·090, the amount of free acid, estimated as tartaric acid, varying from 0·4 to 1·2 per cent., and that of sugar from 4 to 10 per cent.

APPLE-TREE. (*Pyrus Malus.*)—The ash of the branch of an apple-tree contained, after deducting the carbonic acid, in 100 pts.: 19·24 potash; 0·45 soda; 63·60 lime; 7·46 magnesia; 2·41 ferric phosphate; 4·15 phosphoric acid; 0·45 chloride of sodium; 0·93 sulphuric acid; and 1·31 silica. (Fresenius, Handw. d. Chem. 2te Aufl. i. 171.)

APPLE-OIL. *Maloïle.*—A yellowish oil formed in apples when kept. It is lighter than water, has a yellowish-grey colour, a sharp and harsh taste, boils at 190° C., and distils completely; burns with a slightly fuliginous flame; dissolves sparingly in water, but readily in alcohol and ether. Contains 64·15 per cent. carbon, 20·65 hydrogen, and 15·20 oxygen. Forms a crystalline compound with hydrochloric acid, but is decomposed by chlorine. (Handw. d. Chem. 2te Aufl. i. 172.)

APPLE-OIL (ARTIFICIAL). This name is given to a solution of valerate of amyl in 6 or 7 parts of alcohol, which has the smell of apples, and is used as a perfume. (Hofmann, Ann. Ch. Pharm. lxxxi. 87.)

APYRIN. See Apirin.

APYRITE. *Siberite, Rubellite, Red tourmaline.* See Tourmaline.

AQUA FORTIS. This name is given to a weak and impure nitric acid commonly used in the arts. It is distinguished by the terms *double* and *single*, the single having only half the strength of the other. The artists who use these acids call the more concentrated acid, which is much stronger even than the double aqua fortis, *spirit of nitre.* (See Nitric Acid.)

AQUAMARINE. See Beryl.

AQUA-REGIA or **REGIS.** A mixture of nitric and hydrochloric acid, so called from its property of dissolving the noble metals, gold and platinum. (See Nitro-hydrochloric Acid).

AQUA-VITÆ. Ardent spirit of the first distillation has been distinguished by this name in commerce. The distillers of malt and molasses spirits call it *low wines.*

AQUILA ALBA, MITIGATA, CŒLESTIS, MERCURII. An old name for subchloride of mercury; also *mercurius dulcis,* or *mild muriate of mercury.*

ARABIC (GUM). This gum exudes spontaneously from several species of acacia (*Acacia vera, A. arabica*) &c. It was formerly imported into Europe from Egypt and Arabia, but is now obtained chiefly from Senegal. The coarser and cheaper varieties mostly used by calico printers and other manufacturers are known by the name of gum-senegal. (See Gum.)

ARABIN. The principal constituent of gum arabic, in which, according to

Neubauer (Ann. Ch. Pharm. cii. 105), it exists in combination with lime, magnesia and potash. By treating the gum with hydrochloric acid and alcohol, these compounds are decomposed, and the arabin is separated in the form of a gum, which exhibits the properties of an acid. In the moist state, it dissolves readily in cold water, forming a gummy solution, from which it is precipitated by alcohol. After drying at 100° C. it no longer dissolves in cold water, but merely swells up to a gelatinous mass. Dried at 100° C. it has the composition $C^{12}H^{22}O^{11}$, $\frac{1}{11}$ of the hydrogen being replaceable by metals.

ARACHIDIC ACID, $C^{20}H^{40}O^2 = \left.\begin{matrix}C^{20}H^{39}O\\ H\end{matrix}\right\}O$. — Produced by the saponification of oil of earth-nut (*Arachis hypogæa*). The oil is saponified with soda; the mixture of fatty acids separated from the soap by hydrochloric acid, is macerated with five or six times its bulk of cold alcohol to remove the volatile acids; the insoluble portions are pressed and dissolved in alcohol; and the solution, heated nearly to the boiling point, is mixed with such a quantity of acetic acid, that on adding an excess of alcoholic acetate of lead, no precipitation takes place while the liquid remains hot. The crystals which separate after the liquid has remained in the cold for forty-eight hours, are separated from the liquid and mixed with alcohol and hydrochloric acid; the resulting ethers of the fatty acids, after being filtered off from the chloride of lead and freed from part of the alcohol by evaporation, are decomposed by boiling with soda-ley after the alcohol has been completely expelled; the resulting soda-soap is decomposed by hydrochloric acid: and the mixture of fatty acids thus separated, is again dissolved in alcohol, and fractionally precipitated with alcoholic acetate of magnesium. The portions first precipitated contain arachidic acid, which after several crystallisations is obtained pure.

Arachidic acid crystallises in very small shining scales; melts at 75° C., and solidifies again at 73°·5, forming a radiated mass, which after a while assumes the appearance of porcelain. It is but very slightly soluble in cold alcohol of ordinary strength, but dissolves easily in boiling absolute alcohol and in ether. (A. Gössmann, Ann. Ch. Pharm. lxxxix. 1.)

The acid is monobasic, belonging in fact to the series of fatty acids, $C^nH^{2n-1}O^2.H$. The ammonium, potassium, and sodium salts, are soluble in water, the rest insoluble or sparingly soluble in water, but soluble in boiling alcohol. The silver-salt, $C^{20}H^{39}O^2,Ag$, is a white precipitate which separates from boiling alcohol in slightly lustrous prisms, not altered by exposure to light. (Gössmann and Scheven, Ann. Ch. Pharm. xcvii. 257.)

Arachidate of Ethyl, $C^{20}H^{39}O^2,C^2H^5$, obtained by passing hydrochloric acid gas through an alcoholic solution of the acid at 80° or 90° C., is a crystalline, slightly tenacious mass, which melts at 52·5°, and solidifies at 51°. (Gössmann.)

Arachamide, $(C^{20}H^{39}O^2.N^2)N$, is obtained by leaving earth-nut oil for several weeks in contact with ammonia. It forms prisms grouped in stars, insoluble in water, dissolving with tolerable facility in boiling alcohol, melting at 98° or 99° C. When fused with hydrate of potassium, it gives off ammonia.

Arachin, or *Arachidate of Glyceryl*, is obtained by heating equal parts of arachidic acid and syrupy glycerin to 210° C. in a sealed tube. It is a lustrous fatty substance which melts at 70° C., and solidifies in a crystalline mass when slowly cooled. It dissolves sparingly in alcohol of 90 per cent., more freely in absolute alcohol, and still more in ether. It gave by analysis 76·2 per cent. carbon, and 12·6 hydrogen; whereas the formula of *triarachidate of glyceryl*, $C^3H^5O^3.(C^{20}H^{39}O)^3$, requires 77·62 C and 12·6 H (Gössmann and Scheven). Berthelot (Ann. Ch. Phys. [3] xlvii. 355) regards the product obtained by Gössmann and Scheven as a mixture of diarachin with free arachidic acid. He prepares the pure neutral arachins by melting in a flask the crude product obtained by heating glycerin with arachidic acid, then adding slaked lime to neutralise the free acids, digesting with ether for fifteen minutes, and afterwards boiling with ether, which dissolves the neutral fat and leaves the lime-soap undissolved. The ethereal solution when evaporated, leaves the neutral fat, which, if quite free from adhering fatty acids, should form with boiling alcohol a solution which does not redden litmus. In this manner Berthelot has obtained the three neutral arachins, corresponding to the acetins, viz. *monoarachin*, $C^3H^5O^3.C^{20}H^{39}O.H^2$, *diarachin*, $C^3H^5O^3.(C^{20}H^{39}O)^2.H$, and *triarachin*, $C^3H^5O^3.(C^{20}H^{39}O)^3$.

ARACHIS HYPOGÆA. *Earth-nut.* — A leguminous creeping plant, indigenous to India and the coasts of South Africa and South America, and cultivated in North America and in the south of Europe. The flower-bearing stems exhibit, as soon as the fruit begins to form, a tendency to bury themselves in the soil, those which remain above ground bearing little or no fruit. Hence in the cultivation of the plant, the main point to be attended to is to cover up with earth all the flower-bearing stems as soon as the flowers fade. The seeds contain about half their weight of fat oil, *earth-nut oil* (*huile d'arachide, huile de pistache de terre, Erdnuss-öl*), which is extracted from them by pressure. The cold-pressed oil is nearly colourless, has a faint agreeable odour, and may be used for culinary purposes instead of olive oil, only it becomes rancid more quickly. The warm-pressed oil is coloured, and has a disagreeable taste and smell. The cold-pressed oil has a density of 0·916 at 50° C.; and solidifies at − 3° C. When it is exposed for some time to a temperature of + 3°C. a solid fat resembling stearin separates from it. It dissolves but sparingly in alcohol, more readily in ether and essential oils. It saponifies slowly when boiled with caustic soda, yielding a hard, white, odourless soap, which is manufactured in France, and to some extent also in Germany. This soap, when decomposed by the stronger acids, yields two peculiar fat-acids, viz. arachidic acid, $C^{20}H^{40}O^2$, belonging to the series $C^nH^{2n}O^2$, and hypogæic acid, $C^{16}H^{30}O^2$, belonging to the oleic acid series, $C^nH^{2n-2}O^2$ besides a large quantity of palmitic acid. The oil consists therefore of arachin, hypogæin, and palmitin.

ARACHYL. $C^{20}H^{39}O$.—The hypothetical radicle of arachidic acid.

ARÆOMETER. See HYDROMETER.

ARÆOXENE (from ἀραιος, rare and ξένος, guest).—A variety of vanadate of lead, in which a considerable portion of the lead is replaced by zinc, giving the formula $VO^4(Pb;Zn)^3$. Von Kobell found 48·7 per cent. oxide of lead, and 16·3 per cent. oxide of zinc. The mineral, which was formerly mistaken for chromate of lead, is found in clefts of a bed of sandstone, at Dahn in the Rheinpfalz. It forms botryoïdal crystalline masses, exhibiting on the fracture traces of radiating structure. Colour, dark red, inclining to brown; slightly translucent. Streak, light yellow. Hardness 3. Melts quickly before the blowpipe, with intumescence. The powder is easily decomposed by heating with hydrochloric acid. (See Kobell, J. pr. Chem. ii. 496.)

ARBOL-A-BREA RESIN. This resin is the produce of the *Canarium album*, a tree belonging to the natural order *Terebinthaceæ*, which grows in the Phillipine Islands; the resin, which is used by the natives for caulking their canoes, is greyish yellow, soft, glutinous, and has a strong agreeable odour. According to Bonastre (J. Pharm. x. 199) it contains in 100 pts. 61·29 pts. of resin, very soluble in alcohol; 25·00 of resin, sparingly soluble in alcohol; 6·25 essential oil; 0·52 free acid; 0·52 bitter extractive matter; 6·42 woody and earthy impurities. Baup (Ann. Ch. Phys. [3] xxxi. 108) has obtained from it four different crystallisable substances, viz.—

Amyrin.—Insoluble in water, sparingly soluble in cold, easily in hot alcohol, easily also in ether, whence it crystallises in satiny fibres, having a strong lustre. Melts at 174° C. Contains, according to Dumas, 85·3 per cent. carbon and 11·7 hydrogen, and is perhaps identical with crystallised elemi-resin.

Breïdin.—Crystallises in transparent rhomboïdal prisms of 102° and 78°, terminated by four sided pyramids. Dissolves in 260 pts. of water at 10° C. much more abundantly in hot water; easily in alcohol, sparingly in ether,. The crystals become opaque at a gentle heat, melt at a temperature a little above that of boiling water, and sublime undecomposed at a higher temperature, yielding a slightly pungent vapour which excites coughing.

Breïn.—Insoluble in water, soluble in 70 pts. of 85 per cent. alcohol at 20° C.; more soluble in absolute alcohol; very soluble in ether. When slowly crystallised from an alcoholic solution, it forms transparent rhomboïdal prisms of about 70° and 110°, terminated by dihedral summits whose faces meet at about 80°. By rapid cooling acicular crystals are formed. Melts at 187° C. Neutral.

Bryoïdin.—Crystallises from water in white silky filaments. Has a slightly bitter and burning taste, and when heated gives off a vapour which excites coughing. Melts at 135° C., begins to volatilise before melting, and sublimes in colourless needles. Sparingly soluble in cold, much more in hot water, very easily in alcohol and ether. The aqueous solution is neutral to test-paper, but precipitates acetate and subacetate of lead.

ARBOR DIANÆ, ARBOR MARTIS, ARBOR SATURNI, &c. These names are applied to the arborescent metallic precipitates formed by the slow reduction of one metal in solution by another, *e.g.* lead by zinc.

ARBUTIN. A crystalline substance discovered by Kawalier (Ann. Ch. Pharm. lxxxi. 241; lxxxiv. 356) in the leaves of the red bear-berry (*Arctostaphylos Uva Ursi*). The aqueous infusion of the leaves forms with neutral acetate of lead a yellow precipitate containing gallic acid; the filtered liquid freed from excess of lead by hydrosulphuric acid, and then concentrated to the consistence of a syrup, deposits crystals of arbutin, which may be purified by pressure, solution in boiling water, and treatment with animal charcoal. Arbutin forms groups of colourless bitter crystals, which are soluble in water, alcohol, and ether; the solutions are neutral to test-paper.

When heated it melts and gives off water of crytallisation. Its aqueous solution does not form any precipitate with ferric salts, or with acetate or subacetate of lead.

A solution of arbutin mixed with emulsin (extracted from sweet-almonds), and left for some days in a warm place, acquires a reddish tint, and leaves when evaporated over the water-bath, a reddish brown residue, from which ether extracts arctuvin, and leaves a quantity of insoluble saccharine matters. This decomposition of arbutin is represented, according to Kawalier, by the equation:

$$\underset{\text{Arbutin.}}{C^{32}H^{44}O^{19}} = \underset{\text{Arctuvin.}}{C^{20}H^{20}O^{7}} + \underset{\text{Glucose.}}{C^{12}H^{24}O^{12}}$$

but according to Gerhardt, by the equation

$$\underset{\text{Arbutin.}}{C^{18}H^{22}O^{10}} = \underset{\text{Arctuvin.}}{C^{12}H^{10}O^{4}} + \underset{\text{Glucose.}}{C^{6}H^{12}O^{6}}$$

Kawalier's analysis of arbutin gives 52·4 per cent. carbon, and 6·1 hydrogen. His formula requires 52·4 C and 6·0 H; Gerhardt's, 54·2 C and 5·5 H. (Gerhardt, Traité, iv. 266.)

ARCANITE. See GLASERITE.

ARCHIL, ORCHIL, or **ORSEILLE.** A fine purple dye obtained from various species of lichen. There are two varieties, called in France *orseille de mer* and *orseille de terre.* The former is obtained from various lichens of the genus *Rocella* growing on the rocky coasts of the Azores, the Canary and Cape de Verd isles, also of the Cape of Good Hope, Madeira, Corsica, Sardinia, &c.; the latter from *Variolaria orcina*, from Auvergne, *Variolaria dealbata*, from the Pyrenees, *Lecanora tartarea*, from Sweden, and others. None of these lichens contain the colouring matter ready formed, but they contain certain colourless acids, *erythric, lecanoric acid*, &c., which are susceptible of transformation into a colourless neutral body called *orcin* (*q.v.*); and this, when acted upon by the air and by ammonia, changes into a purple substance called *orcein*, which is the colouring principle of archil.

To prepare archil, the lichens, after being ground between stones, are rubbed up to a thin paste with water and putrefied urine or carbonate of ammonium, and left to ferment, with addition of quick lime, a small quantity of alum or arsenious acid being sometimes added, perhaps, to prevent the fermentation from going too far. In a week, a violet colour is obtained, which becomes brighter in a few days longer. When carbonate of potassium or sodium is added to the lichens as well as ammonia, a different change takes place, and a blue colouring matter called *Litmus* is obtained, which is never produced by the action of ammonia alone. (See LITMUS.)

Dyers rarely employ archil by itself, on account of its dearness, and the perishableness of its beauty. The chief use they make of it is for giving a bloom to other colours, as pinks, &c. This is effected by passing the dyed cloth or silk through hot water slightly impregnated with the archil. The bloom thus communicated soon decays upon exposure to the air. The addition of a little solution of tin gives a durable dye, the colour of the archil being at the same time changed toward a scarlet, and becoming more permanent in proportion as it recedes the more from the natural tint.

Prepared archil very readily gives out its colour to water and to alcohol; it is the substance principally made use of for colouring the spirits of thermometers. As exposure to the air destroys its colour upon cloth, so does the exclusion of the air produce a like effect in these hermetically sealed tubes, the spirits of large thermometers becoming in a few years colourless. The Abbé Nollet observes (in the Memoirs of the Académie des Sciences for the year 1742) that the colourless spirit, upon breaking the tube, soon resumes its colour, and this for a number of times successively; that a watery tincture of archil, included in the tubes of thermometers, lost its colour in three days; and that in an open deep vessel it became colourless at the bottom, while the upper retained its colour.

A solution of archil in water, applied on cold marble, stains it of a beautiful violet or purplish-blue colour, far more durable than the colour which it communicates to other bodies. M. du Fay says he has seen pieces of marble stained with it, which in two years had suffered no sensible change. It sinks deep into the marble, sometimes above an inch, and at the same time spreads upon the surface, unless the edges be bounded by wax or some similar substance. It seems to make the marble somewhat more brittle.

There is a considerable consumption of a variety of archil manufactured in Glasgow. It is much esteemed, and sold by the name of *cudbear.* It affords very beautiful colours on silks, of various shades, from pink and crimson to a bright mazarine blue, which are said to be very permanent.—U. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 175.)

ARCTIZITE. See Wernerite.

ARCTOSTAPHYLOS UVA URSI. The *bear-berry.*—An ericaceous plant which grows wild in the mountainous parts of England and Scotland, and in the north of Europe. It possesses strongly astringent properties. The leaves boiled with water yield a liquid which contains tannic acid and a large quantity of gallic acid, and may therefore be used for making ink. The same decoction contains, according to Kawalier, (Ann. Ch. Pharm. lxxx. 356) arbutin, sugar, ericolin, a resinous substance, wax, fat, chlorophyll, vegetable fibre, and a body resembling emulsin, which has the power of inducing the transformation of arbutin. The resin may be separated from the mother-liquor of the preparation of arbutin, by heating it with hydrochloric acid. It is brittle, nearly black, dark brown after trituration, and is said to consist of $C^{20}H^{17}O^{\frac{15}{2}}$, perhaps rather $C^{20}H^{17}O^{8}$. Besides these substances, H. Trommsdorff (Chem. Gaz. 1853, p. 61) also found in the leaves another crystallisable substance which could be extracted by ether, viz. *ursone.*

ARCTUVIN is deposited by evaporating the ethereal solution of the brown residue obtained by the decomposition of arbutin (p. 354), in colourless crystals, which are purified by recrystallisation from water, alcohol, and ether, with the aid of animal charcoal. It forms long prisms, which are bitter, fusible, and may be sublimed when cautiously heated. It contains, according to Kawalier's analysis, 64·4 C and 5·6 H. The formula $C^{20}H^{20}O^{7}$ requires 64·5 C and 5·4 H. Gerhardt's formula, $C^{12}H^{12}O^{4}$, requires 65·4 C and 5·4 H. If sesquichloride of iron be added, drop by drop, to an aqueous solution of arctuvin, the mixture assumes a bluish tint, gradually changing to green. With a solution of subacetate of lead containing a little ammonia, arctuvin forms a white precipitate, which soon turns brown. Arctuvin moistened with ammonia and exposed to the air gradually forms a black substance, which Kawalier calls *arctuvein;* it contains 35·9 C, 3·0 H, 12·5 N, and 48·6 O. (Gerhardt, Traité iv. 266.)

ARECA NUTS, the fruit of the areca palm (*Areca catechu, L.*), contain, as their chief constituents, catechu, a variety of tannic acid, and gallic acid, together with acetate of ammonium, fats, oil, gum, nitrogenous substances, and a dye called *areca-red*, which is of a brown colour, without taste or smell, insoluble in cold water and in ether, soluble in boiling water and alkaline liquids, whence it may be precipitated by acids. Boiled with nitric acid, it yields oxalic acid. (Morin, J. Pharm. viii. 449.)

ARENDALITE. See Epidote.

ARETHASE, a name given by Laurent to a product of the decomposition of chloride of cacodyl by alcoholic potash. (See Arsenic-radicles, Organic.)

ARFWEDSONITE. A ferruginous variety of hornblende. Colour black. Cleavage-faces much more brilliant than those of hornblende, which scratches it. Specific gravity 3·44. Melts even in the flame of a candle; boils up strongly before the blowpipe, and yields a black magnetic globule. Not soluble in acids or in caustic potash. Its composition may be represented by the general formula $Si^{6}M^{10}O^{17} = 5M^{2}O.6SiO^{2}$. A specimen from Greenland, analysed by Kobell (J. pr. Chem. xiii. 3) yielded results agreeing nearly with the formula $(15Fe^{2}O.4Na^{2}O.Ca^{2}O).24SiO^{2}$.

ARGAL or **ARGOL.** The commercial name of crude tartar in the state in which it is taken from the inside of wine-casks.

ARGENTAN. Syn. of Nickel-silver or German silver. See Nickel.

ARGENTAMMONIUM. A metallic ammonium-radicle (p. 198), containing 1 at. silver in place of hydrogen. Its oxide $(NH^{3}Ag)^{2}O$ is commonly called *fulminating silver.* (See Silver.)

ARGENTINE. A schiefer-spar mixed with silica, found at Southampton and Williamsburgh, in Massachusetts. (See Calcspar.)

ARGENTINE FLOWERS OF ANTIMONY. An old name of tetroxide of antimony, or antimonate of antimony (p. 324).

ARGENTITE or **ARGYROSE.** Syn. of Silver-glance.

ARGILLACEOUS EARTH. See Alumina and Clay.

ARGYRITES. See Lead-oxide. — **ARGYROSE.** See Silver-glance.

ARICINE. $C^{23}H^{26}N^2O^4$ (*Cinchovatine, Cusconine, Quinovine*).—An alkaloid, discovered in white cinchona bark from Arica, by Pelletier and Corriol (J. Pharm. [2] xv. 575). Manzini (J. Pharm. [3] ii. 95) afterwards, found in a fibrous white cinchona from Jaen, an alkaloid which he called *cinchovatine*, but which has been shown by Winckler (Buchner's Répert. d. Pharm. [2] xxxi. 294; xlii. 25 and 231; *ibid.* [3] i. 11) to be identical with aricine.

Aricine is extracted from the cinchona bark in the same manner as quinine (*q. v.*), viz. by boiling the bark with acidulated water, treating the liquor with lime, and digesting the lime-precipitate in alcohol. The solution, filtered at the boiling heat, yields a very dark-coloured liquid, which, after a while, deposits the greater part of the aricine in crystals. An additional quantity may be obtained from the mother-liquor by expelling the alcohol by distillation, treating the residue with a slight excess of hydrochloric acid, separating the greater part of the colouring matter by means of a saturated solution of common salt, then precipitating the aricine by ammonia, dissolving the precipitate in alcohol, decolorising with animal charcoal, and crystallising.

Aricine forms white prismatic crystals, more elongated than those of cinchonine; they are inodorous, and have a bitter taste, which, however, does not show itself for some time, on account of the sparing solubility of the alkaloid. It dissolves easily in alcohol, especially when warm, less readily in ether. The solution blues reddened litmus, and turns syrup of violets green. The crystals, which are anhydrous, melt at 188° C., forming a brownish liquid, which blackens at a higher temperature, yielding fetid empyreumatic products. Aricine dissolves with decomposition in strong nitric acid, forming a deep green solution: this is a very characteristic reaction.

The *salts of aricine* are, for the most part, easily soluble and crystallisable. They are obtained by dissolving aricine in dilute acids; the solutions are precipitated by alkalis. The *acid sulphate*, $C^{23}H^{26}N^2O^4.SO^4H^2$, crystallises in flattened needles (Pelletier), which are anhydrous (Manzini). The *neutral sulphate* does not crystallise from solution in water, but forms a gelatinous mass, which dries up to a horny substance (Pelletier, Ann. Ch. Phys. [2] li. 185). The *platinum-salt*, $C^{23}H^{26}N^2O^4.HCl.PtCl^2$, is soluble in alcohol, and is deposited from the solution by spontaneous evaporation in crystalline plates.

ARISTOLOCHIA CLEMATITIS. *Birthwort.*—The root of this plant, which has a sharp bitter taste, and was formerly much used in medicine, has been examined by several chemists: but the results hitherto obtained are not very definite. When distilled with water, it yields about 0·004 of an essential oil of specific gravity 0·903, and said by Walz to be composed of $C^{11}H^8O^3$. A volatile acid, *aristolochic acid* also passes over, the barium-salt of which contains, according to Walz, $C^9H^6Ba^2O^9$. From the aqueous extract of the root, Walz obtained an impure bitter compound, *clematidine*, $C^9H^5O^6$, which is perhaps identical with the aristolochine obtained by Chevalier from *Aristolochia serpentaria*. Frickinger obtained from the root a bitter uncrystallisable body, and also a yellow crystalline substance, *aristolochia-yellow*, perhaps identical with aristolochine or clematidine. The root also contains a resin soluble in alcohol and ether. The inorganic constituents of the root are: potash 10·3, soda 4·2, chloride of sodium 8·6, lime 9·1, magnesia 3·0, phosphoric acid (PO^5) 14·2, sulphuric acid (SO^3) 1·4, sesquioxide of iron 3·1, silica 4·5, sand, charcoal, and carbonic acid 4·35. (Winckler, Jahrb. pr. Pharm. xix. 71; Frickinger, Buchn. Répert. [3] vii. 1; Walz, Jahrb. pr. Pharm. xxiv. 65; xxvi. 65.)

ARISTOLOCHIA SERPENTARIA. The root of this plant, which had once a great repute in medicine, is now nearly fallen into disuse. Chevalier states that the active principle of it is a yellow bitter substance, which he calls *aristolochine*. The root also contains an essential oil, resins, gum, &c.

ARKANSITE. See Brookite.

ARKI. See Arsa.

ARKOSE. A felspathic sandstone, often having a porphyritic structure, found near Poivin in the Vosges. According to Delesse (Arch. d. Sc. Phys. et Nat. de Genève vii. 177) it has been metamorphosed in the humid way, by taking up the constituents of felspar and hyalite, and gradually transformed into the Vosges sandstone above and granite below.

ARMENIAN STONE. *Lapis Armenius, Armenite.*—An old name for a mixture of earthy azure copper and limestone, sometimes mixed with copper or iron pyrites; or for quartz coloured blue by azure copper.

ARNICA, OIL OF. Both the roots and the flowers of *Arnica montana* contain volatile oils. The oil is obtained from the flowers has a yellow to brownish green colour, dissolves in 100 pts. of alcohol, of specific gravity 0·85, becoming turbid and flocculent, and in 10 to 60 pts. of absolute alcohol, and forms a solid resin when treated with nitric acid. The oil from the roots has a specific gravity of 0·98 to 0·99, and a wine-yellow to brownish yellow colour; dissolves in 2 pts. of alcohol of specific gravity 0·85, and in all proportions of absolute alcohol, and becomes viscid when treated with nitric acid. Both oils have a slight acid reaction. (Zeller, "Studien über ätherische Oele," Landau, 1850.)

ARNICINE. A bitter principle in the flowers of the *Arnica montana.*

ARPIDELITE. See SPHENE.

ARQUERITE. A silver amalgam from the mines of Arqueros in Coquimbo, Chili.

ARRACK. A spirit obtained by fermenting infusion of rice. In Ceylon it is obtained from cocoa-nut toddy (palm wine).

ARRAGONITE. *Rhombic Carbonate of Lime.*—This mineral, which derives its name from the locality where it was first found, viz. in Arragon, occurs sometimes in regular crystals, sometimes in fibrous or radiated crystalline masses, sometimes as a deposit or sinter from hot calcareous springs.

The crystals belong to the trimetric, rhombic, or right prismatic system, and are derived from a right rhombic prism with angles of 116° 16′ and 63° 44′, exhibiting two directions of distinct cleavage parallel to the faces of this prism. Twin-crystals also frequently occur, likewise globular, reniform, and botryoïdal masses, sometimes columnar, composed of straight or divergent fibres.

The crystals of arragonite are seldom colourless, mostly exhibiting a variety of colours; yellowish, greenish, reddish, brown, grey, &c. They have a vitreous lustre, and the powder exhibits phosphorescence on a plate of hot iron. Specific gravity in the pulverulent state, and when free from air, from 2·92 to 3·8; larger masses have occasionally a specific gravity as low as 2·77. Hardness about from 3·5 to 4.

Crystals of arragonite are found in various localities; in clay and gypsum in Arragon; in clefts and cavities of the newer volcanic rocks, especially of basalt, as at Bilin in Bohemia, in Hungary, Scotland, the Feroe Isles, &c.; also in the dolerite on the Kaiserstuhl in the Breisgau; in gneiss and syonite near Dresden and in North America; in the lava of Etna and Vesuvius, &c. *Radiated arragonite*, which forms crude masses having a radiated structure, is found chiefly on the Kaiserstuhl in the Breisgau, at Gergovie in Auvergne, and in Scotland. *Fibrous arragonite, iron-bloom,* or *flos ferri*, occurs in globular, kidney-shaped or stalactitic mass, having a fibrous or laminar texture, and a mother-of-pearl lustre. It is found in veins of iron ore in Carinthia and Styria, Hungary and Transylvania. *Sprudelstein*, a fibrous variety of carbonate of calcium deposited from hot calcareous springs, contains both arragonite and calcspar. *Mountain milk, Rock milk* (*Bergmilch, Chaux carbonatée pulvérulente*), is, according to H. Rose, arragonite mixed with chalk; it occurs in thick, spongy, globular, or kidney-shaped masses, or as a deposit in limestone cavities in Wurtemberg, Switzerland, Bohemia, and other localities. Specific gravity 2·72 to 2·82. It contains traces of organic matter, and leaves a small quantity of charcoal when ignited in a close vessel. *Friable aphrite* (*Schaumkalk, Schaumerde*) was formerly supposed to be a variety of calcspar, but has been shown by Gustav Rose to be arragonite, pseudo-morphosed in the form of gypsum. It occurs sometimes in the form of gypsum-crystals, sometimes as a crystalline or laminar, white or yellowish-white mass. The crystals exhibit a strong nacreous lustre on the cleavage-faces. Its specific gravity, after thorough boiling with water to free it from air, is 2·98. *Alm* or *albene* is a mineral resembling mountain-milk, extensive formations of which are found in Southern Bavaria, where indeed it forms a subsoil many feet in thickness. *Osteocolla* (*Beinbruchstein*) is a carbonate of calcium mixed with sand and organic remains, which collects round decaying roots, and takes their peculiar forms; it is found in the neighbourhood of Berlin. Its specific gravity is 2·82. It exhibits, under the microscope, the form of arragonite mixed with granular masses.

Arragonite consists of carbonate of calcium, CO^3Ca^2, or $CaO.CO^2$, sometimes pure, sometimes mixed with small quantities of the isomorphous compound, carbonate of strontium, which, in the arragonite of Molina, amounts to 4 per cent.; small quantities of the carbonates of magnesium, manganese, iron, &c., are also occasionally found in it. A peculiar variety called *tarnowitzite*, from Tarnowitz in Upper Silesia, contains 3·86 per cent. of carbonate of lead. The chemical properties of arragonite are essentially the same as those of carbonate of calcium in its other forms; dilute acids, however, act upon it less quickly than on calcspar, so that when a mixture of calcspar and arragonite is immersed in a very dilute acid, a residue of arragonite is obtained after a while.

Carbonate of calcium, in its two forms of calcspar (rhombohedral), and arragonite (rhombic or right prismatic), exhibits one of the most striking examples of dimorphism, that is to say, of the same chemical compound crystallising in two forms belonging to different systems (see DIMORPHISM). Formerly, when the existence of dimorphism was unknown, the deviation of arragonite from the more ordinary form of carbonate of calcium was attributed to the presence of carbonate of strontium, which always crystallises in the rhombic system. It was found, however that this mineral was present in arragonite, often in extremely minute quantities, or indeed absent altogether, the form still remaining the same; and thus the fact of the dimorphism of carbonate of calcium became apparent.

Arragonite and calcspar exhibit many differences in their physical properties. Arragonite has two axes of double refraction; calcspar only one. Arragonite has less specific heat (0·1966) than calcspar, greater hardness and greater density. Large crystals of arragonite frequently decrepitate when heated, then swell up suddenly and fall to powder; smaller pieces, or fibrous arragonite, become turbid and rotten. The mineral after this change is found to have the density of calcspar; indeed the change appears to consist in the passage of the arragonite to the form of calspar. This action may explain the pseudomorphoses of calcspar in the form of arragonite. Mitscherlich describes a crystal of arragonite from Vesuvius, which had been converted into calcspar on the outside by the action of the red-hot lava, while its interior still retained the structure of arragonite.

The circumstances which have determined the crystallisation of carbonate of calcium in one form or the other are not precisely known; it appears, however, to assume by preference the form of arragonite, when it crystallises from hot solutions. According to H. Rose (Pogg. Ann. xlii. 363), the precipitate formed on mixing the boiling solutions of chloride of calcium and carbonate of ammonium, consists of microscopic crystals of arragonite, which, however, change into rhombohedrons of calcspar if left for some time under the cold liquid.

The occurrence of arragonite in the deposits of hot calcareous springs points to the same conclusion. The concentration of the liquid appears also to exert some influence. According to Becquerel (Compt. rend. xxxiv. 29 and 573), when gypsum is immersed at ordinary temperatures in a concentrated solution of acid carbonate of sodium, carbonate of calcium is deposited in the form of arragonite, but if the solution of the acid carbonate of sodium is dilute, the deposit takes the form of calcspar. On the whole it would appear that the tendency to the assumption of the arragonite form increases with the rapidity of the crystallisation.

ARROW-ROOT. The starch of the *Maranta arundinacea*, a plant belonging to the order *Marantaceæ*, and cultivated both in the East and West Indies. According to Benzon, the root has the following composition: — Starch 26·00 per cent.; woody fibre 6·00; albumin 1·53; chloride of calcium 0·25; water 65·60 per cent. In the island of St. Vincent, the skinned tubers are washed and ground in a mill, and the pulp is washed in cylinders of tinned copper with perforated bottoms. To obtain the fecula free from impurity, great care must be used in every step of the process. Palette knives of german silver are used for skinning the deposited fecula, and even shovels of the same material for packing it. The drying is effected in pans, covered by white gauze to exclude dust and insects.

The term arrow-root is applied generically to indicate a starch or fecula; thus Portland arrow-root is obtained from *Arum maculatum;* East India arrow-root, from *Curcuma angustifolia;* Brazilian, from *Iatropha manihot;* Tahiti arrow-root, from *Tacca oceanica;* English, from the potato.

Arrow-root, like the rest of the starches, contains $C^{12}H^{20}O^{10}$. The cheaper feculas are sometimes substituted for genuine arrow-root; but they are readily detected by the microscope. Arrow-root is one of the most palateable and digestible of the starches. The expressed juice of the plant has been used as an antidote to poisons and to the bites and stings of venomous insects. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 182.)

ARSA. An alcoholic liquor, procured by the Tartars from fermented mare's milk (Kumis). In the weak state it is called *araca;* after rectification, *arsa.*

ARSENIC. (*Arsen, Scherbenkobalt, Fliegengift, Näpchenkobalt, Arsenicum, Regulus Arsenici*, the ἀρσενικὸν of Dioscorides.) *Symbol*, As. *Atomic weight*, 75. *Vapour-density*, 150 (hydrogen = 1); *Atomic volume*, ½.

History.—This element has been known from very early times, chiefly as sulphide and arsenious acid. The first accurate investigation of its chemical nature was made by Brandt in 1733. Scheele, in 1755, discovered arsenic acid and arsenetted hydrogen gas. Sir H. Davy discovered the solid arsenide of hydrogen. The stoïchiometrical relations of arsenic and its numerous sulphur-compounds, were specially investigated by Berzelius. Bunsen in 1842 discovered cacodyl, an organic radicle containing arsenic and methyl, and several other organic arsenic-radicles have since been discovered by Landolt and others.

Occurrence.—Arsenic is found native, but much more frequently associated with other metals and with sulphur. The ores from which it is prepared on the large scale, as a principal product, in the form of metallic arsenic or arsenious oxide, are: *native arsenic*, As; *arsenical iron*, two species, FeAs, and $Fe^4.As^3$; and arsenical pyrites, $FeAs + FeS^2$. Metallic arsenic and arsenious oxide are likewise obtained as secondary products from *smaltine*, *cloanthite*, *arsenical cobalt*, *cobalt-glance*, *nickel-glance*, *copper-nickel*, *arsenical nickel*, *arsenical fahl-ores*, and other ores of similar character.

These arsenical ores are found more or less abundantly in various parts of the world, but chiefly in the mining districts of Germany and in the Spanish province of Catalonia. In small quantities, arsenic is very widely diffused, being found in the ferruginous deposits of mineral waters (Will, Ann. Ch. Pharm. lxi. 192); in nearly all iron ores (Walchner, *ibid.* 209); in the various kinds of pyrites, and in native sulphur. Hence also it is almost always found in sulphuric acid, and in numerous chemical and pharmaceutical products, in the preparation of which sulphuric acid is used. In short, arsenic in small quantities is one of the most widely diffused substances in nature. It was said by Orfila (J. Chim. méd. xv. 462, 632) to exist also in the bones and muscles of men and animals in a state of health; but the experiments of other chemists have shown this statement to be erroneous.

Preparation.—Metallic arsenic is obtained on the large scale by heating native arsenide of iron, FeAs or Fe^4As^3, or arsenical pyrites, Fe^2AsS, in earthen tubes or retorts: the whole of the arsenic then sublimes, and iron or protosulphide of iron (Fe^2S) remains behind. The retorts are laid horizontally in a long furnace, a tube made by rolling up a piece of thin iron plate, is inserted into their mouths, and an earthen receiver luted on. The arsenic condenses chiefly in the iron tube, in the form of a coherent internally crystalline mass, and when the tube has cooled, is detached by unrolling it. The arsenic thus obtained is purified, if necessary, by a second sublimation. The metal is also prepared by heating arsenious oxide with charcoal in earthen crucibles, surmounted by inverted crucibles, or by conical iron caps. This is the process adopted at Altenberg, in Silesia. It is more productive and economical than the former, but the metal which it yields is grey and pulverulent, whereas the former is compact and nearly white. Arsenic may also be obtained from its sulphides, by heating those compounds with a mixture of charcoal and an alkaline carbonate or cyanide of potassium. (Kerle's Hüttenkunde, iii. 4.)

Properties.—Arsenic is a very brittle metal, of a steel-grey colour. Its specific gravity in the solid state is, according to different observers, between 5·62 and 5·96. Vapour-density = 10·3995 (air = 1), or 150 (hydrogen = 1), which is double the atomic weight; hence the atomic volume of arsenic vapour is anomalous, being only half that of hydrogen. (See ATOMIC VOLUME.) Arsenic crystallises in rhombohedrons, isomorphous with tellurium and antimony. It volatilises at a dull red heat, without previous fusion, emitting a characteristic disagreeable odour resembling that of garlic. Its physical properties vary considerably with the manner in which it is sublimed. When very strongly heated, or when it condenses on a part of the subliming apparatus, the temperature of which is but little below that at which arsenic volatilises, so that the metal is deposited in an atmosphere of its own vapour, it condenses in a compact, nearly white mass, having a strong metallic lustre. This compact arsenic scarcely oxidises in the air, even when pulverised and exposed to a temperature of 80° C. Such is the condition of the metal obtained by heating arsenical pyrites. When, on the contrary, the arsenic, as it passes into the gaseous form, becomes mixed with other gases (as when it is reduced from arsenious acid by charcoal), or when it is deposited on the colder parts of the subliming apparatus, it solidifies in a dark grey crystalline powder, less dense than the preceding, and oxidising readily in the air, especially when heated.

Native arsenic forms botryoïdal, kidney-shaped, spherical, and conchoïdal masses, varying in texture from fine-grained to compact; less frequently, indistinct rhombohedral crystals. In the recent state, it has a light lead-grey colour, but soon becomes greyish-black by exposure to the air. In its chemical properties, it resembles artificially prepared arsenic. It is found in various localities of the Saxon and Bohemian mining districts, at Andreasberg in the Harz, at Kapnik in Transylvania, Kongsberg in Norway, and several places in the United States of America.

Arsenic forms two principal series of compounds, analogous to those of antimony and phosphorus, viz. the arsenious compounds in which it is triatomic, *e.g.* $\overset{'''}{As}H^3$, $\overset{'''}{As}Cl^3$, $(\overset{'''}{As})^2O^3$, $(\overset{'''}{As})^2S^3$, &c., and the arsenic compounds in which it is pentatomic, *e.g.* $(\overset{v}{As})^2O^5$, $(\overset{v}{As})^2S^5$, &c. Besides these, there are a few compounds into which it enters in other proportions, *e.g.* the sulphide AsS, and several alloys.

Many compounds of arsenic are isomorphous with the corresponding compounds of phosphorus and antimony, *e. g. rhombic* arsenious oxide is isomorphous with native trioxide of antimony: the salts of arsenic acid are isomorphous with the corresponding phosphates.

Detection and Estimation of Arsenic.

I. *Reactions in the dry way.*—Metallic arsenic, heated with but slight access of air, as in a narrow test-tube, is converted into a vapour having the peculiar alliaceous odour already mentioned, and condenses on the cold part of the tube in a shining, brownish-black, metallic, ring. With greater access of air, as when a small quantity of the metal is heated in a wide test-tube, or in a tube open at both ends and held over a lamp in a slanting position, the arsenic is converted into arsenious oxide, which condenses on the cold part of the tube in a white crystalline ring, soluble in boiling water.

The oxides of arsenic heated with charcoal or other deoxidising substances, are reduced to the metallic state, the metallic arsenic thus liberated exhibiting the characters just mentioned. If a small quantity of arsenious oxide be placed on charcoal, and the point of the blowpipe flame directed upon it, a greyish-white smoke is immediately evolved, accompanied by a powerful alliaceous odour; and if the arsenious oxide be mixed with perfectly dry and coarsely pounded charcoal, and heated to redness at the bottom of a small test-tube, a ring of metallic arsenic will be deposited on the cold part of the tube.

The sulphides of arsenic, and the salts of arsenious and arsenic acid, are not easily reduced by ignition with charcoal alone, but when heated with carbonate of potassium or sodium, or with a mixture of an alkaline carbonate and charcoal, or cyanide of potassium, they yield metallic arsenic with its characteristic properties.

II. *Reactions in the wet way.* a. Of *Arsenious Compounds.*—*Hydrosulphuric acid gas* passed into an aqueous solution of arsenious acid, colours it yellow, and on addition of hydrochloric acid, throws down the whole of the arsenic in the form of bright yellow trisulphide. The precipitate is said to be perceptible in a solution containing not more than 1 pt. of arsenious acid in 160,000 pts. of water. The precipitate dissolves easily in ammonia, carbonate of ammonium, and sulphide of ammonium, and is reprecipitated without alteration by hydrochloric acid. It is likewise soluble in a considerable quantity of boiling water, and in boiling dilute hydrochloric acid, with liberation of hydrosulphuric acid gas. (Odling, Guy's Hospital Reports [3] i. 239.)

Nitrate of silver added to aqueous arsenious acid produces a scarcely appreciable yellow turbidity, and on cautiously adding ammonia, a canary-yellow precipitate of arsenite of silver, which dissolves with great facility in nitric acid, acetic acid, and excess of ammonia. Hence, if the quantity of arsenic present is but small, it is difficult to avoid adding too much ammonia, and thus preventing altogether the formation of the precipitate. This inconvenience may however be obviated by using a solution of *nitrate of argentammonium*, commonly called *ammonio-nitrate of silver*, prepared by treating a solution of nitrate of silver with a quantity of ammonia sufficient to redissolve only a portion of the precipitated oxide of silver, and filtering. Such a solution contains exactly the proportion of ammonia required to precipitate the arsenious acid as arsenite of silver. If, however, an excess of nitric acid is present, a further quantity of ammonia will be required to neutralise it. In a neutral solution of an arsenite of alkali-metal, nitrate of silver produces an immediate precipitate of arsenite of silver.

With *sulphate of copper*, on addition of ammonia, arsenious acid forms a bright green precipitate of arsenite of copper (Scheele's green), easily soluble in acids and in ammonia. In this case also, it is convenient to use a solution of *sulphate of cuprammonium*, or *ammonio-sulphate of copper*, $SO^4(NH^3Cu)^2$, prepared in the same manner as the ammonio-nitrate of silver.

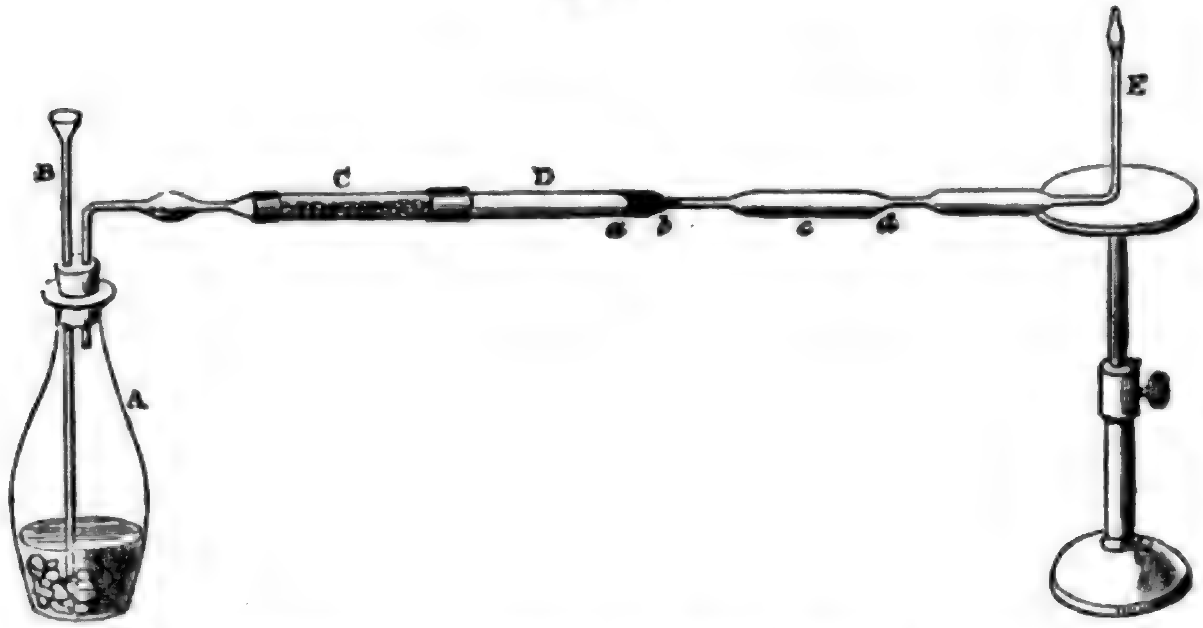
Nitric acid, *hypochlorous* acid, *chromic* acid, and other *oxidising agents*, convert arsenious acid into arsenic acid. With a solution of *trichloride of gold*, it yields arsenic acid, and a black precipitate of metallic gold.

A piece of metallic *copper* immersed in a hot solution of arsenious acid or an arsenite, mixed with hydrochloric acid, becomes covered with a grey film of metallic arsenic, which may be sublimed and converted into arsenious oxide by heating the coated metal in a dry glass tube (Reinsch's test).

Zinc immersed in a solution of arsenious acid or an arsenite acidulated with hydrochloric or sulphuric acid, likewise reduces the arsenic to the metallic state, part of the reduced arsenic being deposited as a black film on the zinc, while the rest unites with the nascent hydrogen and escapes as gas; and from this gas, which burns with a peculiar greyish flame, the arsenic may be separated in the metallic state, either by passing the gas, after drying with chloride of calcium, through a narrow glass tube, one part of which is heated to redness over a lamp, the metal being then deposited in the cold part of the tube beyond the flame; or else by burning the gas at the extremity of the tube drawn out to a fine jet, and holding in the flame, near the orifice, a plate of clean white porcelain. The arsenic is then deposited on the plate in brownish-black, shining metallic films, which may be distinguished from those of antimony formed in like manner (pp. 320, 322), by their solubility in aqueous hypochlorite of sodium, and by other characters to be noticed hereafter.

This reaction, which is known as *Marsh's test*, is extremely delicate, and is therefore much used in searching for minute quantities of arsenic, especially in cases of poisoning. A convenient apparatus for the purpose is that represented in *fig.* 72. A is the generating vessel, provided with a funnel-tube B, for introducing the acid and the solution to be tested. C is a drying-tube containing chloride of calcium; D E the reduction-tube which should be of hard glass, free from lead. It is convenient to have this tube contracted at one or two points, as shown in the figure, and turned up at right angles at the end, so as to form a vertical jet. The first thing to be done is to ascertain whether the zinc and acid are free from arsenic. For this purpose, they must be introduced into the generating vessel, without the solution under examination, and after the evolution of gas has continued long enough to expel atmospheric air, the reduction-tube is to be heated at *a* by a lamp-flame for about a quarter of an hour, and the gas set on fire at the jet E, a piece of white porcelain being held in the flame. If no deposition of arsenic takes place either in the tube or on the porcelain, the liquid to be tested is then to be poured in through the funnel-tube and the heating continued. If arsenic is present, it will be deposited in a shining mirror at *b*, a little beyond the flame. After a sufficient deposit has been obtained at that point, the lamp may be removed to *c*, when a second deposition will take place at *d*, and so on. If the quantity of arsenic is considerable, spots may also be obtained on a plate of porcelain held in the flame at E. The portions of the reduction-tube containing the deposits may then be cut off with a file, sealed, and reserved for further examination. Instead of burning the escaping gas at E, it may be passed, by means of a tube joined to the reduction-tube by a caoutchouc connector, into a solution of nitrate of silver. Metallic silver will then be deposited, and the whole of the arsenic will remain in solution as arsenious acid.

Fig. 72.



A solution of arsenious acid acidulated with hydrochloric or sulphuric acid, is decomposed by the *electric current*, the greater part of the arsenic eliminated at the negative pole being given off in the form of arsenetted hydrogen, which may be examined as above (Bloxam, Chem. Soc. Qu. J. xiii. 14). The apparatus used consists of a two-ounce narrow-mouthed bottle, the bottom of which has been cut off and replaced by a piece of vegetable parchment tightly stretched over it, and secured by a ligature of platinum wire (any ligature of organic nature, even vulcanised caoutchouc, would be quickly destroyed by the ozone evolved at the positive pole). The bottle is furnished with a cork, carrying a small tube bent at right angles, and attached to the reduction-tube by a caoutchouc joint, also a funnel-tube for introducing the liquid to be tested. Through the cork there likewise passes a platinum wire, carrying a plate of the same metal, which forms the negative pole of the voltaic circuit. The bottle is placed within a glass of such a size as to leave a small interval between the two, this glass standing in a vessel of cold water. An ounce of dilute sulphuric acid is introduced into the apparatus, so as to fill the bottle and the outer space to about the same level, the positive plate being immersed in the acid contained in this outer space. The current of a voltaic battery (6 Grove's cells of ordinary size) is then passed through the arrangement, and the shoulder of the reduction-tube is heated to redness for about a quarter of an hour, to ascertain whether any deposit of arsenic is produced from the sulphuric acid itself: if the result be negative, the liquid to be tested is then introduced through the funnel-tube and the heating of the reduction-tube is continued. This method is extremely delicate, even $\frac{1}{1000}$ of a grain of arsenious acid diffused through a considerable quantity of liquid, producing a perceptible deposit in the reduction-tube after 15—30 minutes.

The electrolytic method of eliminating arsenic possesses certain advantages over that of Marsh:—1. It avoids the use of zinc, and thereby obviates a frequent source of error arising from the presence of arsenic in that metal.—2. It introduces no substance into the liquid that can interfere with its subsequent examination for other metals.—3. If any other metals are present, it precipitates them on the surface of the negative plate. Even antimony is for the most part precipitated in this manner. When the reduction is effected by zinc, antimony if present is evolved, together with the arsenic (p. 322), and the subsequent separation of these metals is troublesome; but with the electrolytic method, as above described, only a very small quantity of antimony is evolved as antimonetted hydrogen; and even this quantity may be completely arrested by adding to the liquid a solution of hydrosulphuric acid. Both antimony and arsenic are then converted into sulphides; but the sulphide of arsenic is reduced by the electrolytic hydrogen as easily as arsenious acid (see below), whereas the sulphide of antimony completely resists the action of that agent, and remains in the liquid.

β. Of *Arsenic Compounds.*—A solution of arsenic acid gives with *nitrate of silver*, without addition of ammonia, a red-brown precipitate of arsenate of silver easily soluble in ammonia and in nitric acid. It does not precipitate *sulphate of copper* until ammonia is added, and the precipitate then produced is of a pale bluish-white colour, quite distinct from Scheele's green. With *sulphate of magnesium, ammonia*, and *chloride of ammonium* (the last being added to prevent the precipitation of hydrate of magnesium), arsenic acid forms a white crystalline precipitate of arsenate of magnesium and ammonium, $AsMg^2(NH^4)O^4 + 6H^2O$, similar in appearance and in constitution to the phosphate of magnesium and ammonium. If the solution is very dilute, the precipitate does not appear immediately but is deposited in crystals, after a few hours on the sides of the tube. *Molybdate of ammonium* added in excess to a solution of an arsenate containing free nitric acid, yields, when the liquid is heated, a bright yellow precipitate of arseno-molybdate of ammonium; exactly similar to the phosphomolybdate (see Phosphoric Acid). This precipitate is insoluble in acids, but soluble in ammonia, and in excess of the arsenic solution; hence it is especially adapted for detecting small quantities of arsenic acid, and is indeed one of the most delicate tests for that acid, provided no phosphoric acid is present. With *sesquisalts of iron* and *uranium*, arsenic acid forms yellowish-white precipitates. With *lead-salts*, it forms a white precipitate of arsenate of lead, which when heated on charcoal in the inner blowpipe flame, gives off the odour of arsenic, and yields a button of metallic lead. *Hydrosulphuric acid gas* passed through a solution of arsenic acid colours it yellow at first, and after a long time produces a yellow precipitate of trisulphide of arsenic, mixed with sulphur, the precipitation being accelerated by heat. A solution of a neutral arsenate of alkali-metal, through which hydrosulphuric acid gas is passed, yields the same precipitate on addition of hydrochloric acid. *Sulphurous acid, phosphorous acid*, and other *deoxidising agents* reduce arsenic acid in solution to the state of arsenious acid. Hence in a solution of arsenic acid mixed with sulphurous acid or a soluble acid sulphite, hydrosulphuric acid produces an immediate precipitate of trisulphide of arsenic.

Nascent hydrogen evolved by the action of zinc on dilute sulphuric or hydrochloric acid, converts arsenic acid into arsenetted hydrogen, which is evolved as gas (Scheele, L. Gmelin); but the action is much slower than with arsenious acid. When an *electric current* is passed through a solution of arsenic acid, metallic arsenic is deposited on the negative pole (Gmelin's Handbook, iv.), and arsenetted hydrogen is evolved *provided no chlorides are present* (Bloxam); on adding sulphurous acid, or acid sulphite of sodium to the solution, whereby the arsenic acid is reduced to arsenious acid, the evolution of arsenetted hydrogen is greatly accelerated. The same effect is produced, even with greater certainty on adding aqueous hydrosulphuric acid to the solution. This effect is also chiefly due to the reduction of the arsenic acid to arsenious acid; but even when the hydrosulphuric acid is added in excess, the evolution of the arsenetted hydrogen still takes place, the arsenic uniting with the hydrogen in preference to the sulphur. (Bloxam, Chem. Soc. Qu. J. xiii. 138.)

Compounds insoluble in water, may be examined for arsenic by dissolving them in hydrochloric acid; passing hydrosulphuric acid gas through the solution; digesting the precipitate with sulphide of ammonium, to dissolve out the sulphide of arsenic; and precipitating the sulphide of arsenic by hydrochloric acid. The precipitate may then be dried, and reduced by heating with carbonate of sodium and charcoal, or dissolved in hydrochloric acid, with addition of chlorate of potassium, and the solution, which will contain arsenic acid, tested as above.

The following characters *taken together* are sufficient to distinguish arsenic from all other substances.

1. Formation of a black shining metallic sublimate by one of the methods of reduction above described.

2. Conversion of this metallic deposit into white crystalline arsenious oxide by sublimation in contact with the air.

3. Solution of this sublimate in boiling water, and production of the reactions characteristic of arsenious acid, viz. yellow with hydrosulphuric acid, yellow with ammonio-nitrate of silver, light green with ammonio-sulphate of copper.

4. Solution of the metallic sublimate in hot nitric acid, and production of the reactions characteristic of arsenic acid, viz. red-brown with nitrate of silver, white crystalline with ammonia and magnesium-salts, bright yellow with molybdate of ammonium.

The metal with which arsenic is most likely to be confounded, is antimony, especially when the reduction to the metallic state is effected by Marsh's method, (pp. 320, 322.) The arsenical and antimonial deposits obtained in this manner, may however be distinguished by the following characters:

The arsenic-mirror has a strong lustre, and a black-brown, or brown-black colour; thin films of it formed in a glass tube, appear perfectly translucent, with brown colour, when held before white paper. On account of the volatility of arsenic, the deposit is formed only at a certain distance from the heated portion of the tube, and always on the side *towards* which the stream of gas is directed. The spots formed on porcelain have a black-brown, or when very thin, a brown or light brown colour. The antimony mirror on the contrary is formed in the reduction tube on both sides of the flame and close to it. Where most strongly heated, it has a whiter colour, and when examined by a lens, exhibits small fused metallic globules. It is brownish in thin films, but not continuously brown and shining, like that of arsenic. Antimony-spots formed on porcelain are velvet black, and without lustre, unless very thin; in that case they have an iron-black, or dark plumbago colour, brownish-grey at the edges.

If the part of the reduction-tube containing the arsenic-mirror be cut off, and heated in a *small* lamp flame, the flame exhibits the characteristic greyish colour, and the strong garlic odour of arsenic becomes perceptible. If the pieces of tube covered with arsenic are heated in a narrow test-tube, the characteristic white crystalline sublimate of arsenious oxide is formed, perfectly soluble in boiling water, and exhibiting the characters above-mentioned.

The antimony-deposit does not give off any odour when heated in a lamp-flame, and if heated in a wide test-tube, yields a white shining sublimate of oxide, which is insoluble in water and in ammonia, but dissolves readily in hydrochloric acid, the solution yielding with hydrochloric acid the characteristic red precipitate of antimonious sulphide.

The arsenic-mirror dissolves readily in an alkaline solution *hypochlorite of sodium*, the solution exhibiting the characters of arsenic acid. The antimony-mirror is insoluble in the same liquid, provided it does not contain free chlorine.

Nitric acid of specific gravity 1·2 to 1·3 dissolves the arsenic deposit in the cold, or at a gentle heat, the solution exhibiting the characters of arsenious acid; at a stronger heat, arsenic acid is formed. The same acid likewise dissolves the antimony mirror, but the solution is turbid, gives no precipitate with nitrate of silver and ammonia, orange-yellow, with hydrosulphuric acid.

A very good way to identify arsenic spots is to collect one or more in a watch-glass, add a drop or two of nitro-hydrochloric acid—evaporate quite to dryness, moisten with water, and then add nitrate of silver solution.

Yellow *sulphide of ammonium* dissolves arsenic spots with great difficulty, and never completely; and on evaporating to dryness, there is always left a grey stain of arsenic in the midst of the yellow orpiment. Antimony spots dissolve at once and completely, and the orange-red sulphide of antimony left on evaporation, dissolves completely in hydrochloric acid, being converted into chloride, which volatilises, or leaves only a slight residue of white antimonious oxide.

The arsenic-deposit is easily dissolved in the cold by *hydrochloric acid with addition of chlorate of potassium*, and the solution yields, with magnesium-salts, mixed with ammonia and tartaric acid, the crystalline precipitate characteristic of arsenic acid.

The antimony-deposit similarly treated, dissolves only when heated, and the solution mixed with tartaric acid and ammonia is not precipitated by magnesium-salts.

When arsenetted hydrogen is passed into a solution of *nitrate of silver*, metallic silver is precipitated, and all the arsenic remains in solution as arsenious acid, which may be precipitated by sulphuretted hydrogen, &c.; but when antimonetted hydrogen is passed into nitrate of silver, the whole of the antimony is precipitated in the metallic state, together with the silver, and the solution, after being freed from excess of silver by hydrochloric acid, gives no precipitate with sulphuretted hydrogen.

It often happens that antimony and arsenic are evolved together as gaseous hydrogen-compounds. In that case, the two metals may be separated by the reaction with nitrate of silver just mentioned *; by dissolving the metallic mirror in hydrochloric acid, with addition of chlorate of potassium, then adding tartaric acid and ammonia, and precipitating the arsenic by sulphate of magnesium; or by gently heating the deposit in a very slow stream of dry sulphuretted hydrogen, whereby both are converted into sulphides, and then passing dry hydrochloric acid through the tube. The sulphide of antimony is thereby converted into chloride, which passes on with the stream of gas, and may be received in water and further tested, while the sulphide of arsenic remains unaltered. If the hydrochloric acid gas is not perfectly dry, a small portion of the antimony will be left behind as oxide.

For other methods of separating arsenic and antimony, see page 368.

Detection of Arsenic in cases of Poisoning.—Nearly all compounds of arsenic are poisonous, the most soluble being, generally speaking, those which act with the greatest violence. But arsenious oxide, commonly called *arsenious acid*, being the most generally known and easily procured, is that which is most likely to be met with in cases of poisoning by arsenic, whether accidental or intentional.

As arsenious oxide is but sparingly soluble in water, and is generally administered in the solid state, mixed with viscid articles of food, such as gruel or rice, it sometimes happens that, by careful examination, small lumps of it may be found adhering to culinary vessels, &c., or even to the coatings of the stomach and intestines after death. When this is the case, the arsenic may be picked out and reduced to the metallic state by heating it with charcoal.

If the arsenious oxide is too finely divided to be picked out in this manner, it may sometimes be separated by stirring up the mass several times with water, and leaving the heavier particles to settle. Any solid arsenious acid that may be present will be sure to be found in the residue, and may then be washed with cold water and dried over the water-bath.

The oxide thus separated may be reduced to the metallic state by heating it in a small test-tube with charcoal, as described as page 361. A good way of effecting the reduction, is to place the dried granules or powder at the bottom of a small test-tube, drawn out as shown in *fig.* 73, and place above it a splinter of well-dried charcoal, *a*. The tube is first held in a horizontal position with the part *a* in the flame of a lamp, so as to heat the charcoal to redness; it is then gradually inclined to volatilise the arsenious acid, and cause the vapour to pass over the ignited charcoal. A speculum of metallic arsenic then collects at the shoulder of the tube, and may afterwards be reconverted into arsenious oxide by sublimation in contact with the air, as already described (p. 361).

Fig. 73.

More frequently, however, the arsenic is intimately mixed with large quantities of organic matter, such as articles of food, vomited or evacuated matters, portions of the animal body, as the stomach, liver, &c. In such cases, Reinsch's test (p. 361) may be very conveniently applied. The suspected matter, if liquid, is acidulated with about one-sixth of its bulk of hydrochloric acid and boiled. The solid tissue is cut up into very small pieces and boiled for some time in a mixture of 1 pt. of hydrochloric acid, and 6 parts of water, till the whole is completely disintegrated, and then strained through muslin, or filtered through paper previously wetted. Pieces of copper-gauze or foil are then to be immersed in the boiling liquid, and if any grey deposit is produced, fresh pieces must be added as long as any perceptible alteration of colour takes place on the surface of the metal. They are then to be removed, washed with distilled

---

* The best mode of detecting small quantities of antimony thus precipitated is, after carefully washing out the arsenious acid, to digest the precipitate in aqueous tartaric acid; the antimony then alone dissolves, and may be tested by hydrosulphuric acid. (Hofmann, Chem. Soc. Qu. J. xiii. 79.)

water, and dried between bibulous paper, folded up, introduced into a dry test tube, and heated over a lamp. The arsenic is thereby converted into arsenious oxide, which collects on the cold part of the tube in the form of a crystalline sublimate. It may be dissolved in water and tested with nitrate of silver, &c. Inasmuch as Reinsch's process involves the solution of a minute quantity of copper, the foil or gauze employed should be so far free from arsenic that the solution of four or five grains of it should not yield a trace of the poison.

The arsenic may also be detected by other methods which, however, for the most part require more complete destruction of the organic matter. This may be effected by one of the following processes:

1. The organic matter is mixed with about a fourth of its weight of strong sulphuric acid, and heated till the whole is reduced to a dry friable carbonaceous mass; and this residue, after being pulverised, is treated with nitric acid mixed with a small quantity of hydrochloric acid, in order to bring the arsenic to the state of arsenic acid, which is very soluble in water. The mixture is then evaporated to dryness, and the residue boiled with water and filtered. If the organic matter contains alkaline chlorides, which is frequently the case, care must be taken not to heat it more strongly than is necessary for complete incineration, otherwise a portion of the arsenic may be converted into chloride and lost by volatilisation.—2. The organic matter is gently heated in a tubulated retort with strong hydrochloric acid, and nitric acid is added by small portions at a time. The organic matter is thereby completely destroyed, with the exception of the fat. The liquid, which is transparent and colourless, is then decanted from the fatty matters; the latter are well washed with water; and the washings, together with the distillate in the receiver, are added to the main bulk of the liquid (Gaultier de Claubry, J. Pharm. [3] xvii. 125).—3. Chlorate of potassium may also be added in successive portions instead of the nitric acid.—4. The organic matter, after being comminuted as much as possible, may be suspended in water, and chlorine gas passed through the liquid till the organic matter is partly destroyed and partly deposited in brown flakes.—5. The organic matter, after being dried, is mixed with nitre, and the mixture projected by successive portions into a red-hot crucible. The arsenic is thereby converted into arsenate of potassium, which dissolves readily in water. (Wöhler.)

Mr. Graham finds that a most effective separation of the organic matter capable of interfering with the precipitation of arsenic by reagents, may be effected by his apparatus for the diffusion of liquids. A flat hoop of white wood or gutta-percha, about ten inches in diameter, is covered with a sound sheet of parchment-paper, so as to form an instrument like a tambourine in form. The organic fluid is placed within the instrument so as to cover the parchment bottom to the depth of half an inch, and the whole is then floated upon distilled water, contained in a basin. Three-fourths of the arsenious acid present are found to escape by diffusion and enter the water below, in the course of twenty-four hours, giving a perfectly colourless solution. To this liquid, when concentrated, all the ordinary tests of arsenic may be applied. (See DIFFUSION OF LIQUIDS.)

A clear solution having been obtained, the arsenic may be separated from it in either of the following ways:

1. *By Precipitation as Trisulphide.*—The clear arsenical solution is saturated with sulphurous acid to reduce the arsenic acid to arsenious acid, the excess of sulphurous acid is expelled by gentle heating, and a stream of sulphuretted hydrogen gas passed through the liquid for a considerable time. The precipitated trisulphide of arsenic is then carefully washed with cold water, dried, and reduced to the metallic state by heating it in a small tube having a bulb blown at the end with a mixture of dry carbonate of sodium and charcoal, or cyanide of potassium. The bulb, after the introduction of the mixture, should first be gently heated over a lamp to expel moisture, the tube then wiped out with filtering paper, and the bulb strongly heated in the blowpipe flame. A ring of metallic arsenic is then deposited in the tube, and may be treated as already described.

2. *By Conversion into Arsenetted Hydrogen.*—This may be effected either by Marsh's or by Bloxam's process (p. 362). The former has long been used by toxicologists. It is extremely delicate, and indeed has nearly superseded all other methods, excepting that of Reinsch. If the liquid to be tested has been effectually freed from organic matter by either of the methods just given, so that there is no longer any danger of frothing, it may be introduced, together with the zinc and sulphuric acid, into an ordinary gas-generating vessel, provided with a drying tube and reduction-tube (p. 362). Peculiar forms of apparatus have, however, been devised for performing the process without the trouble of completely removing the organic matter. Such is the original apparatus of Marsh, a figure and description of which are given in Graham's Elements of Chemistry, 2nd ed. vol ii. p. 215. Another form of apparatus, contrived for the purpose by a committee of the Prussian government, and

simplified by the late Dr. Ure, is described in *Ure's Dictionary of Arts, Manufactures, and Mines*, new edition, i. 189.

It is found however, that the presence of organic matter sometimes completely prevents the detection of minute quantities of arsenic by Marsh's process (Odling, Guy's Hospital Reports,[3] v. 367; Pharm. J. Trans. [2] i. 374). Hence it is better in all cases, before applying this test, to eliminate the organic matter by one of the processes above described. It must be observed, however, that all these processes yield the arsenic in the form of arsenic acid, so that it becomes necessary to add sulphurous acid or acid sulphite of sodium, in order to reduce it to arsenious acid. Another mode of proceeding, recommended by Odling (*loc. cit.*), is to mix the suspected substance with strong hydrochloric acid, distil to dryness and test the distillate. In this case the addition of sulphurous acid is unnecessary.

Bloxam's electrolytic process is of recent introduction and has not, so far as we are aware, been yet applied in judicial investigations; but it appears to present several advantages over that of Marsh, especially in securing, by the addition of hydrosulphuric acid to the liquid, the complete separation of arsenic and antimony, the former being then evolved as arsenetted hydrogen, the latter remaining wholly in the liquid. The certainty of this separation is of especial importance in the investigation of cases of poisoning by arsenic, inasmuch as tartar-emetic is often given in such cases to produce vomiting.

In all processes of testing for arsenic, it is of the utmost importance to ensure that the indications obtained of the presence of that substance do not proceed from the reagents themselves. Arsenic is very widely diffused in the mineral kingdom, and hence it is by no means an easy matter to procure reagents absolutely free from it. Sulphuric acid, hydrochloric acid, and zinc are often contaminated with it, and consequently Marsh's process, in which these reagents are employed, is very liable to give incorrect indications, unless the precaution be taken of testing the reagents in the manner already described (p. 362) before introducing the suspected liquid. Sulphuretted hydrogen, evolved by the action of dilute sulphuric acid on sulphide of iron often contains arsenic, proceeding from one or both of the substances used; but that which is evolved by heating native sulphide of antimony with hydrochloric acid is generally free from it, because sulphide of arsenic, even if present in the sulphide of antimony, is not decomposed by hydrochloric acid. The complete destruction of organic matter by the processes described at page 366, requires the use of considerable quantities of sulphuric or hydrochloric acid; consequently the arsenic contained in the acid is likely to accumulate in the resulting liquid in sufficient amount to make itself visible in the subsequent examination, even though the proportion of it contained in the acid may be too small to be perceptible in the comparatively small quantities required for the actual testing. This consideration tends rather to induce a preference for methods which do not require so complete a destruction of the organic matters, such as Reinsch's or the electrolytic process.

Quantitative Estimation of Arsenic.—When arsenic is contained in a solution entirely in the form of arsenic acid, it is best to precipitate it in the form of arsenate of magnesium and ammonium, $AsMg^2(NH^4)O^4 + 6H^2O$, by mixing the solution with excess of ammonia, and then with sulphate of magnesium, adding also a quantity of chloride of ammonium sufficient to prevent the precipitation of hydrate of magnesia by ammonia. The liquid is left to stand for some hours, and the precipitate is collected on a weighed filter, and washed with water containing ammonia. It may then be dried, either in vacuo or sulphuric acid, in which case it retains all its water of crystallisation—or more expeditiously at 100 °C., in which case it loses $\frac{11}{12}$ of its water, and is reduced to $AsMg^2(NH^4)O^4 + \frac{1}{2}H^2O$, or rather $2[AsMg^2(NH^4)O^4] + H^2O$, from which the quantity of arsenic is easily calculated.

If arsenic exists in solution in the form of arsenious acid, it may either be brought to the state of arsenic acid by oxidation with nitric acid, and the arsenic determined as above, or the arsenic may be precipitated as trisulphide by hydrosulphuric acid, the solution being previously acidulated with hydrochloric acid, and the precipitate collected on a weighed filter, washed and dried at a temperature a little above 100° C. If the trisulphide were quite pure and definite, its quantity might be at once determined by deducting the weight of the filter from the gross weight, and the quantity of arsenic calculated from the formula As^2S^3. But, as the precipitate almost always contains free sulphur, the quantity of arsenic in it must be estimated by oxidising the sulphur with strong nitric acid, and proceeding in a manner exactly similar to that which has been described for the estimation of antimony (p. 321).

Arsenious acid may also be estimated by its reaction with trichloride of gold, which converts it into arsenic acid, and at the same time yields a precipitate of metallic gold, every 4 at. of gold corresponding to 3 at. arsenious acid:

$$4AuCl^3 + 6H^2O + 3As^2O^3 = 4Au + 12HCl + 3As^2O^5.$$

The gold solution used for the purpose is the sodio-chloride or ammonio-chloride (see Gold): it must be free from nitric acid.

When arsenious and arsenic acids exist together in solution, the latter may be precipitated as ammonio-magnesian arsenate (a considerable quantity of chloride of ammonium being added to prevent the simultaneous precipitation of the arsenious acid); the arsenious acid in the filtrate is converted into arsenic acid by oxidation with chlorate of potassium and hydrochloric acid, and then precipitated in the same manner; or the arsenious acid may be estimated by chloride of gold, as just described.

Atomic Weight of Arsenic.—Berzelius (Schw. J. xxxiii. 172) determined the atomic weight of arsenic from the quantity of sulphurous anhydride produced by heating arsenious oxide with sulphur. The equation, $2As^2O^3 + S^9 = 2As^2S^3 + 3SO^2$, shows that 1 at. As^2O^3, yields $1\frac{1}{2}$ at. SO^2. Now in an experiment made by Berzelius, 2·203 grm. As^2O^3 gave 1·1069 SO^2. Therefore:

$$As^2O^3 = \frac{2{\cdot}201}{1{\cdot}069} \,.\, 96 = 197{\cdot}84$$

and deducting $O^3 = 48$, there results $As^2 = 149{\cdot}84$ and $As = 74{\cdot}92$. Pelouze (Compt. rend. xx. 1014) decomposed pure trichloride of arsenic with water, and determined the quantity of hydrochloric acid produced by means of a standard solution of silver. His results (calculated with the atomic weights of silver and chlorine now adopted ($Ag = 108$; $Cl = 35{\cdot}5$), give as a mean of three experiments, $As = 75{\cdot}08$. The mean between this number and that of Berzelius is exactly 75.

Separation of Arsenic from other Elements.—From other metals of the second and third groups (Analysis, Inorganic), and from all non-metallic elements, excepting selenium, arsenic is separated by precipitation with hydro-sulphuric acid gas in acid solutions. From those metals of the first group whose sulphides are insoluble in alkaline sulphides, *lead*, *copper*, *silver*, &c., it is separated by precipitating with hydrosulphuric acid, digesting the precipitate with sulphide of ammonium, and acidulating the filtered solution with hydrochloric acid. From *selenium* and *tellurium*, it is separated by sulphurous acid, which precipitates those elements from their solutions in the free state.

Separation from Antimony.—When arsenic and antimony exist together in the form of an alloy, they may be completely separated by heating the compound to low redness in a stream of carbonic anhydride, the arsenic then volatilising and the antimony remaining. Antimony is, however, the only metal from which arsenic can be completely separated in this manner; if the alloy contains any other metal, some of the arsenic will be retained, and the method is no longer applicable. When this is the case, the alloy may be dissolved in hydrochloric acid, to which nitric acid or chlorate of potassium is gradually added; the solution diluted with water after addition of tartaric acid, is then mixed with a considerable quantity of chloride of ammonium and excess of ammonia, and the arsenic precipitated by addition of sulphate of magnesium. The antimony may then be precipitated from the filtrate by hydrosulphuric acid. This mode of separation is equally applicable when the two metals are in the state of sulphides; as, for instance, when they are precipitated together from solution by hydrosulphuric acid. When they occur together as oxides, they may be dissolved in hydrochloric acid, mixed with tartaric acid, and treated as above; or they may be separated by fusion with caustic soda in the manner to be presently described.

The separation of arsenic from *tin* may be effected by converting the two metals into sulphides, and separating them, after drying and weighing the whole, by ignition in a stream of hydrosulphuric acid gas. The mixed sulphides are introduced into a weighed glass bulb, having a tube attached to it on each side. One of these tubes, the exit-tube, must be at least a quarter of an inch in diameter, to prevent stoppage, and bent downwards so as to dip into a flask containing ammonia. The whole is then weighed, hydrosulphuric acid gas passed through the apparatus, and the bulb heated till the whole of the sulphide of arsenic is sublimed. Part of the sulphide of arsenic passes into the ammoniacal liquid, by which it is dissolved, and the rest sublimes in the wide tube. When the operation is ended, and the apparatus has cooled, the wide tube is cut off at a short distance from the bulb, then broken, and the pieces digested in caustic potash to dissolve out the sulphide of arsenic. The solution thus obtained is added to the ammoniacal liquid in the flask; the sulphide of arsenic is precipitated by hydrochloric acid, and oxidised, without previous filtration, with hydrochloric acid and chlorate of potash; and the resulting arsenic acid is precipitated by ammonia and sulphate of magnesium. The sulphide of tin remaining in the bulb is converted into stannic oxide by treating it with strong nitric acid.

Separation of Arsenic from Antimony and Tin together.—The separation of these three metals is attended with considerable difficulty. The best mode of effecting it is to convert them into arsenate, antimonate, and stannate of sodium, and treat the mixture with dilute alcohol of a certain strength, which dissolves the arsenate and stannate of sodium, and leaves the antimonate undissolved.

If the three metals exist together in solution, they are precipitated as sulphides by hydrosulphuric acid, and the sulphides are fused in a silver crucible with a mixture of nitre and caustic soda; or, better, they are oxidised by heating them with strong nitric acid; and the solution, together with the insoluble stannic and antimonic acids, is mixed with excess of caustic soda and evaporated to a small bulk, then transferred to a silver crucible, evaporated to dryness, and fused for some time at a red heat. The fused mass, consisting of arsenate, antimonate, and stannate of sodium, is disintegrated by digestion in warm water, the contents of the crucible are transferred to a beaker glass, and the crucible is well rinsed out with a measured quantity of water. The greater part of the arsenate and stannate of sodium then dissolves, while the antimonate remains undissolved. But to effect complete separation, a quantity of alcohol of specific gravity 0·833, is added equal in bulk to one-third of the water used; the mixture is left to stand for 24 hours and frequently stirred; and the antimonate of sodium, which has then completely settled down, is collected on a filter and washed, first with a mixture of 1 vol. of the same alcohol and 3 vols. water; then with 1 vol. alcohol to 2 vols. water; next with a mixture of equal measures of water and alcohol; and, lastly, with 3 vols. alcohol to 1 vol. water.

The antimonate of sodium, separated by this process, is digested in a mixture of hydrochloric and tartaric acids, which dissolves it completely; the antimony is then precipitated by hydrosulphuric acid, and its quantity estimated in the manner already described (p. 320).

The filtrate containing the arsenate and stannate of sodium is supersaturated with hydrochloric acid, which throws down a bulky precipitate of stannic arsenate; hydrosulphuric acid gas is passed through the liquid till the white precipitate is completely converted into a brown mixture of the sulphides of tin and arsenic; the whole is left to stand till the odour of hydrosulphuric acid is no longer perceptible; the precipitate is collected on a weighed filter; and the filtrate is heated for some time to expel the greater part of the alcohol, then mixed with sulphurous acid, and again treated with hydrosulphuric acid, whereby a small quantity of sulphide of arsenic is generally precipitated. This quantity of sulphide of arsenic being quite free from tin, need not be added to the mixed sulphides on the filter. These mixed sulphides are dried at 100° C., their total weight determined, and a known quantity heated in a stream of hydrosulphuric acid gas in the manner described at page 368. The residual sulphide of tin is then converted into stannic oxide, and the sublimed sulphide of arsenic, together with the small quantity separately precipitated, is converted into arsenic acid by treatment with hydrochloric acid and chlorate of potassium, and the arsenic precipitated as ammonio-magnesian arsenate. (H. Rose, Analyt. Chem. 1851, ii. 229.)

This method is long and tedious, but gives accurate results. The most troublesome part of it is the disintegration of the fused mixture of the sodium-salts, which is very hard. To obviate this inconvenience, Professor Williamson dissolves the precipitated sulphides of the three metals in a mixture of sulphide of sodium and caustic soda, and mixes the solution with hypochlorite of sodium. The sulphides are thereby converted into arsenic, antimonic, and stannic acids, which combine with the soda, and may be separated by treatment with dilute alcohol as above.

If the three metals are in the state of solid oxides, the mixture may be dissolved in hydrochloric acid, with addition of tartaric acid, and the metals precipitated as sulphides as before. If the metals are mixed in the form of an alloy, they may be dissolved in aqua-regia, the solution mixed with tartaric acid, then diluted, and precipitated in the same manner.

The method just described may, of course, be applied to the separation of antimony from tin or arsenic alone. In these cases, however, the simpler methods above given are preferable.

Bunsen has lately introduced a new method of separating arsenic from antimony and tin, depending on the action of acid sulphite of potassium on the sulphides of those metals. When recently precipitated trisulphide of arsenic is digested with a solution of sulphite of potassium containing excess of sulphurous acid, it dissolves at first; but on raising the heat to the boiling point, the liquid becomes turbid from deposition of sulphur, which, however, is dissolved for the most part by continued boiling. Sulphurous acid is also given off, and the liquid contains arsenite and hyposulphite of potassium:

$$2As^2S^3 + \underset{\text{Acid sulphite of potassium.}}{16KHSO^3} = \underset{\text{Arsenite of potassium.}}{4KAsO^2} + \underset{\text{Hyposulphite of potassium.}}{6K^2S^2O^3} + 3S + 7SO^2 + 8H^2O$$

The sulphides of tin and antimony are not affected by acid sulphite of potassium. Consequently, when a solution of these three sulphides in sulphide of potassium is precipitated by a large excess of sulphurous acid, the liquid digested for some time over the water-bath, and then boiled to expel the excess of sulphurous acid, the sulphides of tin and antimony remain undissolved, while the whole of the arsenic passes into solution, and may be precipitated from the filtrate by hydrosulphuric acid. If only sulphide of antimony is present in the residue, it may be washed with pure water; but disulphide of tin thus washed is sure to pass through the filter; hence, if tin is also present, the residue must be washed, first with a saturated solution of chloride of sodium, and then with a slightly acid solution of acetate of ammonium to remove the chloride of sodium; after which it may be dried, the ammonium salt then volatilising. The washing cannot be performed with acetate of ammonium alone, because arsenic is never completely precipitated by hydrosulphuric acid from a solution containing acetate of ammonium, that salt being in fact partly decomposed by hydrosulphuric acid into free acetic acid and sulphide of ammonium, which retains the arsenic in solution. Hence the liquid which runs through in washing out the chloride of sodium by acetate of ammonium must not be added to the first wash-water containing the arsenic. (Ann. Ch. Pharm. cvi. 8.)

Valuation of Arsenic Ores. — To ascertain the amount of metallic arsenic that can be obtained from an ore, the ore is gradually heated to redness in a retort or earthen cylinder, either alone or, if it be a sulphide, with potash or quick lime. The greater part of the sublimed arsenic may be collected on a thin iron plate rolled up and inserted into the neck of the retort, and the rest on a cone of copper foil luted on to the neck, a small aperture being left to allow the escape of gases. The sublimed arsenic is then collected and weighed. Commercial arsenious acid may be assayed in a similar manner by heating it with 16 to 20 per cent. of charcoal.

It is seldom required to ascertain the quantity of arsenious acid (anhydrous) that an ore will yield by roasting. A more frequently occurring problem is to determine the proportion of pure anhydrous arsenious acid contained in a crude product. If no other volatile substances are present, the amount of the pure anhydrous acid may be determined by sublimation in a retort; in the contrary case, the arsenious acid may be dissolved out by boiling water, and its amount ascertained by weighing the residue.

The quantity of pure sulphide which may be obtained from an ore, realgar, orpiment, arsenical pyrites, &c., is found by sublimation. (Kerl's *Hüttenkunde*, Bd. iii. 1^te^ Abth. S. 2.)

ARSENIC, ALLOYS OF. *Arsenides.*—Arsenic unites by fusion with most metals, forming alloys which are generally brittle. With *potassium* and *sodium* it forms alloys which give off arsenetted hydrogen gas when thrown into water. With *iron*, *zinc*, and *tin*, it forms brittle compounds; with *copper*, a white malleable alloy; with *gold* and *silver*, grey brittle alloys; with *lead* and with *antimony*, hard, brittle, very fusible compounds. It is introduced into the lead used in the manufacture of shot, to prevent tailing, and cause the metal to run into regular globules.

Metallic arsenides heated out of contact of air, either retain the arsenic altogether or give it up but partially. The alloys of arsenic and antimony are completely decomposed by ignition at a moderate heat in an atmosphere of carbonic anhydride, the arsenic volatilising and the antimony remaining. When an alloy of arsenic is heated in contact with the air, part of the arsenic is evolved as arsenious oxide, while the rest remains in the form of a metallic arsenite or arsenate. The arsenides of the alkali-metals dissolve in hydrochoric or dilute sulphuric acid, with evolution of arsenetted hydrogen; the arsenides of heavy metals are little, if at all, attacked by any acid, except nitric acid or aqua-regia. By fusion with nitre, metallic arsenides are converted into basic arsenates; when the arsenides of the heavy metals are fused with nitre and an alkaline carbonate or hydrate, and the fused mass is treated with water, the whole of the arsenic dissolves as arsenate of alkali-metal, and the heavy metal remains in the form of oxide free from arsenic. Arsenides are not decomposed by fusion with alkaline carbonates alone or mixed with charcoal, but if sulphur be added, a sulpharsenite or sulpharsenate of the alkali-metal is formed, and the other metal remains as sulphide free from arsenic.

Many metallic arsenides are definite compounds in atomic proportion, and in that respect differ from the generality of alloys, which are mere mixtures of their constituent metals in indefinite proportions. In this respect, as in some others, arsenic resembles the metalloïds rather than the true metals. The distinction is, however, not absolute, as many of the metals proper form with one another alloys constituted in definite atomic proportions.

Many metallic arsenides occur as natural minerals, *e.g. copper-nickel*, Ni^2As, *white nickel pyrites*, NiAs, *tesseral pyrites* (Co; Ni; Fe) As, &c.

Arsenide of Antimony, also called *Allemontite*, is found at Allemont, in the Chalanche Mountains, department of Isère; also at Andreasberg, Przibram, &c.; occurring in veins in gneiss, together with native antimony, antimony ores, and arsenical cobalt. It forms fine-grained, spherical, and kidney-shaped masses, with uneven fracture. Specific gravity 6·2. Hardness 3·5. It is of a tin-white colour, opaque, with a faint lustre, and in general appearance more or less resembling native arsenic. It contains, according to Rammelsberg's analysis, 37·9 per cent. Sb to 62·1 As, corresponding to 1 at. Sb : 2·6 at. As [Sb = 120·3], whence it would appear that the two metals are not combined in atomic proportions, but isomorphously mixed.

The other metallic arsenides will be described with the several metals.

ARSENIC, BROMIDE OF, $AsBr^3$, is prepared by shaking arsenic in powder into a retort filled with bromine vapour—the bromide of arsenic being distilled from the excess of arsenic; also, according to Nicklès (Compt. rend xlviii. 837), by treating pulverised arsenic with a solution of bromine in sulphide of carbon: it then crystallises from the solution. It forms a white crystalline mass, which melts at 20°–25° C. to a pale yellow liquid, boils at 22° C., and in the fused state fumes but slightly in the air: in contact with water it is converted partly into arsenious acid and hydrobromic acid, partly into oxybromide of arsenic (p. 385).

ARSENIC, CHLORIDE OF. *Butter of Arsenic; Caustic Oil of Arsenic*, $AsCl^3$.—This is the only known chloride of arsenic, and corresponds to arsenious oxide, As^2O^3. It is produced when finely divided arsenic is brought in contact with chlorine—the metal becoming ignited by the intensity of the combination. The same compound is obtained by distilling a mixture of 1 part of metallic arsenic and 6 pts. of corrosive sublimate; also by distilling arsenious oxide with strong hydrochloric acid, or with common salt and sulphuric acid in excess. A colourless, oily, and very heavy liquid is obtained, which is decomposed by water into arsenious and hydrochloric acid; if the quantity of water is insufficient for complete solution, oxychloride of arsenic (p. 386) is produced. It does not solidify even at −29° C. Boils at 132°, producing a vapour whose density is 6·3006 (Dumas). It evaporates in the air at ordinary temperatures, producing white fumes of arsenious oxide. It is highly poisonous.

Ammonio-chloride of Arsenic, $As^2H^{21}N^7Cl^6 = 2AsCl^3.7NH^3$ (H. Rose, Pogg. Ann. 62 lii.), or $2(NH\overset{'''}{As}.Cl).4NH^4Cl.NH^3$ (Pasteur, Ann. Ch. Pharm. lxviii. 207).—Dry ammonia gas passed into chloride of arsenic is rapidly absorbed, forming a white solid body, which is soluble in water and in alcohol, and crystallises therefrom without alteration. It is decomposed by heat, and according to Pasteur, ammonia is first given off, and then the residue volatilises completely, yielding a sublimate, in which cubes of sal-ammoniac can be detected by the magnifying glass. It is decomposed by hot water, ammonia being evolved, and arsenious acid and sal-ammoniac remaining in solution. When cold water is poured upon it, it becomes heated, gives off ammonia, and forms a solution, yielding by spontaneous evaporation six-sided tables, which may be regarded as a compound of chloride of arsenammonium with arsenious oxide and water, $2(NH\overset{'''}{As}.Cl).As^2O^3.4H^2O$. This compound treated with strong aqueous ammonia is converted into a hard mass of long six-sided tables, consisting of *monammonic arsenite*, $As(NH^4)O^2$, which quickly decomposes in solution, and still more quickly in the solid state, giving off the greater part of its ammonia.

ARSENIC, FLUORIDE OF, AsF^3, is produced by mixing 1 pt. of fluor-spar, purified by ignition, with 1 pt. of arsenious oxide and 3 pts. of strong sulphuric acid in a leaden retort, and heating the mixture till it boils. It is a transparent, colourless liquid, of specific gravity 2·73, very volatile, boiling at 63° C., and fuming strongly in the air even, at ordinary temperatures. The vapour is about four times as heavy as atmospheric air. A drop of the liquid coming in contact with the skin evaporates almost instantly, but nevertheless produces a painful wound, which suppurates for a long time like a burn. It attacks glass but slowly in a close vessel, but in contact with moisture, it is decomposed, yielding arsenious acid and hydrofluoric acid, which corrodes the glass. With water, it forms a clear liquid, which corrodes glass, but scarcely attacks zinc or tin.

ARSENIC, HYDRIDE OF. Arsenic contains two compounds with hydrogen, one solid and the other gaseous. The *solid arsenide of hydrogen* is obtained by passing an electric current through water, the negative pole being formed of metallic arsenic; or by dissolving arsenide of potassium or sodium in water. It is a brown powder, which evolves hydrogen when heated in a close vessel, and burns when heated in the air (Davy). From Soubeiran's analysis, it appears to be AsH^2.

TRIHYDRIDE OF ARSENIC, ARSENETTED HYDROGEN, AsH^3, a gas analogous in composition to ammonia, is obtained:—1. By dissolving arsenide of potassium in water, the solid arsenide being formed at the same time.—2. By dissolving an alloy of 1 at. arsenic and 3 at. zinc or tin, in hydrochloric or dilute sulphuric acid:

$$\mathrm{AsZn^3 + 3ClH = AsH^3 + 3ClZn.}$$

3. By dissolving zinc in hydrochloric or dilute sulphuric acid containing arsenious acid (p. 361.)

$$\mathrm{As^2O^3 + 12Zn} + \left\{\begin{matrix}\mathrm{12Cl} \\ \mathrm{or\ 6SO^4H^2}\end{matrix}\right. \mathrm{= 2AsH^3 + 3H^2O} + \left\{\begin{matrix}\mathrm{12ClZn,} \\ \mathrm{or\ 6SO^4Zn^2.}\end{matrix}\right.$$

4. By dissolving zinc, tin, or iron in aqueous arsenic acid or in a mixture of that acid with hydrochloric or sulphuric acid:

$$\mathrm{2AsH^3O^4 + 16Zn = 2AsH^3 + 8Zn^2O.}$$

This last mode of formation was first given by Scheele, and afterwards denied by Fischer (Pogg. Ann. ix. 261), who stated that aqueous arsenic acid, if quite free from arsenious acid, evolves nothing but hydrogen when treated with zinc. Gmelin, however, obtained arsenetted hydrogen with perfectly pure arsenic acid and zinc. (Handbook, iv. 264.)

5. By the electrolysis of arsenious or arsenic acid. (Bloxam, p. 361.)

The gas obtained by either of the above processes is never pure, but always mixed more or less with free hydrogen. It may be collected over water, but the most scrupulous care must be taken that not the smallest quantity be inhaled, as it is excessively poisonous, and has proved fatal in more than one instance.

Arsenetted hydrogen is a colourless gas, which liquefies at 30° C., but does not solidify even at 110° C. It has an extremely repulsive odour, and even when largely diluted with air, produces nausea, giddiness, and oppression. Small animals are instantly killed by it. It does not redden litmus. Its specific gravity, according to Dumas, is 2·695 (air = 1). One volume of the gas contains $1\frac{1}{2}$ vol. hydrogen and $\frac{1}{4}$ vol. vapour of arsenic: $[\frac{3}{2} \,.\, 0{\cdot}0693 + \frac{1}{4} \,.\, 10{\cdot}39 = 2{\cdot}701]$.

Arsenetted hydrogen is slightly soluble in water. It does not combine either with acids or with bases. It decomposes the solutions of many of the metals which are precipitated by hydrosulphuric acid, its hydrogen alone being oxidised, and the arsenic precipitated in combination with the metal. From a solution of sulphate of copper, for example, it throws down arsenide of copper, $\mathrm{AsCu^3}$:

$$\mathrm{2AsH^3 + 3SO^4Cu^2 = 3SO^4H^2 + 2AsCu^3.}$$

When a mixture of this gas with free hydrogen is placed over a solution of sulphate of copper, the arsenetted hydrogen is completely absorbed and the hydrogen remains. From the salts of silver, gold, and platinum, arsenetted hydrogen precipitates the metals, and is converted into arsenious acid, which remains in solution, *e. g.*:

$$\underset{\text{Nitrate of silver.}}{\mathrm{6NO^3Ag}} + \mathrm{AsH^3 + 3H^2O = 6Ag} + \underset{\text{Nitric acid.}}{\mathrm{6NO^3H}} + \underset{\text{Arsenious acid.}}{\mathrm{AsH^3O.^3}}$$

Arsenetted hydrogen is decomposed at a red heat into free hydrogen and metallic arsenic. It burns in the air with a bluish-white flame, quite different in appearance from that of pure hydrogen, forming water and arsenious acid, which rises in white smoke, and is deposited in a white crust on a cold body, such as a piece of porcelain held just above the flame; but if the porcelain be held in the middle of the flame so as to cool it partially, then the hydrogen is alone burnt, and the arsenic, being less combustible is deposited on the porcelain in metallic spots (p. 362). This effect is precisely similar to the deposition of soot on a glass rod or other cold body held in the flame of a candle.

ARSENIC GLASS. See ARSENIC, SULPHIDES OF (p. 386).

ARSENIC, IODIDE OF. $\mathrm{AsI^3}$.—Arsenic and iodine unite when gently heated together, the combination being attended with considerable evolution of heat. By distilling 3 pts. of iodine with 1 pt. of metallic arsenic, in a retort having its bulb immersed in a sand-bath, the iodide is obtained as an orange-coloured crystalline sublimate having the lustre of gold. It may also be prepared, like the bromide, by treating metallic arsenic with a solution of iodine in sulphide of carbon. It dissolves in 3·32 pts. of boiling water, and the solution, if boiled down, leaves pure iodide of arsenic; but, if left to cool slowly, deposits crystals of a compound of arsenious oxide with oxyiodide of arsenic (p. 368). The iodide may be recrystallised from boiling alcohol, and is then obtained in shining laminæ of a fine brick-red colour. Iodide of arsenic has been used in the treatment of cancer.

ARSENIC, LIVER OF. An old term for the alkaline sulpharsenites (p. 388).

ARSENIC, ORES OF. (pp. 360, 370.)

ARSENIC, OXIDES OF. Arsenic forms two well-defined oxides, viz. the *Trioxide* or *Arsenious Oxide*, As^2O^3, or AsO^3, and the *Pentoxide* or *Arsenic Oxide*, As^2O^5, or AsO^5. The black film which forms on the surface of the metal when exposed to the air is by many supposed to be a suboxide, but it is more probably a mixture of metallic arsenic with the trioxide.

ARSENIOUS OXIDE (or ANHYDRIDE), As^2O^3; in the hydrated state, ARSENIOUS ACID.—This compound occurs native in the mineral *arsenite* or *arsenolite* (*q. v.*) which forms capillary crystals investing ores of nickel, cobalt, &c. It is formed when arsenic volatilises in contact with free oxygen, as when the metal is heated in a glass tube through which a current of air is passing.

On the large scale, arsenious oxide is obtained as an accessory product in the roasting of arsenical ores of tin, cobalt and nickel, and as a principal product in the roasting of arsenical pyrites. The ores are sometimes roasted on the hearth of a reverberatory furnace, where they are in direct contact with the flame, more generally in muffles which are surrounded by the flame but prevent it from touching the material. The latter method involves a larger consumption of fuel, but yields a purer product, inasmuch as when the flame comes in contact with the ore, the arsenious oxide produced by the oxidation becomes mixed with carbonaceous matter, which, in the subsequent sublimation, reduces a portion of the arsenic to the metallic state, and gives the product a grey colour.

At Reichenstein, in Silesia, arsenious oxide is prepared from arsenical pyrites. The ore reduced to powder, is roasted in a muffle-furnace, and the vapour of arsenious oxide is made to pass into a condensing chamber, divided into partitions, where it is deposited in the pulverulent state, as *crude arsenic* or *poison-flour* (*Giftmehl*). This product is refined by sublimation in cast-iron pots, the tops of which are contracted into cones, and terminate in pipes which also pass into a condensing chamber. Lastly, the refined arsenious oxide is again sublimed at a higher temperature, and collects in the upper part of the subliming vessel in the form of a glass (vitreous arsenious oxide).

At Ribas, in Catalonia, arsenious oxide is obtained from arsenical pyrites by roasting in a reverberatory furnace without muffles; in other respects, the series of operations is similar to that just described. At Andreasberg, in the upper Harz, argentiferous native arsenic is roasted to extract the silver, and arsenious oxide is obtained as a secondary product. It is also produced in large quantity in the roasting of tin ores and cobalt ores at Altenberg in Saxony, and of tin ores in Cornwall. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 185; Kerl's *Hüttenkunde*, iii. 1^{te} Abtheilung, S. 14.)

Properties.—Arsenious oxide is a white solid, which occurs in two crystalline forms and likewise in the amorphous state.—1. *Amorphous, vitreous* or *glassy* arsenious oxide is produced, when the vapour condenses on a surface whose temperature is but little below the volatilising point of the oxide, so that before solidifying it passes through the semi-fluid state. It is transparent when first prepared, but gradually becomes opaque, and passes into the crystalline state. Its specific gravity, according to Guibourt, is 3·7385.—2. *Octahedral arsenious oxide.* This variety is produced by sublimation when the vapour is cooled so quickly that it solidifies at once, without passing through the semi-fluid state. A hot saturated aqueous solution deposits the oxide in regular octahedrons on cooling. Vitreous arsenious oxide is transformed into the octahedral variety by keeping, especially in contact with the air, and also by solution in water or hydrochloric acid. When 2 or 3 pts. of the vitreous oxide are dissolved in a mixture of 12 pts. of fuming hydrochloric acid and 4 pts. of water, and the solution is left to cool slowly, the arsenious oxide crystallises in transparent octahedrons, the formation of each crystal being accompanied by a flash of light (H. Rose). The specific gravity of octahedral arsenious oxide is 2·695 (Guibourt).—3. *Right Rhombic Arsenious Oxide.* This variety, which is isomorphous with native oxide of antimony, is occasionally obtained by sublimation (Wöhler), also, according to Pasteur, when a boiling solution of potash is saturated with arsenious acid and left to cool. It is converted into the octahedral variety by sublimation or by solution in hot water.

Arsenious oxide volatilises at about 218° C., forming a colourless vapour of specific gravity 13·85. The vapour is perfectly inodorous, provided the oxide has not been heated in contact with charcoal or other reducing agent. The vitreous oxide may be fused before it volatilises to any considerable extent; but the crystallised oxide sublimes before fusion. Under pressure, the oxide may be melted to a glass.

Arsenious oxide dissolves but sparingly in cold *water*, more readily in boiling water, the vitreous oxide dissolves more readily than the crystalline variety. A hot saturated solution contains 1 pt. of the oxide or anhydrous acid in 10 or 12 pts. of water, and on cooling deposits the greater portion, leaving a solution containing 1 pt. of the anhydrous acid in 30 pts. of water. The statements of different authors regarding the solubility of arsenious acid in water differ considerably, the discrepancy probably arising from the simultaneous occurrence of the vitreous and crystalline modification in the acid submitted to experiment (Gm. iv. 257). No definite hydrate of arsenious acid appears to exist. The aqueous solution is transparent and colourless, and slightly reddens litmus. (For its behaviour with hydrosulphuric acid, nitrate of silver, and other reagents, see page 361.)

Arsenious oxide dissolves in hot *dilute acids* more readily than in water, but separates out completely on cooling, without forming any definite compound. It has therefore little or no basic power. With *tartaric acid*, however, it forms a potassic double salt analogous to tartar-emetic. (See TARTARIC ACID.)

It dissolves in *alkalis*, forming arsenites of alkali-metals.

It is nearly insoluble in *alcohol*, quite insoluble in *ether*.

Arsenious oxide, whether in the dry state or in solution, is one of the most violent of the acrid poisons, a dose of two or three grains being certain to cause death, unless it be very speedily ejected by vomiting, or rendered innocuous by conversion into an insoluble compound. Nevertheless it appears to be possible, by commencing with small doses and gradually increasing them, to accustom the human body to sustain without injury, doses of 4 grains or even more; and it is moreover stated, apparently on good authority, that arsenic thus taken produces a plump and healthy appearance in those who use it, and especially increases the power of the respiratory organs, and consequently facilitates mountain-climbing under heavy burthens. The Tyrolese peasantry are said to swallow arsenic in considerable quantities for this purpose. Those who are accustomed to taking arsenic in this way, are also said to experience great depression and loss of strength if they discontinue it.

Arsenious acid in small doses is much used in medicine, chiefly in cases of skin-disease. The form in which it is most frequently administered is that of *Fowler's solution*, which is an arsenite of potassium.

The best antidote to poisoning by arsenic is *hydrated sesquioxide of iron*, which, when administered in excess, converts the arsenious acid into a basic ferric arsenite, perfectly insoluble in water and in the fluids of the alimentary canal. It may be prepared by precipitating a solution of ferric chloride or sulphate with ammonia, and washing by decantation, and should then be kept under water, because when dry, its power to lay hold of arsenious acid is very much diminished. It is most efficacious when recently precipitated, the absorbing power being somewhat diminished, even by keeping under water (Bunsen and Berthold, "Das Eisenoxyd ein Gegengift der arsenigen Säure." Göttingen, 1834). Still more efficacious, according to Fuchs, is a mixture of hydrated ferric oxide with magnesia, obtained by precipitating a solution of ferric chloride or sulphate with excess of calcined magnesia. It should be prepared at the time when it is wanted, and may be used at once, without washing, the soluble magnesium-salt produced by the reaction being rather beneficial than otherwise, inasmuch as it exerts a purgative action. When ammonia is used as the precipitant, the washing cannot be dispensed with, because arsenite of iron is somewhat soluble in ammoniacal salts. The magnesia used for precipitating the ferric hydrate must not be very strongly calcined. Magnesia itself is likewise capable of abstracting arsenious acid from solution, and forming an insoluble compound with it; but ferric hydrate is more powerful in this respect, and the mixture of the two prepared in the manner just mentioned, is more efficacious than either, probably because the ferric hydrate is spread over the surface of the particles of magnesia in a state of fine division. (Handw. d. Chim. 2te Aufl. ii. 294.)

Arsenious oxide acts both as an oxidising and as a reducing agent. It partially deoxidises many compounds rich in oxygen, *e.g. nitric acid, manganic acid, chromic acid, hypochlorous acid*, &c., being itself converted into arsenic oxide or acid. It quickly reduces *gold* from the solution of the trichloride. *Potassium, charcoal, sodium, sulphur, phosphorus*, and *zinc* deoxidise it at a red heat, separating metallic arsenic. Distilled with *acetates*, it yields cacodyl, a compound of 1 at. arsenic with 2 at. methyl, $As(CH^3)^2$, which may be recognised by its peculiar and intolerable odour. When vapour of arsenious oxide is passed over red-hot *lime*, part off it is resolved into metallic arsenic, which sublimes, and arsenic oxide which unites with the lime, forming an arsenate (Wollaston), while another portion, greater as the heat is less, unites directly with the lime, forming an arsenite (Simon). Heated with *carbonate of potassium*, it likewise yields metallic arsenic and an arsenate (Gay-Lussac). As an oxidising agent, arsenic oxide is used in the manufacture of glass, for the purpose of converting protoxide of iron into sesquioxide, which yields less highly coloured glasses than the protoxide.

ARSENITES.—Arsenious acid unites with bases in several proportions, but the salts are not very stable, and have been but little examined. Those whose composition is $MAsO^2$ or $M^2O.As^2O^3$, are generally regarded as neutral; and besides these there are basic arsenites containing $M^4As^2O^5$, or $2M^2O.As^2O^3$, and M^3AsO^3, or $3M^2O.As^2O^3$, besides acid salts.* Arsenious oxide dissolves in caustic *potash* or *soda*, but does not neutralise the alkali; the concentrated solutions are decomposed by the carbonic acid in the air, and yield, after a while, very large and well formed crystals of anhydrous arsenious acid. The acid dissolves in *ammonia* more readily than in water, and remains free from ammonia when the solution is evaporated. *Lime*, *baryta*, and *strontia*, dissolve when boiled with water and excess of arsenious acid, and on adding lime-, baryta-, or strontia-water in excess to the solutions, basic salts are precipitated in white flocks. These precipitates dissolve in acids and in ammoniacal salts: hence arsenious acid cannot be precipitated by the alkaline earths from solutions containing ammoniacal salts. The other arsenites are insoluble in water, and are obtained by precipitation. They dissolve in hydrochloric acid, and some of them in acetic acid, also in sulphate, hydrochlorate, and nitrate of ammonium.

Solutions of the alkaline arsenites give a light green precipitate with *cupric salts*, egg-yellow with *nitrate of silver*.—*Hydrosulphuric acid* produces no precipitate unless a stronger acid is present in excess; but all arsenites when dissolved in hydrochloric acid give a precipitate with hydrosulphuric acid; and if the metallic base of the arsenite is likewise precipitable by hydrosulphuric acid, a compound metallic sulphide may be produced.

Most arsenites are decomposed by *heat:* some give off arsenious oxide, and leave the base in the form of oxide: but the arsenites of the alkali-metals and the alkaline earth-metals, give off metallic arsenic and leave a salt of arsenic acid ($5As^2O^3 = 3As^2O^5 + As^2$). Arsenite of silver gives off arsenious oxide and leaves a mixture of metallic silver and arsenate of silver; arsenite of lead alone withstands a red heat without decomposition, and arsenite of magnesium is but imperfectly decomposed (Simon, Pogg. Ann. xi. 435).—Arsenites heated with *charcoal* give off metallic arsenic.

Arsenite of Ammonium, NH^4AsO^2, or $(NH^4)^2O.As^2O^3$, according to Pasteur; $(NH^4)^4As^2O^5$, or $2(NH^4)^2O.As^2O^3$, according to Stein, is produced, according to Pasteur, when very strong aqueous ammonia is poured upon arsenious oxide, and forms a hard mass composed of microscopic six-sided tables belonging to the trimetric system. It exists only in contact with ammonia, quickly giving off ammonia in contact with the air. It forms a yellow precipitate with silver-salts, the solution turning acid. It is insoluble in alcohol and in ether.

Arsenite of Antimony.—Produced by digesting metallic antimony with aqueous arsenic acid, and is precipitated on diluting with water. It may also be obtained as a transparent, fused, vitreous mass, by heating metallic arsenic with antimonic oxide.

Arsenite of Barium, $BaAsO^2$, or $Ba^2O.As^2O^3$, is obtained by mixing a solution of chloride of barium with acid arsenite of potassium, separating after a few hours as a gelatinous mass or in dendritic ramifications. In this state it is very soluble in water, but becomes sparingly soluble after drying: the liquid decanted from the jelly likewise yields the salt by evaporation, as a heavy sparingly soluble powder. The gelatinous salt is probably a hydrate. A salt containing $2Ba^2O.As^2O^3 + 4H^2O$ is obtained, according to Stein, by dropping baryta-water into aqueous arsenious acid, as long as a precipitate continues to form, and washing with dilute alcohol. It gives off 2 at. water at 100° C., and the rest at a higher temperature, arsenic, however, volatilising at the same time.

A concentrated solution of arsenious acid is immediately precipitated by baryta-water, a very dilute solution after some time only, or not at all (L. Gmelin). Arsenite of ammonium precipitates solution of chloride of barium after a while.

Arsenite of Calcium.—The several arsenites of potassium, added to solution of chloride of calcium, yield precipitates, but not of constant composition (Filhol). The neutral salt, $CaAsO^2$, is obtained, according to Simon, by precipitating chloride of calcium with ammonia saturated with arsenious acid; the precipitate is increased by adding excess of ammonia, but dissolves partially when washed with water. When, on the other hand, an aqueous solution of arsenious acid is mixed with excess of lime-water, a white heavy powder ($2Ca^2O.As^2O^3$, with water) is precipitated, which is very little soluble in water, somewhat more soluble in the presence of ammonia-salts, or of chloride of potassium or sodium. According to Stein, the precipitate thus obtained is a mixture of several basic salts, but on adding sufficient arsenious acid to dissolve part of it, the residue consists of $3Ca^2O.2As^2O^3 + 3H^2O$; this salt gives off 1 at. water at 100° C., the rest at a temperature at which decomposition begins.

---

* If $O = 8$, the formulæ are $MO\ AsO^3$, $2MO.AsO^3$, and $3MO.AsO^3$ respectively.

According to Kühn (Jahresb. f. Chem. 1852, 379), a boiling solution of arsenious acid added to excess of lime-water throws down the salt, $3Ca^2O.As^2O^3$, or Ca^3AsO^3.

Arsenite of Cobalt, $3Co^2O.2As^2O^3 + 4H^2O$, is obtained by quickly mixing arsenite of potassium with a solution of chloride of cobalt containing a large excess of sal-ammoniac.

Arsenite of Copper, $Cu^4As^2O^5$, or $2Cu^2O.As^2O^3$, is obtained by precipitating a salt of copper with arsenite of potassium, or with arsenious acid and a sufficient quantity of ammonia to neutralise the acid present (p. 361). It is a light green precipitate (Scheele's green), which dissolves in excess of ammonia without colour, yielding a solution of arsenic acid and cuprous oxide. Arsenite of potassium containing excess of alkali dissolves it readily, with blue colour, but the solution quickly decomposes into arsenate of potassium and cuprous oxide. Vapour of arsenious oxide passed over red-hot cupric oxide does not combine with it.

Aceto-Arsenite of Copper. $3CuAsO^2.C^2H^3CuO^2$. *Schweinfurt Green*, or *Imperial Green*. —This compound, the preparation of which is given at page 15, is much used as a pigment, on account of its splendid green colour. A great deal of needless alarm has lately been excited about the supposed deleterious effects of this pigment. It is extensively employed for staining wall-papers, and persons inhabiting rooms thus papered are said to have had their health seriously deranged by the *arsenical fumes* evolved from it! Now it is utterly impossible that arsenic should volatilise from such a compound at ordinary temperatures: it does not decompose at any temperature below redness. The only way in which danger could arise from the use of paper stained with an arsenical colour, is that particles of the compound might be brushed off in in dusting the paper, and thus become mixed with the air of the apartment; but it is not in this way that the supposed accidents are said to have occurred; the panic has arisen from a mistaken notion as to the volatility of the arsenic. That the use of the pigment is not really dangerous may be safely inferred from the fact that no bad effects are experienced by the workmen engaged in its manufacture. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 157.)

Arsenite of copper forms a similar double salt with *butyrate* of copper.

Arsenites of Iron.—There are several basic *ferric arsenites*. When recently precipitated ferric hydrate is digested with a concentrated solution of arsenious acid, in such proportion that the quantity of anhydrous ferric oxide present is equal to ten times the weight of anhydrous arsenious acid, the acid is completely removed from the liquid. With a smaller proportion of ferric oxide, the precipitation is nearly though not quite complete. The products formed are basic arsenites containing $3Fe^4O^3.As^2O^3$, &c., from which part of the arsenious acid may be extracted by water. It is this power possessed by hydrated ferric oxide of removing arsenious acid from a solution, which renders it so useful as an antidote to arsenious acid (p. 374).

Arsenious acid, or arsenite of potassium, forms with ferric acetate an ochre-yellow precipitate, which dries up to a brown mass containing $4Fe^2O^3.As^2O^3 + 5Aq$, and when heated gives off water and the greater part of the acid (Bunsen), the whole, according to Simon. Water removes part of the arsenious acid; strong mineral acids dissolves the salt completely. Ferric sulphate or chloride is not precipitated by free arsenious acid: but gives with arsenite of potassium, according to Guibourt, a rusty-brown precipitate, containing when dry, $2Fe^4O^3.As^2O^3 + 7H^2O$. According to Damour, this precipitate is slowly dissolved, with rusty-brown colour, by caustic potash, and when slowly heated, melts before giving off arsenious oxide. A rusty yellow precipitate, likewise containing $2Fe^4O^3.As^2O^3 + 7H^2O$, is obtained by oxidising a solution of ferrous sulphate with aqua-regia, neutralising with ammonia, and precipitating by soda-ley, which has been saturated at the boiling heat with arsenious acid and freed from the excess of that acid by cooling. It is soluble in caustic soda, and the solution, evaporated to dryness, yields a red mass perfectly soluble in water.

Ferrous Arsenite, $2Fe^2O.As^2O^3$, is obtained by mixing ferrous sulphate with a solution of arsenious acid in ammonia, as a greenish white precipitate, which becomes ochre-yellow on drying. The non-oxidised compound is soluble in ammonia.

Arsenite of Lead.—The *neutral* salt, $Pb^2O.As^2O^3$, or $PbAsO^2$, is obtained by precipitating neutral acetate of lead with acid arsenite of potassium, or with arsenious acid (Filhol), or, according to Berzelius, with ammonia which has been saturated with arsenious acid while warm; the precipitate obtained by the latter process contains water, becomes strongly electrical by friction, and when heated gives off some of its acid and water, and melts to a yellowish glass. Neutral arsenite of lead is somewhat soluble in water, insoluble in potash, but soluble in soda. The *tetraplumbic* salt, $Pb^4As^2O^5$, or $2Pb^2O.As^2O^3$, is formed, according to Filhol, by precipitating neutral acetate of lead with basic arsenite of potassium, or, according to Berzelius, by precipitating basic acetate of lead with an ammoniacal solution of arsenious acid. It is a white hydrated powder, insoluble in water and in ammonia-salts, melting to a yellowish glass when heated. According to Simon, it is obtained by passing the vapour of arsenious oxide over red-hot oxide of lead, as a sulphur-yellow, easily fusible glass which sustains a considerable degree of heat without decomposing. A *triplumbic salt*, $3Pb^2O.As^2O^3$, or Pb^3AsO^3, is obtained by precipitating basic acetate of lead with a boiling solution of arsenious acid. (Kühn.)

Arsenite of Magnesium.—Calcined magnesia, boiled with arsenious acid, takes up a portion of it, but not in any definite amount. A precipitate of uncertain composition is obtained by mixing sulphate of magnesium with acid arsenite of potassium, and heating. A solution of sulphate of magnesium is not precipitated by aqueous arsenious acid; but on adding a small quantity of ammonia, a copious precipitate is formed which, according to Stein, has, after drying over sulphuric acid, the composition Mg^3AsO^3, or $3Mg^2O.As^2O^3$. It is insoluble in ammonia, but dissolves in a large excess of sal-ammoniac. (H. Rose.)

Arsenite of Manganese, $3Mn^2O.2As^2O^3 + 5H^2O$, is obtained, by treating a manganous solution with arsenite of ammonium, as a rose-coloured precipitate, which oxidises rapidly in the air, gives off 1 at. water at 100° C., and at a higher temperature gives off arsenious oxide and metallic arsenic, leaving a residue of manganese and manganous arsenate.

Arsenites of Mercury.—The *mercuric* salt is obtained, by precipitating mercuric nitrate with arsenious acid, as a white powder soluble in nitric acid. It dissolves also in arsenite of potassium, and if the solution contains excess of potash, a black deposit of reduced metal is immediately formed. The *mercurous* salt is obtained by double decomposition, or by digesting mercury in arsenic acid, as a white precipitate soluble in nitric acid.

Arsenite of Nickel.—The salt $2Ni^2O.As^2O^3$ is precipitated on adding arsenite of potassium to a nickel-salt. A less basic salt, $3Ni^2O.2As^2O^3 + 4H^2O$, is produced, according to Girard (Compt. rend. xxxiv. 918), by quickly mixing a solution of chloride of nickel containing a large excess of sal-ammoniac, with arsenite of potassium. It is a greenish precipitate, which gives off 10·3 per cent. (4 at.) water at 110° C. When heated in the air, it first gives off its water, and then yields a sublimate of arsenious oxide, leaving yellow infusible arsenate of nickel:

$$3Ni^2O.2As^2O^3 + O^2 = 3Ni^2O.As^2O^5 + As^2O^3.$$

Arsenite of nickel dissolves with violet colour in ammonia. It is converted by nitric acid into arsenate; by hydrochloric acid into arsenious acid and chloride of nickel.

Arsenite of Potassium.—The *neutral* or *monopotassic salt*, $KAsO^2$, or $K^2O.As^2O^3$, is obtained, by boiling the acid salt for some time with carbonate of potassium, and agitating the residual salt several times with alcohol: it then remains as a syrupy mass (Pasteur). Filhol was not able to prepare it pure. An *acid salt*, $K^2O.2As^2O^3 + 2H^2O$, is obtained, by boiling potash-ley with excess of arsenious acid, whereby an alkaline liquid is produced, which gives with silver-salts a yellow precipitate, $2Ag^2O.As^2O^3$, mixed with arsenious acid, the liquid at the same time becoming acid. On mixing the alkaline liquid with alcohol, it becomes thick and turbid, deposits after a few days right rectangular prismatic crystals, adhering to the sides of vessel and after a longer time solidifies completely to a saline mass. The salt gives off 1 at. water at 100° C., whence it should perhaps be regarded as $2KHAs^2O^4 + H^2O$ (Pasteur). The *basic* or *tetrapotassic salt*, $2K^2O.As^2O^3$, is obtained by mixing the neutral salt with excess of potash-ley and precipitating by alcohol. It is very soluble in water, and yields with silver-salts a yellow precipitate of the diargentic salt, $2Ag^2O.As^2O^3$, the liquid remaining neutral.

Arsenite with Iodide of Potassium.—A solution of iodide of potassium yields with arsenious acid or arsenite of potassium, a precipitate, $2KI.3As^2O^3$, which is sparingly soluble in cold water, dissolves in 19 pts. of boiling water, and decomposes at 315° C., when heated with sulphuric acid (Emmet, Sill. Am. J. [2] xviii. 583). By passing carbonic acid gas into a solution of this salt in a small quantity of boiling water mixed with 3 or 4 times its volume of hot alcohol, and evaporating the resulting syrupy liquid, a crystallised compound is obtained, consisting of $2KI . 3(K^2O.H^2O.As^2O^3)$, or $2(KI.3KAsO^2) + 3H^2O$. This salt is soluble in water and in alcohol, and reacts with metallic salts like a mixture of iodide and arsenite of potassium. Strong sulphuric acid decomposes it, forming a red or yellowish precipitate of arsenious iodide. The hot saturated solution of this salt deposits on cooling, nodular masses, or, when carbonic acid gas is passed through it, a white powder, consisting of the salt $2KI.(K^2O.H^2O.3As^2O^3)$, or $2(KI.KHAs^2O^4).As^2O^3$, which is sparingly soluble in water, and when heated in a narrow glass tube, gives off vapour of water and metallic arsenic, together with arsenious oxide. No iodine is given off unless the air has access to the salt. (E. Harms, Ann. Ch. Pharm. xci. 371.)

Arsenite of Silver.—The *tetrargentic* salt, $2Ag^2O.As^2O^3 = Ag^4As^2O^5$, is formed as a yellow precipitate on treating solutions of silver salts with alkaline arsenites (pp. 361, 375). It gradually turns dark grey when exposed to the air, blackens if exposed to light. When heated, it gives off, according to Simon, first water, then arsenious oxide, and leaves a mixture of arsenate of silver with metallic silver.

Another arsenite of silver is obtained, according to Filhol, as a light yellow precipitate on adding ammonia saturated with arsenious acid to an ammoniacal solution of nitrate of silver. Between 140° and 150° C. it blackens suddenly, without loss of weight, and at a higher temperature melts and gives off arsenious oxide.

It is easily soluble in acetic acid (whereby it is distinguished from phosphate of silver); soluble also in potash. The latter solution is not precipitated by chloride of potassium, but, on the contrary, is capable of dissolving an additional quantity of chloride of silver. It slowly deposits metallic silver, while arsenate of potassium remains in solution. When a solution of chloride of palladium or platinum is mixed with arsenite of potassium, and then with arsenite of silver and potassium, the platinum or palladium separates quickly in the metallic state. (Reynoso.)

Sesqui-argentic Arsenite, $3Ag^2O.2As^2O^3$, or $Ag^2O.4(AgAsO^2)$, is produced as a white precipitate, with evolution of ammonia, when nitrate of silver, mixed with a large excess of nitrate of ammonium, is added by drops to arsenite of potassium. It is blackened by light, dissolves in ammonia and in excess of arsenite of potassium, and when heated blackens, yields a sublimate of arsenious oxide, and leaves a fusible residue of a fine red colour. (E. Harms and others.)

Arsenite of Sodium.—According to Pasteur, the sodium-salts of arsenious acid correspond exactly to the potassium-salts, excepting that the acid salt does not crystallise. Filhol did not obtain the neutral salt in a state of purity.

Arsenite of Strontium, $SrAsO^2 + 2H^2O$.—Strontia-water is not precipitated by aqueous arsenious acid in any proportion, even on boiling (Gmelin). Chloride of strontium is precipitated by arsenite of potassium, but only after some days. The precipitate gives off one-fourth of its water at 100° C.

Arsenites of Tin.—Both the *stannic* and the *stannous* salts are white precipitates; the former is difficult to fuse.

ARSENIC OXIDE, As^2O^5, or AsO^5. In the hydrated state, **ARSENIC ACID.**—This compound is produced by oxidising arsenious oxide or arsenious acid with nitric acid, aqua-regia, hypochlorous acid, or other oxidising agents.—1. When 4 parts of arsenious oxide are gradually added to 3 pts. of nitric acid of specific gravity 1·35, the mixture becomes hot, and after 24 hours yields a syrupy liquid like strong oil of vitriol, consisting of arsenic acid, still containing a little arsenious acid, which may be completely oxidised by the addition of a small quantity of nitric acid. This process is used for the preparation of arsenic acid on the large scale (E. Kopp).—2. Four parts of arsenious oxide are heated with 1 pt. of hydrochloric acid, 12 pts. of nitric acid are gradually added (Mitscherlich), and the resulting solution is evaporated to a syrup. Both the oxidation and evaporation must be performed under a chimney having a good draught, because part of the arsenic is converted into chloride, which escapes in vapour.—3. Arsenic acid is also produced, together with hydrochloric acid, by passing chlorine gas into aqueous arsenious acid.

Arsenic acid forms three hydrates analogous to those of phosphoric acid, viz.:

Monohydrate . . $H^2O.As^2O^5$, or $HAsO^3 = \left.\begin{matrix}(AsO^2)'\\ H\end{matrix}\right\}O$ *

Dihydrate . . $2H^2O.As^2O^5$, or $H^4As^2O^7 = \left.\begin{matrix}\overset{iv}{(As^2O^3)}\\ H^4\end{matrix}\right\}O^4$

Trihydrate . . $3H^2O.As^2O^5$, or $H^3AsO^4 = \left.\begin{matrix}(AsO)'''\\ H^3\end{matrix}\right\}O^3$

The syrupy solution obtained as above, deposits, after standing for some time at 15° C. (60° F.), transparent, rather long prisms or rhomboïdal laminæ, containing $3H^2O.As^2O^5 + H^2O$, or $2H^3AsO^4 + H^2O$;—they deliquesce rapidly in the air, and dissolve in water with great reduction of temperature. Both the water of crystallisation and the basic water may be expelled by heat.

The crystals heated to 100° C., first melt, and then yield the *trihydrate*, H^3AsO^4, as a crystalline precipitate. The same compound may be obtained in large transparent crystals by exposing a concentrated solution of arsenic acid to a very low temperature.

---

* If $O = 8$, the formulæ are $HO.AsO^5$, $2HO.AsO^5$, and $3HO.AsO^5$.

It dissolves easily in water, without reduction of temperature. The *dihydrate*, $H^4As^2O^7$, which may be regarded as a compound of the mono- and tri-hydrates, is obtained by heating the crystallised acid, $2H^3AsO^4.H^2O$, for some time to 140°—160° C.; it then separates in hard shining crystals, leaving a mother-liquor of specific gravity 2·36 at 16° C. It dissolves in water with moderate facility, but the solution is attended with great rise of temperature.

The *monohydrate*, $HAsO^3$, is formed by heating the before-mentioned crystals to 200°, and at last to 206° C.; the mass then suddenly becomes pasty, gives off a large quantity of aqueous vapour, and is ultimately converted into a white nacreous substance consisting chiefly of the monohydrate; it dissolves slowly in cold water, with moderate facility in warm water, producing great evolution of heat. (E. Kopp, Ann. Ch. Phys. [3] xlviii. 196.)

Arsenic Oxide, Arsenic Anhydride, Anhydrous Arsenic Acid, Pentoxide of Arsenic, As^2O^5, is obtained by heating either of the hydrates to dull redness, and remains in the form of a white mass, which has no action upon litmus; is nearly insoluble in water, and in ammonia; and scarcely absorbs water from moist air, even in the course of several days, deliquescing only after a long time. At a full red heat, it is resolved into arsenious oxide and free oxygen.

The solutions of the three hydrates and of the anhydride exhibit exactly the same characters; they have a sour metallic taste, and all contain the trihydrate, the other hydrates being immediately converted into that compound when dissolved in water: in this respect, the hydrates of arsenic acid differ essentially from those of phosphoric acid.

Arsenic oxide is reduced to the metallic state by *charcoal*, *metals*, *cyanide of potassium, &c.*, at a red heat, in the same manner as arsenious oxide. Aqueous arsenic acid dissolves *zinc* and *iron*, with evolution of pure hydrogen; but if sulphuric or hydrochloric acid is present, the arsenic acid is reduced, metallic arsenic, and solid arsenide of hydrogen are deposited, and arsenetted hydrogen gas is evolved (p. 363). An *electric current* passed through aqueous arsenic acid acidulated with sulphuric or hydrochloric acid eliminates arsenetted hydrogen, provided the solution does not contain chlorides (Bloxam). *Sulphurous acid* reduces arsenic acid to arsenious acid, with formation of sulphuric acid. *Hydrosulphuric acid* slowly precipitates trisulphide of arsenic, the action being assisted by heat, or by the presence of another acid. *Hyposulphite of sodium* added to a solution of arsenic acid containing hydrochloric acid, likewise throws down trisulphide of arsenic mixed with sulphur:

$$5Na^2S^2O^3 + 2H^3AsO^4 = As^2S^3 + S^2 + 5Na^2SO^4 + 3H^2O.$$

Arsenic acid and its salts are very poisonous, but not in so high a degree as arsenious acid and the arsenites (Wöhler and Frerichs, Ann. Ch. Pharm. lxv. 335). A strong solution of arsenic acid placed upon the skin produces blisters like burns.

Arsenic acid is now extensively used in calico printing, in place of tartaric acid, for developing white patterns on a coloured ground in the chloride-of-lime vat.

Arsenates.—Arsenic acid is a strong acid, expelling all the more volatile acids from their salts at high temperatures. It is tribasic like ordinary phosphoric acid, the general formula of its salts being M^3AsO^4, in which 1 or 2 at. M may be replaced by hydrogen. The solutions of the *tri*- and *di*-metallic salts, M^3AsO^4, and M^2HAsO^4; (sometimes called *basic* and *neutral*) have an alkaline or neutral reaction; those of the *mono*-metallic (or *acid*) salts, MH^2AsO^4, have an acid reaction. The di- and monometallic arsenates give off their water when heated, but take it up again on being dissolved in water: consequently there are no arsenates corresponding to the pyro- and meta-phosphates.

The arsenates of the alkali-metals are soluble in water; of the others, only the monometallic salts are soluble in water; but the di- and tri-metallic salts dissolve readily in free arsenic acid, and in the stronger mineral acids, less easily in acetic acids: hence solutions of salts of the earth-metals and heavy metals are precipitated by arsenate of potassium, but not by free arsenic acid.

The dimetallic arsenates of barium, strontium, and calcium, are insoluble in water, but soluble in ammoniacal salts; hence solutions containing arsenic acid together with large quantities of ammoniacal salts are not precipitated by the salts of barium, strontium, and calcium. When solutions of metallic salts are precipitated by a dimetallic arsenate of an alkali-metal, an insoluble trimetallic arsenate, M^3AsO^4, is often formed, the liquid at the same time acquiring an acid reaction.

A solution of an arsenate in hydrochloric acid is slowly precipitated by *sulphuretted hydrogen*, the precipitate consisting of trisulphide of arsenic and sulphur in the proportion of the pentasulphide; and if the metallic base of the salt is likewise thrown down by sulphuretted hydrogen from an acid solution, a precipitate is formed consisting of a metallic sulpharsenate. A solution of an *alkaline sulphide*, with subsequent addition of hydrochloric acid, acts in the same manner as sulphuretted hydrogen. An aqueous solution of an arsenate boiled with *hyposulphite of sodium*, deposits trisulphide of arsenic and sulphur on addition of hydrochloric acid. *Potash* withdraws from the insoluble arsenates the whole or part of the arsenic acid.

Solutions of the tri- and di-metallic arsenates of alkali-metal give white precipitates with *baryta-* or *lime-water*, also with salts of *barium*, *strontium*, *calcium*, the *earth-metals*, *manganese*, *zinc*, and *lead*, also with *stannous* and *ferric* salts; yellowish-white with *uranic* and *mercurous* salts, yellow with *mercuric*-salts; rose-coloured with *cobalt*-salts, green with *nickel*-salts; pale greenish blue with *cupric* salts; light brown with *platinic* salts; brown-red with *silver*-salts. These precipitates are for the most part soluble in arsenic, sulphuric, hydrochloric, and nitric acid, and in ammoniacal salts: arsenate of silver, however, is not soluble in ammoniacal salts.

Magnesium-salts mixed with sufficient chloride of ammonium to prevent precipitation by ammonia, give with solutions of arsenates, a white crystalline precipitate of arsenate of magnesium and ammonium, insoluble in aqueous ammonia and in chloride of ammonium; the latter character distinguishes it from the corresponding salt of arsenious acid (p. 377).—Solutions of arsenates added to excess of *molybdate* of ammonium containing nitric acid, form, when the liquid is heated, a bright yellow precipitate of arseno-molybdate of ammonium.—All arsenates dissolved in water or in nitric acid, give with *basic acetate of lead*, a white precipitate of arsenate of lead, which when ignited with charcoal, melts and is reduced, with abundant evolution of metallic arsenic. The last three reactions afford very delicate tests for arsenic acid. The reaction with uranic salts is also very delicate, being perceptible to the twenty-thousandth degree of dilution.

The arsenates are isomorphous with the corresponding phosphates.

Arsenate of Aluminium, $2Al^4O^3.3As^2O^5$, is obtained by double decomposition as a white precipitate, easily soluble in free acid, and remaining as a vitreous mass when the solutions are evaporated.

Arsenate of Ammonium.—The *triammonic* salt, $(NH^4)^3AsO^4$, is obtained by supersaturating a strong solution of arsenic acid with ammonia, as a heavy soluble powder, which, when slightly heated, is quickly converted into the following salt:—The *diammonic* salt, $(NH^4)^2.H.AsO^4$, is formed in the manner just mentioned, and also by saturating a strong solution of arsenic acid with ammonia till a precipitate begins to form; by leaving the solution to evaporate, it is obtained in prismatic crystals of the trimetric system, which effloresce in the air, giving off half their ammonia, but no water. When heated, it decomposes, yielding metallic arsenic, ammonia, water, and nitrogen gas. Its solution has an alkaline reaction. The *monammonic* or *acid* salt, $NH^4.H^2.AsO^2$. is obtained by imperfectly saturating arsenic acid with ammonia. It is deliquescent, very soluble in water, and separates from the solution by spontaneous evaporation in square-based octahedrons. It is decomposed by heat like the preceding. Its solution has a strong acid reaction.

Arsenate of Barium.—The *tribarytic* salt, Ba^3AsO^4, is obtained as a white powder, nearly insoluble in water, by precipitating aqueous arsenic acid with baryta-water (Laugier), or better, by gradually dropping trisodic arsenate into chloride of barium (Graham). The *dibarytic* salt, $2Ba^2HAsO^4$, is obtained when a solution of the disodic salt is added drop by drop to an excess of chloride of barium. If, on the other hand, the arsenate of sodium is in excess, the precipitate formed is a mixture of the di- and tri-barytic salts, while monobarytic arsenate remains in solution. The di-barytic salt contains, according to Mitscherlich, $\frac{1}{2}$ at. water $(2Ba^2HAsO^4 + H^2O)$; according to Berzelius, 2 at. It gives up its water at a red heat. In contact with water, it is resolved into the monobarytic salt, which dissolves, and the tribarytic salt which remains undissolved (Berzelius). The *monobarytic* salt, BaH^2AsO^4, is obtained by adding baryta-water to aqueous arsenic acid till a precipitate begins to form; also by treating the dibarytic salt with water, or better, by dissolving it in aqueous arsenic acid, and leaving the solution to crystallise. If a very large excess of arsenic acid be used, the solution evaporated nearly to dryness, and the mass treated with water, there remains a white powder, consisting of an acid salt containing $Ba^2O.3H^2O.2As^2O^5 + 2H^2O$, or $2BaH^2AsO^4.As^2O^5 + 3H^2O$. (Setterberg.)

Arsenate of Barium and Ammonium, $Ba^2(NH^4)AsO^4 + \frac{1}{2}H^2O$, is obtained by mixing the dibarytic salt with ammonia (Baumann), and $Ba(NH^4)HO^4$, by mixing a solution of nitrate of barium with arsenic acid (Mitscherlich); both salts are formed as bulky precipitates, which become crystalline after a while.

Arsenate of Calcium.—The *dicalcic salt* occurs native, as *Haidingerite*, $2Ca^2HAsO^4 + H^2O$, and *Pharmacolite*, $2Ca^2HAsO^4 + 5H^2O$, and may be prepared like the corresponding barium-salt. The *monocalcic salt* is soluble, the *tricalcic salt* insoluble in water; the latter is obtained by precipitating chloride of calcium in excess with trisodic arsenate. (Graham.)

Arsenate of Calcium and Ammonium, $Ca^2(NH^4)AsO^4 + 6H^2O$, is produced, according to Wach (Schw. J. xii. 285), by mixing a hot solution of arsenic acid in excess of ammonia, with nitrate of calcium, and crystallises on cooling in tables arranged like steps; if the solutions are mixed cold, the salt is precipitated as a powder. Any arsenious acid that may be present remains dissolved. Another salt $Ca(NH^4)HAsO^4$ is obtained by adding ammonia in excess to a solution of dicalcic arsenate in nitric acid, as a flocculent precipitate, soon changing to a mass of needle-shaped crystals. If only enough ammonia be added to precipitate a portion of the salt, and the remaining liquid be left at rest, the same salt is obtained in crystals belonging to the regular system: it is therefore dimorphous. (Baumann.)

Cerous Arsenate, $2Ce^2O.As^2O^5$ (?), is a white powder insoluble in water, but dissolving in arsenic acid as an acid salt, which dries up to a vitreous mass. (Hisinger and Berzelius.)

Chromic Arsenate.—*Chromic* salts yield with arsenate of potassium an apple-green precipitate.

Arsenates of Cobalt.—The *cobaltic* salt is a brown precipitate, obtained by adding arsenate of potassium to a solution of cobaltic hydrate in acetic acid.

Cobaltous Arsenate.—The *tricobaltous salt* occurs in red crystals, as *cobalt-bloom*, $Co^3AsO^4.4H^2O$ (Kersten), a secondary product formed by the weathering of cobaltine (see COBALT-BLOOM); and is obtained artificially as a reddish powder by precipitating cobalt-salts with trisodic arsenate.

A basic arsenate of cobalt, known in commerce as *Chaux métallique*, is prepared: 1. By adding carbonate of potassium to a solution of cobalt-glance in nitric acid or aqua-regia, as long as a white precipitate of ferric arsenate continues to form, then filtering, and treating the filtrate with more carbonate of potassium to precipitate cobaltous arsenate.—2. By fusing cobalt-glance with twice its weight of crude potash and a little quartz-sand, exhausting the fused mass with water, which takes up sulphide of potassium, together with arsenic, iron, and potassium, and again fusing the white regulus with potash, whereby a blue slag is obtained, which is used for the preparation of smalt, and a pure regulus of arsenide of cobalt, which, by careful roasting, is converted into the required basic arsenate.

The product obtained by either of these processes is a reddish powder, which dissolves in ammonia with bluish-red, or in hydrochloric acid with red colour. Caustic potash extracts the arsenic acid and leaves a blue protoxide of cobalt, which, when ignited with 1 or 2 pts. of alumina yields a fine blue pigment.

Gentele, by melting *Chaux métallique*, prepared in the wet way, in a porcelain furnace, obtained a mass, the cavities of which contained deep blue prisms, yielding a rose-coloured powder, easily soluble in acids, and consisting of $4Co^2O.As^2O^5$.

The *dicobaltous* salt is not known. The *monocobaltous* salt is obtained by evaporating in vacuo the solution of cobaltous hydrate in excess of arsenic acid.

Arsenate of Copper, Cu^3AsO^4, is obtained as a green powder by precipitating sulphate of copper with disodic arsenate, the liquid at the same time becoming acid. If the liquid, together with the precipitate, be mixed with a sufficient quantity of ammonia to dissolve the precipitate, and the solution be then left to evaporate, crystals are obtained, consisting of $Cu(NH^4)^2AsO^4 + NH^4.H.O$, which are permanent in the air at ordinary temperatures, but are decomposed by exposure to sunshine, or by a temperature of 300° C., ammonia and water first passing off, and arsenious oxide subliming at higher temperatures.

Several *basic* arsenates of copper occur as natural minerals, viz. $4Cu^2O.As^2O^5$, occurring with 1 at. water as *olivenite*, with $7H^2O$ as *euchroite*, and with $10H^2O$ as *liroconite;* also $5Cu^2O.As^2O^5$, occurring with $2H^2O$ as *erinite*, with $5H^2O$ as *aphanese*, and with $10H^2O$ as *leirochroite* (*Kupferschaum*).

Arsenate of Iridium.—Brown precipitate formed on adding arsenate of sodium to chloride of iridium, and heating.

Arsenates of Iron.—A *ferric arsenate*, $2Fe^4O^3.3H^2O.3As^2O^5 + 9Aq$, or $fe^2HAsO^4 + 3Aq$, is obtained by precipitating ferric chloride with disodic arsenate, as a white powder, which turns red and gives off water when heated. At a red heat it glows slightly, and acquires a more yellowish tint. It dissolves in hydrochloric and in nitric acid, separating as a white powder on evaporation. It is insoluble in acetic acid and in ammoniacal salts. Aqueous ammonia dissolves it immediately when recently precipitated, slowly after drying. The solution when evaporated leaves a ruby-red, transparent, fissured mass, consisting of *ammonio-ferric arsenate*, soluble in ammonia, but decomposed by pure water, which extracts arsenate of ammonium, together with the undecomposed portion of the salt, and leaves ferric arsenate. The ammoniacal solution remains clear when mixed with ferrocyanide of potassium, but on addition of an acid yields Prussian blue. When diferrous arsenate is oxidised with nitric acid and ammonia is added in excess, a precipitate is formed consisting of $Fe^4O^3.As^2O^5$, or fe^3AsO^4, insoluble in ammonia. Potash in large excess extracts part of the acid, leaving a compound of 7 pts. arsenic acid (anhydrous) with 79 pts. ferric oxide, corresponding to the formula $16Fe^4O^3.As^2O^5 + 24H^2O$ (Berzelius). On heating this salt to redness, bright incandescence takes place, but no arsenious oxide is given off.

Iron-cinder is a native ferric arsenate containing $2Fe^4O^3.As^2O^5 + 12H^2O$; *scorodite* is $Fe^4O^3.As^2O^5 + 4H^2O$ or $fe^3AsO^4 + 2H^2O$; *cube-ore* is a *ferroso-ferric arsenate* = $Fe^2O.Fe^4O^3.As^2O^5 + 6H^2O$; *pittizite* or *brown iron ore* is a ferric arsenate, $2Fe^4O^3.As^2O^5 + 12H^2O$, combined, or perhaps only mixed, with ferric sulphate and water.

b. *Ferrous Arsenate* is obtained by precipitation as a white powder, which assumes a dirty green colour when exposed to the air.

Arsenate of Lead.—The *triplumbic* salt, Pb^3AsO^4, is prepared by dropping a solution of a lead-salt into excess of disodic arsenate, or by digesting the diplumbic salt with ammonia. When heated, it turns yellow and cakes together, but does not melt. Insoluble in ammonia and ammoniacal salts. A *tetraplumbic* salt, $2Pb^2O.As^2O^5$, or $Pb^4As^2O^7$, is precipitated on mixing a solution of nitrate of lead with arsenic acid, or with less than the equivalent quantity of di-ammonic, dipotassic, or disodic arsenate. It is a white crystalline powder, insoluble in water and in acetic acid, soluble in nitric and in hydrochloric acid.

Arseno-chloride of Lead.—In many varieties of *pyromorphite*, $PbCl.3Pb^3PO^4$, the phosphorus is more or less replaced by arsenic.

Arsenate of Magnesium.—The *trimagnesic* salt, Mg^3AsO^4, is formed by precipitating sulphate of magnesium with disodic arsenate, or by boiling the dimagnesic salt for a long time with a strong solution of arsenate of sodium.—The *dimagnesic* salt, $2Mg^2HAsO^4 + 13H^2O$ (Graham), is formed as a white insoluble precipitate on mixing the dilute solutions of 3 pts. sulphate of magnesium, and 5 pts. disodic arsenate. In the recent state, it dissolves easily in nitric acid, but it is insoluble in acids after ignition. The *monomagnesic* salt dissolves readily in water, and dries up to a gummy mass.

Arsenate of Magnesium and Ammonium, $Mg^2(NH^4)AsO^4 + 6H\ O$, is obtained as a crystalline precipitate by adding arsenic acid strongly supersaturated with ammonia to a solution of a magnesium-salt mixed with sal-ammoniac. At 100° C. it gives off $\frac{11}{12}$ of its water (44·28 per cent.), together with ammonia and a certain portion of arsenic. Like the corresponding phosphate, it is almost insoluble in water containing ammonia, or in sal-ammoniac, and is therefore well adapted for the estimation of arsenic acid, and for separating that acid from arsenious acid. (H. Rose, p. 367.)

An *arsenate of Magnesium and Calcium*, containing $Ca^2HAsO^4.Mg^2HAsO^4 + Ca^3AsO^4.Mg^3AsO^4 + 5H^2O$, occurs native as *picropharmacolite.*

Arsenate of Magnesium and Potassium, Mg^2KAsO^4, is produced by fusing arsenate of magnesium with excess of carbonate of potassium, and adding 1 at. hydrate of potassium: it is easily decomposed by water. The corresponding *sodium-salt* is obtained in like manner.

Arsenate of Manganese, Mn^2HAsO^4, is obtained by saturating arsenic acid with recently precipitated carbonate of manganese.

Arsenate of Manganese and Ammonium, $Mn^2(NH^4)AsO^4 + 6H^2O$.—Reddish-white precipitate, gummy at first, afterwards becoming crystalline: obtained like the corresponding magnesium-salt.

Arsenates of Mercury.—A *mercuric arsenate* is obtained as a yellow precipitate on adding arsenic acid to mercuric nitrate, or arsenate of sodium to mercuric chloride. The same yellow salt is produced, with volatilisation of arsenious oxide, when arsenic oxide is heated with mercury.

Di-mercurous arsenate, $2Hg^4O.H^2O.As^2O^5 + H^2O$, or $Hhg^2.H.AsO^4 + \frac{1}{2}H^2O$ *, is obtained by dropping mercurous nitrate into a strong solution of arsenic acid, as a white precipitate, which turns red in drying. When, on the other hand, arsenic acid or arsenate of sodium is added to the mercurous solution, a double salt of arsenate and nitrate of mercurosum is first formed; but it quickly decomposes, especially if heated, assuming a yellow, orange, red, and ultimately purple tint. When either of these precipitates is dissolved in warm nitric acid, and the acid is gradually neutralised with ammonia, a black precipitate is formed, which turns red when heated for some time.

Dimercurous arsenate is composed of fine needles, sometimes brown-red, sometimes purple-red. When dried at 100° C., and then more strongly heated, it first gives off

---

* Hhg = Hg = 200.

a little water, then mercury, and leaves yellow mercuric arsenate, which, at a higher temperature, is resolved into mercury, arsenious oxide, and free oxygen. With cold concentrated hydrochloric acid, it yields a solution of arsenic acid, and a residue of calomel, which is resolved by boiling into mercury and soluble mercuric chloride. It is converted into mercuric arsenate by boiling with nitric acid, but dissolves unchanged in that acid when cold, the solution being precipitated by ammonia. It dissolves slightly in aqueous nitrate of ammonium, and separates on evaporation with fine red colour and crystalline structure. It is quite insoluble in water, acetic acid, and ammonia. (Simon, Pogg. Ann. xli. 424.)

Monomercurous arsenate, $HhgAsO^3$, or $Hg^4O.As^2O^5$, is produced by boiling mercuric oxide, or the di-mercurous salt, to dryness with aqueous arsenic acid, triturating the dry mass when cold with water, washing the powder, and drying it over the water-bath, whereby the whole of the water is expelled. It is white and amorphous, gives off mercury at a red heat, and leaves mercuric arsenate, which then undergoes further decomposition. By careful addition of potash, it is converted into the dimercurous salt. With hydrochloric acid and with boiling nitric acid, it behaves like the dimercurous salt. In cold nitric acid it dissolves less abundantly than the latter, and on heating with gradual addition of ammonia, it yields a precipitate of the dimercurous salt. It is insoluble in water, acetic acid, and alcohol. (Simon.)

A double salt, consisting of *arsenate* and *nitrate of mercurosum*, $Hhg^4As^2O^7.2HhgNO^3$ is obtained, when water is carefully poured upon an equal volume of a strong solution of mercurous arsenate in moderately strong nitric acid, and an equal volume of aqueous ammonia then added, without allowing the liquids to mix. The double salt is then gradually deposited in white nodules and needles. If the mercurous nitrate be mixed with a very small quantity of nitric acid, the compound is obtained in the form of powder. (Simon.)

Arsenate of Molybdenum.—*Molybdous Arsenate* is a grey precipitate, produced by mixing molybdous chloride with arsenate of sodium. The precipitate redissolves at first, but afterwards becomes permanent.

Arseno-molybdic Acid.—Arsenic and molybdic acids digested together yield a colourless acid solution, and a lemon-yellow basic salt, insoluble in water. The solution evaporated to a syrup, yields colourless crystals, which when treated with alcohol, first yield white flocks, and then dissolve.

Arseno-molybdate of Ammonium.—On adding arsenic acid to a solution of molybdate of ammonium and heating to 100° C., a yellow precipitate is formed, similar to that produced by phosphoric acid. It contains 7 per cent. arsenic, and appears to be analogous to phospho-molybdate of ammonium. (See PHOSPHORIC ACID.)

Arsenate of Nickel, Ni^3AsO^4, occurs as *nickel-bloom*, and is obtained by double decomposition as an apple-green crystalline powder, insoluble in water, soluble in arsenic acid and in other strong acids, also in ammonia; from the latter solution potash throws down hydrate of nickel free from arsenic.

Arsenate of Palladium.—Light yellow precipitate obtained by heating together the solutions of neutral nitrate of palladium and arsenate of sodium.

Arsenate of Platinum.—Light brown powder soluble in nitric acid, obtained by precipitating platinic nitrate with arsenate of sodium.

Arsenate of Potassium.—The *tripotassic* salt, K^3AsO^4, is obtained, by mixing aqueous arsenic acid or the neutral salt with potash-ley, and strong concentration, in small needles, which deliquesce quickly in the air. The *dipotassic salt*, K^2HAsO^4, is a deliquescent non-crystalline mass, produced by saturating arsenic acid with potash, or by fusing arsenious oxide with hydrate of potassium.

The *monopotassic salt*, KH^2AsO^4 (Macquer's *arsenikalisches Mittelsalz*), is prepared: 1. By deflagrating arsenious oxide with an equal weight of nitre, dissolving the fused mass in water, and leaving the solution to crystallise.—2. By mixing aqueous carbonate of potassium with such a quantity of arsenic acid, that the solution reddens litmus-paper but the redness disappears as the paper dries, and then evaporating.—3. A mixture of potash-ley and arsenic acid neutral to vegetable colours, deposits the monopotassic salt when partially evaporated, the alkaline dipotassic salt remaining in solution (Mitscherlich). Monopotassic arsenate is isomorphous with the corresponding phosphates of potassium and ammonium, and with monammonic arsenate. The crystals have a specific gravity of 2·638; they are permanent in the air, and give off but little water, even at 288° C., but at a red heat they melt, give off water, and are converted into a thin liquid, which on cooling solidifies into a white mass, cracked in all directions. They dissolve in 5·3 pts. of water at 6° C., forming a solution of specific gravity, 1·1134; they are much more soluble in hot water, but insoluble in alcohol. The aqueous solution reddens litmus, but the redness disappears on drying.

It does not precipitate the salts of barium, calcium, magnesium, or the other earth-metals.

Arsenate of Rhodium.—Yellowish-white precipitate formed by heating arsenate of sodium with chloride of rhodium and sodium.

Arsenate of Silver.—The *tri-argentic salt*, Ag^3AsO^4, is the only one that can be obtained by precipitating nitrate of silver with soluble arsenates; it is a dark brown precipitate which melts to a brown-red glass when heated, is converted into chloride of silver by hydrochloric acid, dissolves in acetic acid and aqueous ammonia, and when heated, in sulphate, nitrate and succinate of ammonium. It dissolves also in aqueous arsenic acid, and the solution, if left to evaporate, deposits the *monargentic* salt, AgH^2AsO^4. Both this salt and the mother-liquor from which it has separated, are decomposed by water, yielding the brown triargentic salt.

The triargentic salt treated with sulphuric acid yields by evaporation a double salt, $Ag^4As^2O^7.Ag^2SO^4$, which is decomposed by water and by dilute sulphuric acid. (Setterberg.)

Arsenate of Sodium.—The *trisodic salt*, $Na^3AsO^4 + 12H^2O$ is prepared by fusing 1 at. of the disodic salt with carbonate of sodium, or by mixing the aqueous solution of arsenic acid with excess of carbonate of sodium, and evaporating to a small bulk. The salt then crystallises almost completely, the excess of soda remaining dissolved. The crystals are right rhombic prisms permanent in the air; they have an alkaline taste, melt at 86° C., and dissolve in $3\frac{1}{2}$ pts. of water, the solution as well as the ignited salt absorbing moisture from the air. The *disodic salt*, $Na^2HAsO^4 + 12H^2O$, separates from a solution of arsenic acid slightly supersaturated with carbonate of sodium, and left to evaporate below 18° C., in large efflorescent crystals isomorphous with ordinary phosphate of sodium. By leaving a more concentrated solution to crystallise at 20° C. or above, crystals are obtained belonging to the monoclinic system, containing 14 at. water, and not efflorescent. Both kinds of crystals give off the whole of their crystallisation-water, at 200° C., melt easily at a higher temperature, and give off their basic water, leaving the anhydrous salt, $2Na^2O.As^2O^5$, or $Na^4As^2O^7$; this anhydrous salt, however, recovers its basic water when redissolved. According to Setterberg, a salt with 26 at., water of crystallisation separates from a solution cooled to 0° C.

The *monosodic salt*, NaH^2AsO^4, is formed when arsenic acid is added to carbonate sodium till the solution no longer precipitates chloride of barium; it crystallises out after a while in the cold. It is more soluble than the disodic salt, and forms large crystals isomorphous with the corresponding phosphate.

Arsenate of Sodium and Ammonium, $Na(NH^4)HAsO^4 + 4H^2O$, is obtained by mixing the solutions of the di-ammonic and disodic salts, in crystals exactly resembling those of the corresponding phosphate (microcosmic salt). When heated to redness, they leave monosodic arsenate. (Mitscherlich.)

Arsenate of Sodium and Potassium, $KNaHAsO^4 + 16H^2O$. (Mitscherlich).—Obtained by neutralising the monosodic salt with carbonate of potassium. The crystals contain, according to Mitscherlich's analysis, 43·88 per cent. water, the preceding formula requiring 44·16 per cent.; but as they appear to be ismorphous with the disodic salt containing 14 at., L. Gmelin (Handbook iv. 299) considers it probable that they also contain the same quantity of water.

Arseno-fluoride of Sodium, $Na^3AsO^4.NaF + 12H^2O$.—Prepared by gradually introducing a mixture of 1 pt. arsenious oxide, 4 pts. carbonate of sodium, 3 pts. nitrate of sodium, and 1 pt. fluor-spar, into a red-hot crucible, and ultimately heating to complete fusion. On boiling the fused mass with water and filtering, the double salt crystallises out in regular octahedrons, exactly like common alum. They have a specific gravity of 2·849 at 21° C., dissolve in 9·5 pts of water, at 25° C., and in 2 pts. at 75° C. (Briegleb, Ann. Ch. Pharm. xcvii. 95.)

Arsenosulphate of Sodium.—A solution of 3 at. Na^2HAsO^4, mixed with 1 at. sulphuric acid, yields crystals containing $Na^8As^6O^{19}.2Na^2SO^4$, or $4Na^2O.3As^2O^5 + 2(Na^2O.SO^3)$; their solution slightly reddens litmus, but still turns turmeric brown (Mitscherlich). By dissolving sulphate of sodium and disodic arsenate together in equivalent proportions, or by heating anhydrous disodic arsenate in a current of sulphurous anhydride (half the arsenic acid being then reduced to arsenious acid, which volatilises), and subsequent recrystallisation, a salt is obtained, composed of $Na^2SO^4.Na^4As^2O^7$, which does not alter by exposure to the air, and fuses more easily than either of its component salts. (Setterberg.)

Arsenate of Strontium, Sr^2HAsO^4.—Resembles the barium-salt. By precipitating its solution in nitric acid with excess of ammonia, a double salt is produced containing $Sr(NH^4)AsO^4 + \frac{1}{2}H^2O$.

Arsenate of Thorinum, is obtained by double decomposition, as a white flocculent precipitate, insoluble in water and in the aqueous acid.

Arsenate of Titanium.—Arsenic acid added to solution of titanic oxide, throws down white flocks, which dry up to vitreous masses, and are soluble in free titanic acid, as well as in arsenic acid.

Arsenates of Tin.—The *stannic* salt, $2SnO^2.As^2O^5 + 10H^2O$, or $(\overset{''}{Sn})^2As^2O^8.10H^2O$, is precipitated as a gelatinous mass when a mixed solution of stannate and excess of arsenate of sodium is treated with excess of nitric acid. It is transparent when dry, and gives off all its water at 120° C. (Haeffely, Phil. Mag. [4] x. 290.)

Stannous Arsenate is a white precipitate obtained by adding arsenic acid to stannous chloride or acetate. Tin heated with aqueous arsenic acid eliminates hydrogen and forms a gelatinous mass.

Arsenates of Uranium.—*Uranic arsenate*, or *Arsenate of Uranyl*, $(U^2O)^2HAsO^4 + 4H^2O$, is formed by precipitating uranic acetate with arsenic acid, or uranic nitrate with arsenate of sodium. It is a yellow precipitate which gives off its water at 120° C.

A *sodio-uranic nitrate*, $(U^2O)NaAsO + \frac{5}{2}H^2O$, is obtained by mixing a solution of uranic nitrate with trisodic arsenate; and by boiling uranic arsenate with solution of basic acetate of copper (obtained by digesting verdigris with water), a green *cupro-uranic arsenate* is formed, containing $(U^2O).CuAsO^4 + 4Aq$. (Werther.)

Uranous Arsenate, $U^2HAsO^4 + \frac{3}{2}H^2O$, is a green precipitate obtained by treating uranous chloride with disodic arsenate. It dissolves in hydrochloric acid, and the solution mixed with excess of ammonia yields a very bulky precipitate of *tri-uranous arsenate*, U^3AsO^4. (Rammelsberg, Pogg. Ann. lix. 96.)

Arsenates of Vanadium.—A solution of vanadic hydrate in excess of arsenic acid yields by evaporation, a crust of blue crystalline granules, containing 1 at. vanadic oxide (VO) to 1 at. anhydrous arsenic acid. It dissolves very slowly in water, but easily in hydrochloric acid. A more basic salt is obtained as a syrupy mass, mixed with crystals of the preceding salt, by evaporating a solution of arsenic acid saturated with vanadic oxide.

If the solution of the crystalline compound in nitric acid be evaporated till nitrous acid begins to escape, a yellow powder is deposited, which is a compound of vanadic and arsenic anhydrides, $2V^2O^5.3As^2O^5$.

Arsenate of Yttrium.—The *di-yttric* salt obtained by precipitation is a white heavy powder, which dissolves in nitric acid, and separates therefrom in crystalline grains. The nitric acid solution supersaturated with ammonia yields the *tri-yttric* salt. Yttria dissolves in excess of arsenic acid, but the solution when heated deposits the di-yttric salt.

Arsenate of Zinc.—Acetate of zinc treated with arsenic acid or arsenate of sodium, yields a white precipitate, which dissolves in excess of arsenic acid, and separates on evaporation in cubical crystals of an acid salt. Zinc dissolves in aqueous arsenic acid, with evolution of arsenetted hydrogen, and deposition of metallic arsenic mixed with brown solid arsenide of hydrogen. When zinc and arsenic oxide are fused together, a large quantity of arsenic is reduced, with slight detonation.

Trizincic Arsenate, $Zn^3AsO^4 + 4H^2O$, occurs as *Köttigite* in the Daniel cobalt mine near Schneeberg in Saxony, forming monoclinic crystals, or crusts with crystalline structure. Specific gravity 3·1. Hardness 2·5—3. It is of light carmine or peach-blossom colour, translucent, and gives a reddish-white streak. The zinc is partly replaced by cobalt and nickel. Analysis 37·2 per cent. As^2O^5, 30·5 Zn^2O, 6·9 Co^2O, 2·00 Ni^2O, with trace of lime, and 23·4 water. (Köttig, J. pr. Chem. xlvii. 183; Naumann, *ibid.* 256.)

Sulphate of zinc added to a solution of arsenate of sodium containing ammonia produces a precipitate of trizincic arsenate, which soon changes to a crystalline compound containing, according to Bette, $Zn^3AsO^4.NH^3.\frac{3}{2}H^2O$ (?)

Arsenate of Zirconium.—White precipitate insoluble in water.

ARSENIC, OXYBROMIDE OF. *Bromarsenious Acid.* AsBrO.—Arsenious oxide dissolves easily and abundantly in fused arsenious bromide, forming a somewhat viscid dark-coloured liquid, which does not solidify so quickly as the pure bromide. If this liquid be distilled till it becomes rather thick and then allowed to cool to about 150° (C. or F.?) it separates into two layers, the lower of which is a soft dark-coloured mass, consisting of the oxybromide AsBrO, while the upper, which is very viscid, is a compound of the oxybromide with arsenious oxide, probably $6AsBrO.As^2O^3$; both these bodies are decomposed by heat, giving off bromide of arsenic (W. Wallace, Phil. Mag. [4] xvii. 122). An oxybromide of arsenic is likewise formed by the action of water on the bromide (Serullas). When bromide of arsenic is boiled with a quantity of water containing hydrobromic acid not sufficient to dissolve it, the undissolved portion is converted into oxybromide. A cold solution of bromide of arsenic in water containing hydrobromic acid, yields, by evaporation over sulphuric acid, thin white pearly crystals, consisting of hydrated oxybromide, $2AsBrO.3H^2O$. A solution of bromide of arsenic in water, prepared at the boiling heat, deposits on cooling crystals of arsenious oxide; but if the water contains a large quantity of hydrobromic acid, the solution deposits on cooling ,white flocks of a compound, which after drying between filter-paper, consists of $2AsBrO.3As^2O^3 + 12H^2O$.—When bromide of ammonium is added to a cold concentrated solution of bromide of arsenic, six-sided tables are slowly deposited, consisting mainly of anhydrous bromide of arsenic. (Wallace, *loc. cit.*)

ARSENIC, OXYCHLORIDE OF. *Chlorarsenious Acid.* $AsClO$, or $AsCl^3.As^2O^3$. —Pulverised arsenious oxide added in successive portions to boiling chloride of arsenic continues to dissolve till the liquid contains 2 at. chloride to 1 at. oxide. The same solution is obtained by passing dry hydrochloric acid gas into a vessel containing dry arsenious oxide till the latter is dissolved: great heat is evolved during the reaction. On distilling the solution obtained by either process, till it begins to froth, and leaving the residue to cool, oxychloride of arsenic separates as a viscid, translucent, brownish mass, which fumes slightly in the air, and absorbs oxygen from it, froths when strongly heated, giving off chloride of arsenic, and at the subliming temperature of arsenious oxide, leaves a hard vitreous residue, consisting of $AsClO.As^2O^3$.

Oxychloride of arsenic is likewise produced when chloride of arsenic is treated with a quantity of water not sufficient to dissolve it completely. A solution of chloride of arsenic in the smallest possible quantity of water ($8H^2O$ to $1AsCl^3$) deposits, after some days, small, white, needle-shaped crystals, grouped in stars or like prehnite, and consisting of $AsClO.H^2O$; the mother-liquor yields an additional quantity when mixed with chloride of sodium.

Oxychloride of arsenic unites with metallic chlorides. By mixing aqueous chloride of arsenic with a quantity of hydrochloric acid sufficient to prevent the separation of oxychloride, and then adding a lump of sal-ammoniac, crystals of that salt separate out at first, and after a few days, fibrous needles of the compound $AsClO.2NH^4Cl$, apparently containing ½ at. H^2O, which is given off when the crystals are left over sulphuric acid. (Wallace Phil. Mag. [4] xvi. 358.)

ARSENIC, OXYIODIDE OF. $As^8I^2O^{11} = 2AsIO.3As^2O^3$.—A hot aqueous solution of arsenious iodide deposits, when concentrated by boiling, fine red needles of the anhydrous iodide; but if left to cool slowly, it deposits thin pearly laminæ, which after drying between bibulous paper, are composed of $2AsIO.3As^2O^3 + 6H^2O$, and give off all their water over sulphuric acid. They are decomposed by water, and when heated yield a sublimate chiefly consisting of iodide of arsenic, while arsenious oxide remains behind (Wallace, Phil. Mag. [4] xvii. 122). The formation of this compound had previously been observed by Plisson and by Serullas and Hottot, who regarded it as a compound of arsenious oxide with arsenious iodide. (Gm. iv. 282.)

ARSENIC, OXYSULPHIDE OF. See SULPHOXARSENATE OF POTASSIUM (p. 395).

ARSENIC, SULPHIDES OF. The sulphides of arsenic are more numerous than the oxides. There are three well defined sulphides, AsS, As^2S^3, and As^2S^5 [or AsS^2, AsS^3, and AsS^5, if $S = 16$], all of which act as sulphur-acids. The first two occur as natural minerals, *realgar* and *orpiment*, and may also be obtained in the free state by artificial processes; the third is known only in combination. Besides these compounds, there is a *subsulphide*, $As^{12}S$ (?), which remains as a brown powder when the disulphide AsS is digested with caustic alkalis; and, according to Berzelius, a *persulphide*, AsS^9, obtained in yellow crystalline scales, by mixing a solution of dipotassic or disodic sulpharsenate with alcohol, and evaporating to about two-thirds; but the product thus obtained is most probably a sulpharsenate with excess of sulphur. When arsenious oxide is fused with sulphur, sulphurous anhydride is evolved, and a sulphide of arsenic containing excess of sulphur remains. On distilling this residue, sulphur passes over, accompanied by a continually increasing quantity of arsenic. Much of the ordinary sulphur of commerce is a compound of this nature.

DISULPHIDE OF ARSENIC. AsS. *Realgar, Red Orpiment,* or *Ruby Sulphur; rothes Rauschgelb, Arsenic sulphuré rouge, Risigallo; Sandaraca* of Pliny and Vitruvius; σανδαρακη of Theophrastus and Dioscorides. In combination: HYPOSULPHARSENIOUS ACID.—This compound occurs native as realgar, crystallised in oblique rhombic prisms of the monoclinic system, having an orange-yellow or aurora-red colour, resinous lustre, and more or less translucent: streak varying from orange-red to aurora-red; fracture conchoïdal, uneven; sectile. Specific gravity = 3·4 to 3·6.

Hardness = 1·5 to 2. It is found accompanying ores of silver and lead, at Andreasburg in the Harz, Kapnik and Nagyag in Transylvania, Felsöbanya in Hungary, Joachimsthal in Bohemia, and Schneeberg in Saxony. At Tajowa in Hungary, it occurs in beds of clay; at St. Gothard imbedded in dolomite; near Julamerk in Koordistan; also in the Vesuvian lavas, in minute crystals. Strabo speaks of a mine of *sandaraca* at Pompeiopolis, in Paphlagonia. (Dana.)

Disulphide of arsenic may be prepared by melting metallic arsenic with sulphur or orpiment, or sulphur with arsenious oxide, in the required proportions. As thus obtained, it is transparent and of a ruby-colour, easily fusible, and crystalline after solidification from fusion. An impure product is prepared on the large scale by heating in a subliming apparatus a mixture of arsenical pyrites and iron-pyrites, and melting the product with arsenic or sulphur, according as a darker or lighter colour is desired. This commercial product is amorphous, usually brown-red, opaque, and of variable composition, generally containing arsenious oxide. It is used as a pigment, though not so much now as formerly.

Disulphide of arsenic burns in the air with a blue flame, forming sulphurous and arsenious oxides. When deflagrated with nitre, it produces a bright white light. *Indian white fire* is a mixture of 24 pts. nitre, 7 pts. sulphur, and 2 pts. realgar. The disulphide heated with nitric acid, yields arsenic acid and free sulpur. With strong *sulphuric acid*, it forms sulphurous and arsenious acids. When it is digested in fine powder with *potash-ley*, part dissolves and there remains a brown powder consisting of $As^{12}S$. (?)

HYPOSULPHARSENITES.—These are sulphur-salts formed by the mixing of disulphide of arsenic with basic sulphides. They are for the most part sparingly soluble in water. The little that is known of them is due to the researches of Berzelius.

The *ammonium-salt* is deposited in small dark brown granules on the sides of a closed vessel in which neutral sulpharsenite of ammonium is kept for a long time. It absorbs ammonia-gas, but gives it off again on exposure to the air.

Hyposulpharsenite of Potassium.—The colourless liquid obtained by boiling trisulphide of arsenic with moderate concentrated carbonate of potassium, deposits in the course of 12 hours, brown-red flocks of the salt $K^2S.AsS$, or K^2AsS^2. If this compound be washed with a small quantity of cold water till it swells up to a jelly, and then treated with more water, the greater part dissolves, forming a red solution of the salt, $3K^2S.2AsS$, and leaving an insoluble dark-brown powder consisting of $K^2S.4AsS$, which melts easily when heated, and solidifies on cooling to a transparent dark red mass. The basic salt $3K^2S.2AsS$, remains perfectly soluble in water, even after complete drying.

The *sodium hyposulpharsenites* resemble those of potassium.

Other hyposulpharsenites are obtained by precipitation. The *barium* and *calcium salts* are red-brown; the *magnesium-salt* is brown; the *manganese-salt* dark red.

TRISULPHIDE OF ARSENIC, or ARSENIOUS SULPHIDE. In combination: SULPHARSENIOUS ACID. **As^2S^3, or AsS^3.** *Orpiment, Yellow Sulphide of Arsenic, Gelbes Rauschgelb, Risigallum, Auripigmentum* (Vitruvius); *Arsenicum* (Pliny); **'Αρσένικον** (Dioscorides); **'Αῤῥένικον** (Theophrastus).—This sulphide occurs native in rhombic prisms belonging to the trimetric system, easily splitting parallel to ∞P∞ into thin flexible laminæ. They are translucent, of lemon-yellow colour, inclining to orange-yellow, with pearly lustre on the cleavage-faces, resinous elsewhere; powder lemon-yellow; specific gravity 3·459 (Karsten), 3·48 (Mohs, Haidinger), 3·4 (Breithaupt).

Trisulphide of arsenic is obtained in the pure state by passing hydrosulphuric acid gas into a solution of arsenious acid or an arsenite acidulated with one of the stronger acids. As thus prepared, it has a fine lemon-yellow colour, becoming darker by heat, and produces an orange-yellow powder: it melts easily and volatilises at a higher temperature.

An impure trisulphide is prepared on the large scale by subliming 7 parts of pulverised arsenious oxide with 1 pt. of sulphur. It always contains more or less oxide, inasmuch as to convert that compound completely into trisulphide requires 7·3 pts. of sulphur to 10 pts. of the oxide: hence this preparation is much more poisonous than the pure artificial sulphide or the native sulphide. It was formerly much used as a pigment, under the name of *King's yellow*, but is now almost entirely superseded by chrome-yellow. The arsenious oxide may be extracted from it by boiling with water, or with dilute aqueous acids, or cream of tartar.

Arsenious sulphide is also used in calico printing, the pattern being printed with a preparation containing arsenious acid, and then passed through water containing hydrosulphuric acid. A solution of orpiment in potash-ley is used in dyeing as a deoxidising agent, especially for reducing indigo. A paste composed of slaked lime, orpiment, and water, is employed by some nations as a depilatory for removing the beard; but it is a dangerous preparation, and, according to Böttger may be replaced for this purpose by sulphydrate of calcium.

Decompositions.—1. Arsenious sulphide, like all the other sulphides of arsenic, is converted by *oxidising agents* into oxides of sulphur and arsenic. When it is fused with *acid sulphate of potassium*, sulphurous oxide (SO^2) is given off, and arsenite of potassium remains mixed with neutral sulphate.—2. Exposed to the action of *chlorine gas*, it becomes heated, and deliquesces to a brown liquid consisting of a sulphochloride of arsenic, $As^2Cl^6S^3$ (H. Rose).—3. The vapour of arsenious sulphide passed over red-hot *iron*, *silver*, and other metals, is decomposed, yielding a metallic sulphide and free arsenic, which, if the other metal is in excess, unites with it.

4. When the vapour is passed over red-hot lime, arsenic is separated, and arsenate of calcium is produced, together with sulphide of calcium.

5. Arsenious sulphide heated with *carbonate of potassium* or *sodium* in a glass tube, yields a mirror of arsenic, together with sulpharsenate and arsenate of the alkali-metal. If the mixture is heated in an atmosphere of *hydrogen*, or with addition of *charcoal*, the arsenical mirror is increased by the arsenic reduced from the arsenate; the sulpharsenate remains undecomposed. (H. Rose, Pogg. Ann. xc. 565.)

6. When arsenious sulphide is heated in a test-tube with a mixture of *alkaline carbonate* and *cyanide of potassium*, the whole of the arsenic is reduced, according to Fresenius; only part of it, according to H. Rose, because the sulphur-salt of arsenic formed at the same time resists the action of the cyanide of potassium. Hence arsenious sulphide fused with cyanide of potassium and excess of sulphur does not yield any arsenical mirror. The formation of the mirror may also be prevented by the presence of other easily reducible metals, which convert the arsenic into an arsenide, and do not give it up.

7. When arsenious sulphide is boiled with the solution of an *alkaline carbonate*, and the concentrated solution is filtered, a clear liquid is obtained, which deposits a brown powder, consisting of hyposulpharsenite of the alkali-metal, while a sulpharsenate remains in solution. A similar decomposition takes place when a soluble neutral sulpharsenite is treated with water.

8. Arsenious sulphide is readily dissolved by cold caustic potash, soda, or ammonia, undergoing exactly the same decomposition as antimonious sulphide under similar circumstances (p. 322), the oxygen of the alkali converting the arsenic into arsenious acid, while the alkali-metal unites with the sulphur, and the basic sulphide thus formed combines with the rest of the arsenious sulphide:

$$4As^2S^3 + 5K^2O = 3(K^2S.As^2S^3) + 2K^2O.As^2O^3$$

On adding an acid to this solution, no sulphuretted hydrogen is evolved, but the whole of the sulphur and arsenic are separated as arsenious sulphide:

$$3(K^2S.As^2S^3) + 2K^2O.As^2O^3 + 10HCl = 10KCl + 5H^2O + 4As^2S^3$$

SULPHARSENITES.—Arsenious sulphide unites with basic metallic sulphides in three different proportions, forming, with potassium, for example, the compounds $3K^2S.As^2S^3$ or K^3AsS^3, $2K^2S.As^2S^3$ or $K^4As^2S^5$, and $K^2S.As^2S^3$ or $KAsS^2$ [or $3KS.2AsS^3$, $2KS.AsS^3$, and $KS.AsS^3$.—Of these, the *dibasic* or *tetrametallic* salts are the most common, and are regarded as neutral or normal sulpharsenites.

The soluble sulpharsenites are prepared: 1. By igniting sulpharsenates out of contact with the air, 2 at. sulphur then escaping.—2. by dissolving arsenious sulphide in an alkaline sulphide or sulphydrate; in the latter case, sulphuretted hydrogen is evolved.—3. By dissolving arsenious sulphide in a cold solution of caustic alkali.—4. By dissolving arsenious oxide in an alkaline sulphydrate, in which case half of the alkali is converted into arsenite; *e. g.*:

$$As^2O^3 + 2KHS = KAsS^2 + KAsO^2 + H^2O.$$

The only sulpharsenites that are soluble in water are those of the alkali-metals, alkaline earth-metals, and magnesium, and even these are decomposed by water, unless the water is in considerable quantity. Hence the solutions cannot be evaporated to dryness without decomposition. The solutions are colourless or yellowish, tasting hepatic at first, and afterwards disgustingly bitter.—5. The sulpharsenites of the earth-metals and heavy metals are obtained by precipitating a solution of the corresponding compound of an alkali-metal, obtained by either of the methods 2, 3, 4, with a salt of the earth-metal or heavy metal. (Berzelius.)

The sulpharsenites are either yellow or red. Most of them, when ignited out of contact of air, give off all their sulphur-acid; others give up such a quantity that the residue contains 3 at. sulphur-base to 1 at. sulphur-acid; but the sulpharsenites of the alkali-metals, even those which contain equal numbers of atoms of base and acid, give off nothing when ignited. The alkali-metal compounds obtained by the first method, when treated with a small quantity of water, and the dilute solutions obtained by method 2, 3, or 4, when they evaporate in the air, are resolved into brown hyposulpharsenite which is precipitated, and sulpharsenate which remains in solution; but the decomposition is not complete till the solution is concentrated to the crystallising point of the latter salt. If the decomposed mass be digested in a large quantity of water and boiled, the whole is reconverted into sulpharsenite and redissolved. The solutions of the barium, strontium, calcium, and magnesium salts, containing 1 at. base to 1 at. acid, deposit, on boiling, a portion of the arsenious sulphide; the ammonium, potassium, sodium, and lithium compounds remain undecomposed. On adding alcohol to the aqueous solution of a compound of 1 at. of arsenious sulphide with 2 at. of the sulphide of an alkali-metal, a compound containing 3 at. of sulphur-base is precipitated, while a compound containing 1 at. of sulphur-base remains in solution:

$$2(2K^2S.AsS^3) = 3K^2S.AsS^3 + K^2S.AsS^2.$$

But the precipitated tribasic salt soon turns black, being resolved into hyposulpharsenite and sulpharsenate. The potassium and sodium compounds exhibit this blackening on the addition of alcohol, even when the solution contains nothing but tribasic salt ($3K^2S.As^2S^3$); but with the ammonium, barium, strontium, and calcium salts, it does not take place unless the solution contains dibasic salt ($2Ba^2S.As^2S^3$). — Aqueous solutions of sulpharsenites exposed to the air are decomposed by oxidation (more slowly in proportion to the excess of sulphur-base), depositing orpiment and a brown compound of disulphide of arsenic with the sulphur-base. Hydrated oxide of copper, added to a solution containing a compound of sulpharsenious acid with the sulphide of an alkali-metal, decomposes that compound, yielding twelve-basic sulpharsenite of copper, which remains undissolved, and a hyacinth-red solution, containing an alkaline arsenite and tribasic sulpharsenite of copper, and deposits the latter on the addition of hydrochloric acid. Perhaps in this manner:

$$9(K^2S.As^2S^3) + 27Cu^2O = 2(12Cu^2S.As^2S^3) + 3Cu^2S.As^2S^3 + 3(3K^2O.2As^2O^3).$$

If the hydrated oxide of copper is in excess, the arsenious acid contained in the solution is converted into arsenic acid, and the protoxide of copper reduced to sub-oxide. — Oxide of silver in excess decomposes the solution, forming sulphide of silver and alkaline arsenite:

$$KAsS^2 + 2Ag^2O = 2Ag^2S + KAsO^2.$$

Sulpharsenite of Ammonium, $2(NH^4)^2S.As^2S^3$. — The solution of arsenious sulphide in sulphide of ammonium or caustic ammonia yields, when mixed with alcohol, a precipitate of this composition, which, however, soon turns brown. If previously mixed with sulphydrate of ammonium, it deposits white feathery crystals of the basic salt $(3NH^4)^2S.As^2S^3$. Finely divided arsenious sulphide absorbs 6½ per cent. of ammonia-gas, but gives it up again when exposed to the air.

Sulpharsenite of Barium.—The solution of arsenious sulphide in sulphydrate of barium dries up to a red-brown gummy mass of the neutral salt, $2Ba^2S.As^2S^3$, perfectly soluble in water. Alcohol precipitates from the solution crystalline flakes of the basic salt, $3Ba^2S.As^2S^3$, which is likewise obtained by treating arsenious sulphide with excess of sulphide of barium.

Sulpharsenite of Bismuth, $2Bi^2S^3.As^2S^3$, is a red-brown precipitate, which turns black in drying. By fusion, a grey metallic-shining mass is obtained, consisting of the basic salt.

Sulpharsenite of Cadmium.—Cadmium-salts mixed with a saturated solution of arsenious sulphide in sulphide of ammonium, yield a yellow precipitate, $2Cd^2S.As^2S^3$. which becomes orange-yellow when dry, and semifluid when heated, giving off part of the arsenious sulphide, and leaving a fused grey compound containing a larger proportion of cadmic sulphide.

Sulpharsenite of Calcium.—When orpiment is digested with milk of lime, and the solution is filtered from the arsenite of calcium, which forms at the same time, a colourless filtrate is obtained, which, by spontaneous evaporation, yields feathery crystals of the basic salt $3Ca^2S.As^2S^3$, surrounded by a brown syrup of the neutral salt $2Ca^2S.As^2S^3$. This syrup digested with an additional quantity of arsenious sulphide turns yellow and deposits a brown powder consisting of *hyposulpharsenite* of calcium, $Ca^2S.2AsS$. The solution of the sulpharsenite containing excess of sulphide of calcium yields, with alcohol, a white precipitate of the basic salt, containing $3Ca^2S.As^2S^3 + 15Aq$.

Sulpharsenite of Cerium, $2Ce^2S.As^2S^3$.—Yellow precipitate, which acquires a deeper colour when dry, melts, and evolves part of the arsenious sulphide when heated, and when roasted gives up all its arsenic, and is completely converted into sulphate.

Sulpharsenite of Chromium, $2Cr^4S^3.3As^2S^3$. — Greyish-yellow precipitate, greenish-yellow after drying. When heated, it melts and gives off part of the arsenious sulphide, and is converted into chromic oxide by roasting.

Sulpharsenite of Cobalt, $2Co^2S.As^2S^3$, is a dark brown precipitate, which becomes black in drying, dissolves in excess of the precipitant, and when ignited in close vessels, leaves a residue having the composition of cobalt-glance.

Sulpharsenite of Copper.—A twelve-basic salt, $12Cu^2S.As^2S^3$, remains undissolved as a brown mass, when cupric hydrate is added to solution of monopotassic sulpharsenate, till the colour of the liquid is no longer altered. The *tribasic salt*, $3Cu^2S.As^2S^3$, is precipitated in light brown flakes on adding hydrochloric acid to the hyacinth-red solution obtained in the manner just mentioned. The neutral salt, $2Cu^2S.As^2S$, is obtained by adding neutral sulpharsenite of sodium to a cupric salt, as a black-brown precipitate, which acquires a metal-grey aspect by trituration. When distilled, it first gives off sulphur, then arsenious sulphide, and leaves a tumefied metal-grey substance, probably consisting of cuprous hyposulpharsenite.

Sulpharsenite of Glucinum, $2G^2S.As^2S^3$, is a yellow precipitate, formed, without evolution of sulphuretted hydrogen, on adding a neutral glucinum-salt to a solution of sulphide of sodium saturated with arsenious sulphide. Acids separate but little sulphuretted hydrogen from it, ammonia partly dissolves it, and leaves pure glucina.

Sulpharsenite of Gold, $2Au^2S^3.3As^2S^3$.—Yellow precipitate, becoming darker as it settles down, black when dry, and yielding by trituration a yellow-brown powder. At a dull red heat, it melts, gives off part of the arsenious sulphide, and solidifies to a transparent yellow-red mass, yielding by dry trituration a yellow-brown mass, which, however, by continued trituration under water, assumes a metallic lustre, as if from reduced gold. To expel the whole of the arsenious sulphide requires a full white heat.

Sulpharsenites of Iron.—The *ferric salt*, $2Fe^4S^3.3As^2S^3$, is an olive-green precipitate, soluble in excess of the precipitating alkaline sulpharsenite, acquiring a green colour when dry, and a fine yellow-green by trituration. It melts easily when heated, and decomposes at a red heat, leaving pure sulphide of iron. The *ferrous salt*, $2Fe^2S.As^2S^3$, is a brown-black precipitate, also soluble in excess of the precipitant; grey-brown when dry, dark greenish after trituration. It is decomposed by heat, leaving pure sulphide of iron. The dried precipitate always contains ferric oxide mixed with the preceding salt.

Sulpharsenite of Lead, $2Pb^2S.As^2S^3$.—Red-brown precipitate, black when dry; melts to a brittle metallic-looking mass, a shining grey crystalline fracture, and yielding a grey powder.

Sulpharsenite of Lithium resembles the potassium- and sodium-salts.

Sulpharsenite of Magnesium.—The aqueous solution evaporated, or cooled to −5° C., becomes light brown, and deposits a brown powder consisting of hyposulpharsenite of magnesium; then dries to a viscid mass, which ultimately solidifies, and is almost wholly soluble in water.

Sulpharsenite of Manganese.—Light red precipitate, becoming orange-yellow when dry. Heated in close vessels, it gives off a considerable portion of the arsenious sulphide, and leaves a yellow-green compound, from which hydrochloric acid extracts the manganese, with evolution of sulphuretted hydrogen, leaving a residue of arsenious sulphide.

Sulpharsenites of Mercury.—The neutral *mercuric salt*, $2Hg^2S.As^2S^3$, is an orange-red flocculent precipitate, which becomes white in presence of excess of mercuric chloride, but retains its colour if the precipitant is in excess. It is dark brown when dry, and gives a yellow powder. When heated, it yields a grey metallic-shining sublimate of $Hg^2S.As^2S^3$, which is translucent in thin films, and yields a yellow powder when finely ground. The *mercurous salt*, $2Hg^4S.As^2S^3$, is a black precipitate, which decrepitates with explosion when distilled, giving off mercury and yielding a sublimate of mercurous hyposulpharsenite in black opaque metallic crusts, which yield a red powder.

Sulpharsenite of Molybdenum.—The solution of molybdic acid in hydrochloric acid forms with sulpharsenite of sodium, a dark brown powder, which becomes black in drying, and decomposes at a red heat, giving off arsenious sulphide and sulphur, and leaving disulphide of molybdenum, MoS.

Sulpharsenite of Nickel, $2Ni^2S.AsS^3$, is a black precipitate, which, when distilled, easily gives off all its arsenious sulphide, and leaves yellow sintered sulphide of nickel.

Sulpharsenite of Potassium.—The neutral salt, $2K^2S.As^2S^3$, is obtained by igniting the corresponding sulpharsenate ($2K^2S.As^2S^5$) till the excess of sulphur is driven off. It is a dark yellow mass, which becomes yellow on cooling. Treated with water, it yields a solution of basic sulpharsenate ($3K^2S.As^2S^3$) and a residue of hyposulpharsenite. When arsenious sulphide is dissolved at mean temperature in aqueous sulphydrate of potassium, till all the sulphuretted hydrogen is eliminated, the solution contains an *acid sulpharsenite*, $K^2S.2As^2S^3$. This solution is decomposed by evaporation, depositing brown hyposulpharsenite of potassium, $K^2S.AsS$. On mixing the solution with alcohol, a white precipitate of $3K^2S.As^2S^3$ is formed at first; but it soon becomes brown and syrupy, and deposits the hyposulpharsenite. When carbonate of potassium is fused with arsenious sulphide till the excess of the latter is expelled, there remains a mass, consisting of $K^2S.As^2S^3$. This salt is decomposed by water, the acid salt, $K^2S.2As^2S^3$, dissolving, and a compound, still richer in arsenious sulphide, remaining undissolved.

Sulpharsenite of Silver, $2Ag^2S.As^2S^3$, is a light brown precipitate, transparent at first, becoming black during collection; when heated in the dry state, it melts and gives off part of the arsenious sulphide. The black fused mass yields a brown powder. When acid sulpharsenite of sodium is precipitated by a saturated solution of chloride of silver in ammonia, a dark yellow precipitate is formed, containing $6Ag^2S.As^2S^3$.

Sulpharsenite of Sodium.—Strictly analogous to the potassium-salt.

Sulpharsenites of Tin.—The *stannous salt*, $2SnS.As^2S^3$, is a dark red-brown precipitate, infusible, but giving off part of its sulphur at high temperatures. The *stannic salt*, $SnS^2.As^2S^3$, is a gummy yellow precipitate, which becomes orange-yellow when dry.

Uranic Sulpharsenite, $2U^4S^3.As^2S^3$, is a dingy yellow precipitate, which melts and gives off part of its sulphur when heated, and, after exposure to a white heat, leaves a grey porous mass, still containing arsenious sulphide.

Sulpharsenite of Zinc, $2Zn^2S.As^2S^3$.—Lemon-yellow precipitate, orange-yellow when dry; gives off arsenious sulphide when heated, leaving a more basic compound, and at a higher temperature, pure sulphide of zinc.

Sulpharsenite of Zirconium, $2Zr^4S^3.As^2S^3$.—Orange-yellow precipitate, quite insoluble in excess of the alkaline sulpharsenite.

PENTASULPHIDE OF ARSENIC, OR ARSENIC SULPHIDE. In combination: SULPHARSENIC ACID. As^2S^5, or *AsS*^{5}.—A substance containing arsenic and sulphur in this proportion is precipitated when a soluble sulpharsenate is decomposed by hydrochloric acid; but it appears to be rather a mixture of the trisulphide with free sulphur. When sulphuretted hydrogen is passed into an aqueous solution of arsenic acid, sulphur is first separated, and remains for a long time suspended in the liquid. The precipitate contains a very small quantity of trisulphide of arsenic, which may be extracted by dilute ammonia, pure sulphur then remaining. The filtered liquid is then found to contain arsenic acid, together with a small quantity of arsenious acid; and, if sulphuretted hydrogen be then rapidly passed through it for a short time, a precipitate of trisulphide of arsenic is obtained. If this precipitate be separated by filtration, and the passage of the sulphuretted hydrogen continued, the liquid again becomes turbid from separation of sulphur, and, by repeating these operations, the whole of the arsenic may be precipitated as trisulphide. (H. Rose, Pogg. Ann. cvii. 186; H. Ludwig, Arch. Pharm. [2] xcvii. 23.)

A sulphide of arsenic corresponding to anhydrous arsenic acid, As^2O^5, does not therefore appear to exist in the free state. Nevertheless, the precipitate thrown down by acids from solutions of sulpharsenates has the composition of the pentasulphide, and as such dissolves completely in alkaline sulphides and in strong ammonia; dilute ammonia, however, dissolves out the trisulphide and leaves the sulphur.

SULPHARSENATES.—These salts may be regarded as compounds of pentasulphide of arsenic with basic metallic sulphides. Our knowledge respecting them is chiefly due to the researches of Berzelius. They are for the most part *mono-*, *di*, or *tribasic*, a few instances only occurring of sulpharsenates with larger proportion either of sulphur-base or sulphur-acid. Their general formulæ are:

Monobasic or Monometallic .	$M^2S.As^2S^5$ or $MAsS^3$	$= \left.\begin{matrix}\overset{\prime}{As}S^2\\ M\end{matrix}\right\\}S$ *
Dibasic or Tetrametallic .	$2M^2S.As^2S^5$ or $M^4As^2S^7$	$= \left.\begin{matrix}\overset{\prime\prime\prime}{As^2}S^3\\ M^4\end{matrix}\right\\}S^4$
Tribasic or Trimetallic .	$3M^2S.As^2S^5$ or M^3AsS^4	$= \left.\begin{matrix}\overset{\prime\prime}{As}S\\ M^3\end{matrix}\right\\}S^3$

* Or $MS.AsS^5$, $2MS.AsS^5$, and $3MS.AsS^5$.

The tetrametallic salts are generally regarded as neutral; the monometallic as acid; the trimetallic as basic.

The sulpharsenates are prepared: 1. By passing sulphuretted hydrogen through the solution of an arsenate in water or in hydrochloric acid, thus:

$$K^3AsO^4 + 4H^2S = K^3AsS^4 + 4H^2O.$$

—2. By fusing orpiment with excess of sulphur and a caustic alkali or alkaline carbonate. —3. By digesting the trisulphide in an aqueous solution of a disulphide or polysulphide of alkali-metal.—4. By dissolving the pentasulphide ($As^2S^3 + 2S$) in a caustic alkali, or in an alkaline carbonate at the boiling heat. In this case an arsenate is formed at the same time.—5. Those sulpharsenates which are insoluble in water may be obtained by precipitation from the solution of an alkaline sulpharsenate.

The dry sulpharsenates of the alkali-metals are lemon-yellow; the others red or brown. They are permanent in the air. Those which are soluble taste hepatic at first, afterwards intensely bitter. The tribasic salts have a tendency to crystallise; the dibasic and monobasic salts are amorphous.

The trimetallic sulpharsenates of potassium, sodium, lithium, and barium may, if air be excluded, be heated almost to whiteness without decomposition; on cooling, they solidify to a yellow mass perfectly soluble in water. The tetrametallic and monometallic sulpharsenates of these metals give off sulphur when heated, and are converted into sulpharsenites. The silver- and mercury-salts (the latter of which sublimes) remain undecomposed at a red heat. The other tetrametallic and monometallic sulpharsenates are decomposed by ignition, first yielding sulphur and a red salt of sulpharsenious acid; and in many cases, the sulpharsenite is resolved by continued ignition into trisulphide of arsenic, which sublimes, and the sulphur-base, which remains behind. The calcium- and magnesium-salts first evolve sulphur, and then the greater part of the trisulphide, and leave a white unfused compound of magnesium- or calcium-sulphide, with a very small quantity of trisulphide; most of the heavy-metal-compounds evolve sulphur at first, and then all the sulphide of arsenic, so that nothing but the sulphur-base remains behind. The sulpharsenates, when heated in the air, give off orpiment and arsenious oxide, and leave a sulphate when the base contains an alkali-metal, and pure oxide if it contains a heavy metal. The aqueous solution of the sulpharsenate of an alkali-metal is decomposed by exposure to the air—the liquid becoming turbid, and depositing sulphur, pentasulphide of arsenic ($As^2S^3 + S^2$) and a brown salt of hyposulpharsenious acid, while alkaline arsenite and hyposulphite are formed, and the latter, by further oxidation, is converted into sulphate; the cooler and more concentrated the solution, the more slowly does the decomposition proceed. Acids, even carbonic acid, decompose the alkaline sulpharsenates, separating hydrosulphuric acid gas of a peculiar odour, and precipitating a mixture of arsenious sulphide and sulphur. Hydrated cupric oxide, introduced into the solution of an alkaline sulpharsenate, decomposes a portion of that compound, forming alkaline arsenate and sulphide of copper, a small portion of which dissolves in the liquid. A similar reaction is produced by other heavy metallic oxides which do not retain their oxygen with very great force. (Berzelius.)

Many sulpharsenates are soluble in water, namely, those of the alkali-metals, magnesium, yttrium, and glucinum. The solutions are either colourless or pale yellow. From the solutions of the dibasic salts alcohol precipitates a tribasic salt, and leaves monobasic salt in solution. When this solution is placed in a shallow dish, and evaporated at a gentle heat, there remains a lemon-yellow residue, from which water extracts a dibasic salt. (Berzelius.)

Sulpharsenate of Ammonium. $2(NH^4)^2S.As^2S^5 = (NH^4)^4As^2S^7$.—The solution of pentasulphide of arsenic in sulphide of ammonium, yields by evaporation, a viscid, reddish-yellow mass, which decomposes partially in drying, and still more when heated, first giving off a liquid containing disulphide of ammonium, and then yielding a sublimate of arsenious sulphide: $(NH^4)^4As^2S^7 = 4NH^4S + As^2S^3$.—The solution becomes brownish-yellow when boiled, and on cooling deposits a yellow powder composed of $(NH^4)^2S.12As^2S^5$. The aqueous solution of the dibasic salt is precipitated by alcohol, the *monammonic* or *acid* salt, NH^4AsS^3, then remaining in solution. If the solution be previously mixed with sulphide of ammonium and heated, alcohol throws down the *tri-ammonic* or *basic* salt $(NH^4)^3AsS^4$, in prismatic crystals.

Sulpharsenate of Antimony is a burnt-yellow, easily fusible precipitate.

Sulpharsenate of Barium.—The *tribarytic-salt*, Ba^3AsS^4, is obtained by decomposing the tetrabarytic or neutral salt: 1, by a red heat; 2, by mixing its aqueous solution with sulphide of barium, the mixture evaporated in vacuo over sulphuric acid at the freezing point, yielding the basic salt in loose, transparent, non-crystalline scales; 3, by precipitation with alcohol: it then falls down as a curdy precipitate, very soluble in water, probably a hydrate:—The *dibasic salt*, $Ba^4As^2S^7 = 2Ba^2S.As^2S^5$, is produced by saturating a solution of neutral arsenate of barium with hydrosulphuric acid. The solution dries up to a fissured lemon-yellow mass, which, if exposed to the air after all its water has been drawn off, absorbs water again, swelling up and falling to pieces at the same time. It dissolves in water in all proportions. With sulphate of potassium, it yields a precipitate of sulphate of barium, and a solution of neutral sulpharsenate of potassium.—The *monobarytic* or *acid* salt, $BaAsS^3$, remains in solution when the neutral salt is precipitated by alcohol. It is decomposed by evaporation, yielding a yellow deposit of the salt, $Ba^2S.3As^2S^3$, while the neutral salt remains in solution.

Sulpharsenate of Bismuth.—Both the basic and the neutral salts are dark-brown precipitates, soluble in excess of the alkaline sulpharsenate.

Sulpharsenate of Cadmium is a light yellow powder.

Sulpharsenate of Calcium.—The *basic salt*, Ca^3AsS^4, is obtained by mixing the solution of the neutral salt with sulphide of calcium, and either evaporating or precipitating with alcohol; it is not crystallisable, and when precipitated by alcohol, forms either a powder or a syrup, according to the quantity of water that it contains. It dissolves easily in water, but is insoluble in alcohol. The *neutral* salt, $Cu^4As^2S^7 = 2Ca^2S.As^2S^5$, is precisely analogous to the barium-salt. Its solution when evaporated, coagulates to a syrup, which, if then left to evaporate further, dries up to a yellow opaque mass, becoming anhydrous at 60° C.: when exposed to the air, it absorbs water, swells up, and detaches itself from the sides of the vessel. There appears to be no acid sulpharsenate of calcium.

Sulpharsenates of Cerium.—The *ceric salt*, $2Ce^4S^3.As^2S^3$, is a yellowish white precipitate, not quite insoluble in water, and consequently not appearing in very dilute solutions. The *cerous salts*, $Ce^2S.As^2S^5$, and $3Ce^2S.As^2S^5$, are obtained by double decomposition as precipitates of a fine yellow colour, which become somewhat darker when dry.

Sulpharsenate of Cobalt, $Co^4As^2S^7 = 2Co^2S.As^2S^5$, is a brown precipitate which becomes black when collected and dried, and dissolves with dark colour in excess of sulpharsenate of sodium.

Sulpharsenate of Copper, $Cu^4As^2S^7 = 2Cu^2S.As^2S^5$, is obtained as a dark brown precipitate, by treating solutions of copper-salts with neutral sulpharsenate of sodium, or by passing sulphuretted hydrogen through an acid solution containing arsenic acid and cupric oxide: if the arsenic acid is in excess, the brown sulphur-salt is first precipitated, and then yellow sulphide of arsenic. From a precipitate of this kind, sulphide of ammonium dissolves not only the sulphide of arsenic, but likewise by its intervention, a large portion of the sulphide of copper. Very dilute ammonia likewise extracts the sulphide of arsenic: stronger ammonia acquires a brown tint by taking up some of the sulphide of copper. (Gm. v. 475.)

Sulpharsenate of Glucinum.—Pentasulphide of arsenic digested with hydrate of glucinum and water, is dissolved to a small amount and reprecipitated by acids. Glucinum-salts are not precipitated by sulpharsenate of sodium.

Sulpharsenate of Gold.—The *tribasic salt*, $(\overset{\prime\prime\prime}{A}u)AsS^4 = (\overset{\prime\prime\prime}{A}u)^2S^3.As^2S^5$, is formed by precipitating a gold-solution with tribasic arsenate of sodium. It is a dark brown precipitate, soluble in pure water. Ferrous sulphate decolorises the solution, and throws a yellow-brown substance not yet examined. The *dibasic salt*, $2(\overset{\prime\prime\prime}{A}u)^2S^3.3As^2S^5$, obtained by precipitation with neutral sulpharsenate of sodium, dissolves in pure water, with brown red colour.

Sulpharsenates of Iron.—The *ferric* salt, $2Fe^4S^3.3As^2S^5$ = or $fe^4As^2S^7$, is a greyish-green precipitate, which dissolves with very dark colour in excess of the precipitant, is not altered by drying, but melts easily when heated, giving off sulphur, and being converted into ferric sulpharsenite.—The *ferrous salt*, $2Fe^2S.As^2S^5 = Fe^4As^2S^7$, is a dark brown precipitate, which dissolves in excess of the alkaline sulpharsenate. It decomposes in drying, assuming a rusty colour, and then consists of a mixture of the preceding salt with ferric oxide.

Sulpharsenate of Lead.—The salts Pb^3AsS^4, and $Pb^4As^2S^7$, are obtained by precipitation. The former is black-brown, the latter of a fine red colour; both turn black in drying.

Sulpharsenate of Lithium.—The *basic salt*, Li^3AsS^4, is precipitated by alcohol from the solution of the neutral salt in shining, colourless crystalline scales, soluble in hot water, and separating therefrom on cooling in six-sided prisms, and by spontaneous evaporation in four-sided tables with rhombic base. The *neutral* salt, $Li^4As^2S^7$, is a non-crystalline lemon-yellow mass, which absorbs moisture from the air, and is perfectly soluble in water. The *acid* salt, $LiAsS^3$, is known only in alcoholic solution, being decomposed by evaporation. The *hyperacid* salt, with 12 at. As^2S^5, is prepared like the corresponding potassium-salt.

Sulpharsenate of Magnesium.—The *tribasic* salt, Mg^3AsO^4 or $3Mg^2S.As^2S^5$, is obtained by adding sulphydrate of magnesium to a solution of the neutral salt as long as sulphuretted hydrogen continues to escape, and afterwards evaporating the solution, or if it be not too dilute, cooling it quickly down. It forms colourless radiating crystals, which become moist on exposure to the air. Alcohol decomposes them, extracting the neutral salt and leaving a compound of 1 at. As^2S^5 with more than 3 at. Mg^2S, which is nearly insoluble in water. The same compound remains as a white unfused mass, when the neutral salt is heated to redness in a retort. Potash added to the aqueous solution of the tribasic salt precipitates magnesia, and forms a solution of tribasic sulpharsenate of potassium.—The *neutral salt*, $2Mg^2S.As^2S^5$, is a non-crystalline, lemon-yellow mass, which does not absorb water from the air, dissolves in water to any amount, and is precipitated from the solution by alcohol.

Sulpharsenate of Magnesium and Ammonium, $(NH^4)Mg^2AsS^4$ (?)—Precipitated on adding alcohol to an aqueous solution of the mixed sulpharsenates of magnesium and ammonium, in delicate white needles, which, when exposed to the air, give off sulphuretted hydrogen and turn yellow. It dissolves easily in water.

Sulpharsenate of Manganese.—The *neutral salt*, $2Mn^2S.As^2S^5$, is obtained by digesting recently precipitated sulphide of manganese with water, trisulphide of arsenic and sulphur, partly dissolving in the water and partly remaining at the bottom in the form of a lemon-yellow powder, which however dissolves in a larger quantity of water. The solution when evaporated, yields sulphur, and afterwards deposits a lemon-yellow mass, no longer completely soluble in water. The neutral salt is likewise obtained, but mixed with arsenate of manganese, when carbonate of manganese is boiled with water and trisulphide of arsenic and sulphur. Manganous salts are not precipitated by sulpharsenate of sodium. A *sexbasic salt*, $6Mn^2S.As^2S^5$, is produced by digesting the yellow powder of the neutral salt in strong ammonia. It is a brick-red powder, somewhat soluble in water, and, when ignited at one point, continues to burn.

Sulpharsenates of Mercury.—The *mercuric salt*, $2Hg^2S.As^2S^5$, is precipitated from mercuric chloride both by basic and by neutral sulpharsenate of sodium, as a dark yellow substance, which retains its colour after drying. It sublimes undecomposed, and yields a powder of the colour of cinnabar. The *mercurous salt*, $2Hg^4S.As^2S^5$, or $Hhg^4As^2S^7$, is precipitated black from solutions free from mercuric oxide; if the latter is present, the precipitate is brownish-yellow, and becomes darker in drying. When distilled, it decrepitates violently and gives off mercury, and at a higher temperature yields a sublimate of the mercuric salt just described.

Molybdic Acid is is not precipitated by sulpharsenate of sodium.

Sulpharsenate of Nickel.—Nickel-salts, if not too dilute, immediately yield a black precipitate, with neutral or basic sulpharsenate of sodium. Very dilute solutions first assume a yellow-brown colour, then yield a precipitate.

Sulpharsenate of Platinum.—The neutral and basic sodium-salts do not precipitate platinum-solutions, but merely colour them dark-brown. Ferrous sulphate added to the brown liquid, throws down a black-brown substance, while the solution becomes colourless.

Sulpharsenate of Potassium.—The *tribasic salt*, $3K^2S.As^2S^5$, or K^3AsS^4, is deposited as an oily concentrated solution, on mixing the aqueous solution of the neutral salt with alcohol. When dried at a gentle heat, it leaves a fibrous deliquescent mass.

The *neutral* or *dibasic* salt, $2K^2S.As^2S^5$, or $K^4As^2S^7$, is produced by saturating an aqueous solution of dipotassic arsenate with hydrosulphuric acid and evaporating in vacuo. The residue is a viscid, yellowish, somewhat crystalline mass, which does not dry up completely, but on exposure to the air first liquefies and then solidifies in a crystalline mass of rhombic tablets.

The *monobasic* or *acid* salt, $K^2S.As^2S^5$, or $KAsS^3$, remains dissolved when the aqueous solution of the neutral salt is precipitated with alcohol. The solution is decomposed by evaporation, and deposits crystals of persulphide of arsenic (see p. 386).—2 Aqueous sulphide of potassium dissolves at ordinary temperatures, more than ½ at. but less than 1 at. of pentasulphide of arsenic. The solution, when evaporated in the air, first becomes covered with a film of sulphur, then deposits a red crust, and by this loss of sulphide of arsenic, is converted into the dibasic salt, which dries up first to a stiff syrup and then to a lemon-yellow mass.

A *hyper-acid* salt, $K^2S.12As^2S^5$, is precipitated when the solution of the neutral salt is decomposed by carbonic acid; similarly on passing hydrosulphuric acid gas through monopotassic arsenate.—It is a yellow powder, containing 2·9 sulphide of potassium and 97·1 pentasulphide of arsenic. (Berzelius.)

Sulphoxarsenate of Potassium. $(K^2O.2H^2O)As^2S^3O^2 = (K^2H^4)As^2S^3O^4$. — Produced when sulphuretted hydrogen is rapidly passed through a cold saturated solution of dipotassic arsenate (p. 383). The liquid first turns yellow, then deposits a small quantity of trisulphide of arsenic mixed with sulphur, and ultimately a colourless crystalline salt. When a certain quantity of this salt has been formed, caustic potash is to be added to the liquid, and the stream of sulphuretted hydrogen continued: by this means, an additional quantity is obtained. The greater part of the sulphide of arsenic must then be rinsed away with the mother-liquor, and the salt washed with very small quantities of water, pressed, and dried in vacuo. It crystallises in small white elongated prisms, sometimes 1 or 2 centimetres long, slightly soluble in water. The dry salt is permanent in the air, and gives up all its water at 170° C., without melting. It fuses over the spirit-lamp, giving off, first arsenic sulphide and then metallic arsenic. The aqueous solution decomposes rapidly at a boiling heat, giving off hydrosulphuric acid and depositing sulphur. If hydrochloric acid be then added, a precipitate of sulphide of arsenic is obtained. From the salt itself, hydrochloric acid precipitates nothing but sulphur, and the precipitation is complete; the filtrate then contains arsenious acid. Lead-salts added to the solution give a white precipitate, which soon turns black. The acid of this salt, $H^6As^2S^3O^4$ (arsenic acid, having part of its oxygen replaced by sulphur), cannot be obtained in the free state. If the lead-salt, immediately after its formation, be collected on a filter and mixed with a quantity of dilute sulphuric acid less than sufficient to decompose it completely, a strongly acid liquid is obtained, which gives no precipitate with barium-salts; but it quickly decomposes and deposits sulphide of arsenic. (Bouquet and Cloez, Ann. Ch. Phys. [3] xiii. 44.)

Sulpharsenate of Silver.—Both the *neutral* and *basic* salts are precipitated from silver-solutions, with brown colour, turning black in drying; the precipitates are very slow in settling down. When they are heated in the air, the sulphide of arsenic burns away, and sulphide of silver remains; but if heated to redness in close vessels, they fuse without giving off sulphur or sulphide of arsenic, and on cooling solidify in the form of a grey, somewhat ductile cake, exhibiting metallic lustre.

Sulpharsenate of Sodium. a. Tribasic salt. $3Na^2S.AsS^5 + 15H^2O = 2Na^3AsS^4 + 15H^2O$.—Obtained: 1. By precipitating a solution of the dibasic salt with alcohol.—2. By leaving a mixture of the dibasic salt *b* and sulphydrate of sodium to evaporate.—3. By digesting the alcoholic solution of pentasulphide of sodium with orpiment, pouring the liquid off, washing the residue with alcohol, then dissolving out the tribasic salt with water, and leaving the solution to crystallise.—4. By dissolving pentasulphide of arsenic in aqueous soda-solution, and leaving the liquid to crystallise. The crystals obtained by either of these methods are washed on a filter with alcohol, then pressed and dried (Berzelius).—*5.* By boiling 1 pt. of sulphur, 1½ pt. of orpiment, and 8 pts. of crystallised carbonate of soda with water, and purifying the crystals obtained from the filtrate by recrystallisation (Rammelsberg, Pogg. Ann. liv. 238). By method (1) the salt is obtained in snow-white crystals; by (4) in ill-defined rhomboïdal tables. It crystallises by slow cooling from a hot aqueous solution, in irregular six-sided prisms, with two of their lateral edges more acute than the rest; by spontaneous evaporation or very slow cooling, in transparent rhombic prisms with dihedral summits resting on the acute lateral edges; and by still slower cooling, till the temperature falls below 0° C., in white, opaque, rhombic octahedrons. The opaque crystals are milk-white; the transparent crystals are yellowish, and have somewhat of a diamond lustre. (Berzelius.)

The salt when dry is permanent in the air; even in vacuo over oil of vitriol, it does not give up its water till gently heated; it then becomes milk-white; when more strongly heated, it gives off a small quantity of hydrosulphuric acid, and turns yellow. Heated in a retort, in fuses it its water of crystallisation, forming a very pale yellow liquid, then gives off water, and is converted into a white salt, which, when more strongly heated, decrepitates slightly, evolves the remaining water and a small quantity of hydrosulphuric acid, and fuses to a dark red liquid; on cooling, this liquid solidifies and forms the yellow anhydrous compound, Na^3AsS^4 (Berzelius). It is decomposed completely by boiling with sulphate of copper, yielding a precipitate of sulphide of copper, while soda, sulphuric acid, and arsenic acid remain in solution:

$$Na^3AsS^4 + 4Cu^2SO^4 + 4H^2O = 4Cu^2S + Na^3AsO^4 + 4H^2SO^4.$$

A similar decomposition takes place with acetate of lead; but the precipitated sulphide of lead [if the acetate is in excess], is mixed with arsenate of lead, because that salt is insoluble in acetic acid (Rammelsberg). The salt dissolves easily and abundantly in water. (Berzelius.)

b. Dibasic or *Neutral salt.* $2Na^2S.As^2S^5 = Na^4As^2S^7$.—The aqueous solution of disodic arsenate saturated with hydrosulphuric acid gas, and then left to evaporate spontaneously, yields a viscid liquid, and afterwards, if gently heated, a dry lemon-yellow mass. This substance melts at a moderate heat, forming a very pale yellow liquid (losing water at the same time if warmed in an open vessel), and on cooling solidifies in a yellow mass, which softens when exposed to the air. (Berzelius.)

c. Monobasic salt. $Na^2S.As^2S^5 = NaAsS^3$.—When the tribasic salt is prepared with alcohol according to method (1), the supernatant alcoholic solution contains the mono-basic salt. On distilling off the alcohol, the liquid often deposits persulphide of arsenic in beautiful crystals.

d. Hyper-acid salt, $Na^2S.12As^2S^5$.—Yellow powder, obtained like the potassium compound. (Berzelius.)

Sulpharsenate of Sodium and Ammonium, $(NH^4)^3AsS^4.Na^3AsS^4$, is obtained by mixing the solutions of the two basic salts with alcohol, and cooling slowly, whereupon it collects on the sides of the vessel in small four-sided tables; or more easily by dissolving sal-ammoniac in an exactly proportional quantity of the basic sodium-salt and leaving the solution to evaporate; it then separates in yellowish six-sided prisms, permanent in the air, and much more soluble in water than the sodium-salt. When distilled, it gives off sulphide of ammonium with a little water, leaving sulpharsenite of sodium.

The neutral sulpharsenates of sodium and ammonium dry up to a yellow mass when mixed.

Sulpharsenate of Sodium and Potassium.—Very regular four-sided tables, having a faint yellowish colour.

Sulpharsenate of Strontium.—The *neutral* salt is obtained in the same manner as the barium-compound. On mixing the solution with alcohol, the *basic* salt is precipitated, sometimes as a syrup, sometimes as a white powder, according as it is more or less purified from the neutral salt.

Sulpharsenates of Tin.—Both the neutral and basic sodium-salts form with *stannous* chloride, a dark chestnut-brown precipitate; with *stannic* chloride, pale yellow gummy precipitates, becoming orange-yellow when dry.

Uranic Sulpharsenate.—The *neutral* salt, $2U^4S^3.As^2S^5$ or $(U^2S)^4As^2S^7$, is a dingy yellow precipitate; the basic salt has a somewhat darker colour. Both dissolve with dark brown colour in excess of the precipitant.

Vanadic salts give no precipitate with sulpharsenate of sodium; but the blue solution is decolorised.

Sulpharsenate of Yttrium.—Resembles the glucinum-salt.

Sulpharsenate of Zinc.—The *neutral* salt is a light yellow precipitate, the *basic* salt till lighter; both are orange-yellow when dry.

Sulpharsenate of Zirconium.—Solutions of zirconium-salts are precipitated, though not immediately, both by basic and by neutral sulpharsenate of sodium; the precipitate is lemon-yellow while moist, orange-yellow after drying. Acids do not extract zirconia from it.

ARSENICAL COBALT, COPPER, IRON, &c. See the several metals.

ARSENICAL PYRITES. See IRON, ARSENIDES OF.

ARSENICAL PYROPHORUS. Arsenite of barium ignited with gum-tragacanth, is said by Osann to yield a greyish-yellow pyrophoric mixture.

ARSENIC-RADICLES (ORGANIC). Arsenic unites with the alcohol-radicles, forming compounds analogous to those of antimony, and containing 1 at. arsenic, combined with 1, 2, 3, or 4 at. of the organic radicle. The following is a list of the compounds of this class at present known. Those to which no formulæ are assigned, have been but imperfectly studied.

Arsenides of Allyl.

Arsenides of Amyl.

Arsenides of Ethyl:

Arsenethyl	$As(C^2H^5)$
Arsendiethyl, or Ethyl-cacodyl	$As(C^2H^5)^2$
Arsentriethyl, or Triethylarsine	$As(C^2H^5)^3$
Arsenethylium, or Tetrethylarsonium . . .	$As(C^2H^5)^4$

Arsen-bromethyl-triethylium	$As(C^2H^4Br)(C^2H^5)^3$
Arsenvinyl-triethylium	$As(C^2H^3)(C^2H^5)^3$
Ethylene-hexethyl-diarsonium	$As^2(C^2H^4)''(C^2H^5)^6$
Ethylene-triethylarsammonium	$AsNH^3(C^2H^4)''(C^2H^5)^3$
Aurarsenethylium	$As(C^2H^5)^3Au$
Platarsenethylium	$As(C^2H^5)^3Pt$

Arsenides of Methyl:

Arsenmethyl	$As(CH^3)$
Arsendimethyl, or Cacodyl	$As(CH^3)^2$
Arsentrimethyl, or Trimethylarsine . . .	$As(CH^3)^3$
Arsenmethylium, or Tetramethylarsonium . .	$As(CH^3)^4$
Arsentrimethyl-ethylium	$As(CH^3)^3(C^2H^5)$
Arsendimethyl-diethylium	$As(CH^3)^2(C^2H^5)^2$
Arsenmethyl-triethylium	$As(CH^3)(C^2H^5)^3$
Arsendimethyl-diamylium	$As(CH^3)^2(C^5H^{11})^2$

Arsenide of Tetryl (or Butyl).

Arsenide of Trityl (or Propyl).

These compounds are produced, like the antimonides of the alcohol-radicles, by distilling the iodides of these radicles with arsenide of potassium or sodium. Arsendimethyl, or cacodyl, is likewise formed by distilling a mixture of arsenious oxide and an alkaline acetate, and was obtained in this manner by Cadet, so long ago as 1760. The di-trityl and di-tetryl compounds appear to be produced in a similar manner, by distilling arsenious oxide with an alkaline valerate or butyrate. The compounds containing 2 and 3 at. of alcohol-radicle, *e. g.* cacodyl and arsentriethyl, have been obtained in the free state; the rest only in combination.

The compounds containing 1 at. alcohol-radicle, such as $As(CH^3)$, are di-atomic and tetr-atomic, uniting with 2 and 4 at. Cl, I, &c.; those with 2 at. alcohol-radicle, cacodyl, for example, are mono- and tri-atomic; those with 3 at. alcohol-radicle, $As(C^2H^5)^3$, for example, are di-atomic; and those which contain 4 at. alcohol-radicle, *e. g.* $As(C^2H^5)^4$, are monatomic and triatomic. (See ORGANO-METALLIC BODIES.)

Arsenides of Allyl. When iodide of allyl is heated with arsenide of potassium, a number of liquid products are formed, having an extremely offensive odour, and rising gradually in boiling point, so that their separation cannot well be effected, and at the same time, a solid crystalline mass is formed, which appears to be the iodide of arsenallylium or tetrallylarsonium, $As(C^3H^5)^4I$. (Cahours and Hofmann, Phil. Trans. 1857, p. 335.)

Arsenides of Amyl. Iodide of amyl distilled with arsenide of potassium, yields compounds analogous to the arsenides of ethyl and methyl. (Cahours and Riche.)

Arsenides of Ethyl.*

Three of these compounds, viz. *arsendiethyl*, $As(C^2H^5)$, *arsentriethyl*, $As(C^2H^5)^3$, and *arsenethylium*, $As(C^2H^5)^4$, are obtained by a process similar to that already described for the preparation of stibtriethyl (p. 341), viz. by subjecting arsenide of sodium mixed with quartz-sand, to the action of iodide of ethyl in an atmosphere of dry carbonic acid gas. The action takes place without external heating, and when it is finished, the resulting arsenides of ethyl may be separated one from the other either by fractional distillation, or by treatment with ether. *Arsenethyl*, AsC^2H^5, is obtained by the decomposition of arsendiethyl.

ARSENETHYL, or ARSENMONETHYL, $As(C^2H^5) = AsE$.—This radicle is not known in the free state; but the di-iodide is obtained (together with iodide of ethyl), by the action of 2 at. iodine on 1 at. iodide of arsendiethyl, or of 3 at. iodine on 1 at. arsendiethyl:

$$AsE^2I + I^2 = EI + AsEI^2$$
$$AsE^2 + I^3 = EI + AsEI^2.$$

The di-iodide distilled with 2 at. *iodine*, yields tri-iodide of arsenic ($AsEI^2 + I^2 = EI + AsI^3$). Treated with excess of *oxide of silver* and *water*, it is converted into arsenmonethylic acid, $As(C^2H^5)H^2O^3$. (Cahours, Compt. rend. l. 1022; Rép. Chim. pure, ii. 256.)

ARSENDIETHYL, or ETHYL-CACODYL, $As(C^2H^5)^2$, is best obtained by treating arsenide of sodium with excess of iodide of ethyl, in the manner just mentioned,

---

* Landolt, Ann. Ch. Pharm. lxxxix. 301; xcii. 365; Gm. ix. 70; Gerh. ii. 949.—Cahours and Riche, Compt. rend. xxxvi. 1001; xxxix. 541; Jahresber. f. Chem. 1853, 487; 1854, 530.—Cahours, Compt. rend. xlix. 87; Jahresber. 1859, 430; further, Compt. rend. l. 1022; Rép. Chim. pure, ii. 255.

digesting the crude distillate with ether, mixing the ethereal extract with absolute alcohol, expelling the ether by evaporation, and mixing the alcoholic solution with water, which precipitates arsendiethyl, and retains in solution the iodide of arsenethylium, formed by the union of arsentriethyl with the excess of iodide of ethyl.

Arsendiethyl is an oily liquid, having a faint yellowish colour, strong refracting power, and a very disagreeable, pungent, alliaceous odour. It sinks in water without mixing. Boils between 185° and 190° C. It absorbs oxygen rapidly from the air giving off vapours of arsenious oxide, and if it has been separated by fractional distillation, it takes fire when a drop of it is let fall on wood or paper; but if it has been precipitated by water from the alcoholic solution, it does not take fire till heated to 180° C. It is rapidly oxidised by strong nitric acid, with evolution of light and heat, less completely by dilute nitric acid, which also forms with it a red substance analogous to Bunsen's *erythrarsin*. Arsendiethyl reduces the noble metals, silver, mercury, &c. from their solutions, and is at the same time converted into *arsendiethylic acid*, $As(C^2H^5)^2HO^2$.

Arsendiethyl also unites directly with *chlorine*, *bromine*, *iodine*, and *sulphur*. These compounds are liquids having a peculiarly repulsive and persistent odour, and attacking the eyes strongly; continued exposure to it produces headache and other unpleasant symptoms. The iodide, $As(C^2H^5)^2I$, is prepared by saturating an ethereal solution of arsendiethyl with an ethereal solution of iodine, and evaporating the ether. It is a yellow oil, insoluble in water, but soluble in alcohol and ether. The alcoholic solution mixed with nitrate or sulphate of silver, yields a precipitate of iodide of silver, and a solution of nitrate or sulphate of arsendiethyl.

On gradually adding a dilute alcoholic solution of *mercuric chloride* to an alcoholic solution of arsendiethyl, a white precipitate is formed, which however disappears on boiling, and the solution yields on cooling a crystalline powder, consisting of $2Hg^2O.As(C^2H^5)^2Cl^2$. This salt is inodorous, sparingly soluble in cold water and in alcohol, more soluble in boiling water: it is decomposed by strong nitric acid. Two other crystalline compounds are formed at the same time, in small quantity.

Arsendiethylic Acid. $As(C^2H^5)^2HO^2$.—When arsendiethyl is triturated with red oxide of mercury under water, mercury separates out, and a solution of arsendiethylate of mercury is formed; and by precipitating the mercuric oxide with baryta-water, removing the excess of baryta by carbonic acid, decomposing the filtered solution of arsendiethylate of barium with sulphuric acid, and evaporating, arsendiethylic acid is obtained in crystals. This acid is also produced by the direct oxidation of arsendiethyl, as when that substance is left for some time in a loosely stoppered bottle; also, when its alcoholic solution is exposed to the air, or more quickly when that solution is shaken up with oxygen gas. The crystals contain $As(C^2H^5)^2HO^2$. They are inodorous, have a slightly acid, afterwards bitter taste, deliquesce in the air, and dissolve readily in water and alcohol, sparingly in ether. They melt at 190° C., forming an oily liquid, which solidifies in a crystalline mass on cooling; but at higher temperatures, they are decomposed, with evolution of arsenious oxide and stinking arsenical products. The acid is not attacked by nitric acid, aqua-regia, or by the milder reducing agents, such as sulphurous acid, and ferrous sulphate; but phosphorous acid reduces it, forming a pungent oily liquid, probably the oxide of arsendiethyl. The aqueous solution of the acid readily decomposes carbonates, and precipitates *ferric*, *mercurous*, and *cupric* salts; also acetate of *lead*. The *mercuric* salt is a deliquescent crystalline mass. The *barium*-salt, obtained by saturating the aqueous acid with baryta-water and evaporating, contains $2BaHO.3As(C^2H^5)^2HO^2 + \frac{1}{2}H^2O$; the water of crystallisation is not completely given off at 120° C.

ARSENTRIETHYL, or **TRIETHYLARSINE**. $As(C^2H^5)^3$.—This is the chief product of the action of iodide of ethyl on arsenide of sodium, and is easily separated from the other products by fractional distillation in an atmosphere of carbonic anhydride: it passes over between 140° and 180° C. It is also produced by the action of trichloride of arsenic on zinc-ethyl (Hofmann and Cahours, Compt. rend. xli. 831). It is a colourless, mobile, strongly refracting liquid, having a disagreeable odour, like that of arsenetted hydrogen. Specific gravity 1·151 at 16·7° C. Under a pressure of 736 mm. it begins to boil at 140° C., but the boiling point quickly rises to 180°, a small quantity of arsenic separating at the same time. Its vapour-density is, by experiment, 5·2783; by calculation (2 vol.) 5·6156.

Arsentriethyl fumes and becomes heated in contact with the air, but seldom takes fire unless it is heated; the products of the oxidation are arsenious anhydride, carbonic anhydride and water. The oxidation takes place slowly, even under water in a closed vessel. Strong *nitric acid* oxidises it rapidly, with vivid combustion and explosion, but nitric acid of specific gravity 1·42, dissolves it slowly, giving off nitric oxide, and producing nitrate of arsentriethyl; but no red compound is formed. This character serves to distinguish arsentriethyl from arsendiethyl: a further distinction is afforded by the fact that arsentriethyl does not reduce the noble metals from their solutions.

Arsentriethyl is a diacid radicle, 1 at. of it uniting with 2 at. of a monatomic acid radicle, *e. g.* $As(C^2H^5)^3.I^2$, and with one at. of a diatomic acid radicle, *e. g.* $As(C^2H^5)^3.S$.

Bromide of Arsentriethyl, $As(C^2H^5)^3Br^2$, is obtained by mixing the alcoholic solutions of bromine and arsentriethyl, the former in slight excess, and evaporating at 100° C. It is a yellowish, deliquescent, crystalline mass, the odour of which excites sneezing. When heated it melts, and burns with a white flame. It is decomposed by chlorine, by nitric acid, and by strong sulphuric acid.

Iodide of Arsentriethyl, $As(C^2H^5)^3I^2$, is obtained by mixing the ethereal solutions of its constituents: it is then deposited in yellow flakes which rapidly turn brown and liquefy on exposure to the air. It dissolves readily in water and alcohol, sparingly in ether.

The *chloride* appears to be formed in small quantity by the action of hydrochloric acid on the oxide or sulphide.

Oxide of Arsentriethyl, $As(C^2H^5)^3O$, is produced when an ethereal solution of arsentriethyl is left to evaporate in the air; but it may be obtained in a state of greater purity by exhausting the mass produced by the action of iodide of ethyl on arsenide of sodium, first with ether, and then with alcohol, evaporating the alcoholic solution, and distilling the residue. It is an oily liquid, heavier than water and not miscible with it, but soluble in alcohol, and precipitated from the alcoholic solution by water. It dissolves in dilute nitric acid, but not in sulphuric or hydrochloric acid. When left for some weeks in a loosely stoppered bottle, it is gradually converted into an inodorous crystalline substance [probably arsentriethylic acid].

Sulphide of Arsentriethyl, $As(C^2H^5)^3S$, is obtained by boiling an ethereal solution of arsentriethyl with flowers of sulphur. It forms beautiful prismatic crystals, which may be purified by recrystallisation from boiling water or alcohol, or better by solution in warm ether, and gradual evaporation. It has a bitter taste, but is quite inodorous when pure. It melts at 100° C., and decomposes at a higher temperature, giving off spontaneously inflammable vapours. It is rapidly oxidised by strong *nitric acid*. Dilute *hydrochloric acid* decomposes it partially, giving off small quantities of hydrosulphuric acid and *chloride of arsentriethyl*, recognisable by its peculiarly pungent odour. It is not decomposed by boiling with *caustic potash*. Its aqueous solution precipitates *metallic solutions* like an alkaline sulphide.

ARSENETHYLIUM or **TETRETHYLARSONIUM**, $As(C^2H^5)^4$, is not known in the free state, but is obtained as an iodide by the action of iodide of ethyl on arsentriethyl; also, according to Cahours and Riche, by the action of metallic arsenic on iodide of ethyl. Its compounds are analogous to those of tetrethylium, and contain 1 at. arsenethylium with 1 at. of a monobasic acid radicle, or 2 at. arsenethylium with 1 at. of a dibasic acid radicle. The *hydrate*, obtained by the action of oxide of silver on the iodide, is a fixed base resembling hydrate of potassium, and dissolves readily in acids, forming salts which crystallise readily, are permanent in the air, have a bitter taste, and do not appear to be poisonous. In this respect, they differ remarkably from the compounds of arsendiethyl and arsentriethyl.

Bromide of Arsenethylium, $As(C^2H^5)^4Br$, is a white, deliquescent, saline mass, which dissolves easily in water and alcohol, and exhibits with acids and metallic salts, the same reactions as bromide of potassium.

Chloride of Arsenethylium forms crystals containing $As(C^2H^5)^4Cl.4H^2O$, which dissolve readily in water and alcohol, but are insoluble in ether. The aqueous solution immediately precipitates chloride of silver from the nitrate and forms an insoluble double salt with *mercuric chloride*. With *dichloride of platinum* it forms the compound $As(C^2H^5)^4Cl.PtCl^2$, which dissolves very sparingly in cold, somewhat more readily in boiling water.

Iodide of Arsenethylium, $As(C^2H^5)^4I$, forms large colourless crystals, easily soluble in water and alcohol, but insoluble in ether. When heated, they fall to powder, give off spontaneously inflammable vapours, and yield a sublimate of arsenic. They are decomposed by nitric and by sulphuric acid. A compound of *iodide of arsenethylium* and *iodide of arsenic* is obtained by heating iodide of ethyl to 100° C. with metallic arsenic:

$$4C^2H^5I + As^2 = As(C^2H^5)^4I.AsI^3.$$

This compound forms splendid red tables, which are decomposed by distillation, yielding iodide of arsentriethyl and iodide of arsendiethyl (Cahours and Riche, Compt. rend. xxxix. 546). It is also decomposed by hot potash-solution, yielding iodide of arsenethylium, iodide of potassium, and arsenite of potassium. Iodide of arsenethylium heated with *iodide of zinc*, yields the compound $As(C^2H^5)^4I.ZnI$; similarly with *iodide of cadmium*.

Arsenethylium likewise forms a *tri-iodide*, $As(C^2H^5)^4I^3$, analogous to the tri-iodide of tetrethylium discovered by Weltzien. (Cahours, Compt. rend. l. 1022; Rép. Chim. pure, ii. 255.)

The *sulphate*, $[As(C^2H^5)^4H]SO^4$, is formed by precipitating a solution of the iodide with an acid solution of sulphate of silver. Granular crystals, easily soluble in water and alcohol, sparingly in ether, and decomposed by heat, with evolution of acid vapours.

ARSEN-BROMETHYL-TRIETHYLIUM, or BROMETHYL-TRIETHYLARSONIUM. $As(C^2H^4Br)(C^2H^5)^3$.—The *bromide* of this radicle is obtained by heating a mixture of triethylarsine with a very large excess of dibromide of ethylene, in sealed tubes at a temperature not above 50° C., extracting the product with water, evaporating and recrystallising from boiling alcohol. It forms beautiful crystals, extremely soluble in water, the form of which exactly resembles that of the corresponding phosphonium-compound (see PHOSPHORUS-RADICLES, ORGANIC). It contains the elements of 1 at. dibromide of ethylene and 1 at. triethylarsine:

$$C^2H^4Br^2 + As(C^2H^5)^3 = [As(C^2H^4Br)(C^2H^5)^3]Br.$$

Nitrate of silver added in excess to the solution of the bromide, precipitates only half the bromine; the other half is precipitated on treating the filtrate with ammonia (see AMMONIUM-BASES, p. 196). The platinum-salt of this radicle forms splendid yellow needles, sparingly soluble even in boiling water. (A. W. Hofmann, Proc. Roy. Soc. xi. 62.)

ARSENVINYL-TRIETHYLIUM, or VINYL-TRIETHYLARSONIUM. $As(C^2H^3)(C^2H^5)^3$.—The hydrated oxide of this radicle is obtained by treating bromide of bromethyl-triethylarsonium with excess of oxide of silver:

$$[As(C^2H^4Br)(C^2H^5)^3]Br + Ag^2O = \left.\begin{matrix}As(C^2H^3)(C^2H^5)^3\\H\end{matrix}\right\}O + 2AgBr.$$

A strongly alkaline solution is obtained which, when treated with hydrochloric acid and precipitated by dichloride of platinum, yields beautiful, rather soluble octahedrons, containing $[As(C^2H^3)(C^2H^5)^3]Cl.PtCl^2$. (Hofmann, *loc. cit.*)

ETHYLENE-HEXETHYLDIARSONIUM. $As^2(C^2H^4)''(C^4H^5)^6$.—Obtained as a dibromide or dichloride, by digesting the bromide or chloride of bromethyl-triethylarsonium with triethylarsine at 150° C. for two hours. The dibromide $[As^2(C^2H^4)''(C^2H^5)^6]''Br^2$, treated with oxide of silver, yields the hydrate $\left.\begin{matrix}[As^2(C^2H^4)''(C^2H^5)^6]''\\H^2\end{matrix}\right\}O^2$, which is a powerful alkali, and forms with acids a series of beautiful salts:

The *platinum-salt*. $[As(C^2H^4)''(C^2H^5)^6]''Cl^2.2PtCl^2$, is a pale yellow crystalline precipitate, soluble in water and in boiling hydrochloric acid, from which it crystallises on cooling.

The *gold-salt*, $[As^2(C^2H^4)''(C^2H^5)^6Cl^2.2AuCl^3$, crystallises from hydrochloric acid in gold-coloured plates. (Hofmann, *loc. cit.*)

ETHYLENE-TRIETHYLARSAMMONIUM $\left[(C^2H^4)''\begin{matrix}(C^2H^5)^3As\\H^3N\end{matrix}\right]''$. The *dibromide* of this radicle is obtained by heating the bromide of bromethyl-triethylarsonium with ammonia to 100° C. for two hours. Treated with oxide of silver, it yields the caustic base $\left.\begin{matrix}[(C^2H^4)''(C^2H^5)^3H^3AsN]''\\H^2\end{matrix}\right\}O^2$. The *platinum-salt* $\left[(C^2H^4)''\begin{matrix}(C^2H^5)^3As\\H^3N\end{matrix}\right]''Cl^2.2PtCl^2$, crystallises from hydrochloric acid in needles, sparingly soluble in boiling water. The *gold-salt* crystallises from hydrochloric acid in golden-yellow plates. (Hofmann, *loc. cit.*)

The reactions by which the last four bases are obtained are precisely similar to those which yield the corresponding compounds of the phosphorus series, and will be more fully considered in the article PHOSPHORUS-RADICLES (ORGANIC), in which also the *phospharsoniums*, containing both phosphorus and arsenic, will be described.

AURARSENETHYLIUM, $As(C^2H^5)^3Au$, and PLATARSENETHYLIUM, $As(C^2H^5)^3Pt$.—The chlorides of these compounds are obtained in fine crystals by treating an alcoholic solution of arsentriethyl with trichloride of gold and dichloride of platinum respectively. (Hofmann, Ann. Ch. Pharm. cvii. 357.)

Arsenides of Methyl.

Cadet discovered, in 1760, that by distilling acetate of potassium with arsenious oxide, a fetid brown-red liquid is obtained, which takes fire on exposure to the air. But the nature of this liquid was not understood till Bunsen undertook its examination, and showed that it contained a metalloïdal radicle, AsC^2H^6, to which he gave the the name Cacodyl (from κακος, bad) on account of its extremely poisonous qualities.

Bunsen, moreover, isolated this radicle, and prepared a great number of its compounds, showing that, in its chemical relations, it is precisely analogous to a simple metal. This was the second instance of the isolation of a compound radicle, the separation of cyanogen by Gay-Lussac having been the first. It has since been shown by Cahours and Riche (Compt. rend. xxxix. 341), that cacodyl or arsendimethyl, $As(CH^3)^2$ may be obtained by the action of iodide of methyl on arsenide of sodium, other arsenides of methyl, viz. $As(CH^3)^3$ and $As(CH^3)^4$ being formed at the same time. Lastly, Baeyer, has obtained several compounds of arsenmonomethyl, $AsCH^3$.

ARSENMETHYL, or ARSENMONOMETHYL, $AsCH^3 = AsMe$.—(Baeyer, Ann. Ch. Pharm. cvii. 279.) The *dichloride* of this radicle (which is not known in the separate state) is produced either by the decomposition of trichloride of arsendimethyl (cacodyl) by heat:

$$\underset{\text{Trichloride of cacodyl.}}{AsMe^2Cl^3} = \underset{\text{Dichloride arsenmethyl.}}{AsMeCl^2} + \underset{\text{Chloride of methyl.}}{MeCl}$$

or by the action of hydrochloric acid on cacodylic acid:

$$AsMe^2O^2H + 3HCl = AsMeCl^2 + MeCl + 2H^2O.$$

When a stream of dry hydrochloric acid gas is passed over cacodylic acid, basic perchloride of cacodyl (p. 408) is first formed; but by the continued action of the gas, this compound is also decomposed, with separation of water, which passes over in the distillate, together with the dichloride.

Dichloride of arsenmethyl is a colourless, heavy, mobile liquid, having a strong refracting power. It boils at 133° C., which is nearly the boiling point of trichloride of arsenic. It does not fume in the air, and is not decomposed by water, but dissolves rather freely in that liquid. It forms a white precipitate with sulphuretted hydrogen. The vapour of this compound exerts a most violent action on the mucous membranes: on smelling it, the eyes, nose, and the whole face swell up, and a peculiar lancinating pain is felt, extending down to the throat.

Tetrachloride of Arsenmethyl, $AsMeCl^4$.—When chlorine is passed over a mixture of dichloride of arsenmethyl and sulphide of carbon cooled to − 10° C., large crystals are obtained, which immediately decompose at temperatures near the freezing point of water, yielding chloride of methyl and trichloride of arsenic: hence the crystals consist of tetrachloride of arsenmethyl:

$$AsCH^3Cl^4 = AsCl^3 + CH^3Cl.$$

Chlorobromide of Arsenmethyl, $AsMeClBr$, appears to be produced by the spontaneous decomposition of chlorodibromide of cacodyl, bromide of methyl being given off at the same time:

$$AsMe^2ClBr^2 = AsMeClBr + MeBr;$$

but the liquid product of the decomposition is too unstable to admit of an examination of its properties.

Iodide of Arsenmethyl, $AsCH^3I^2$, is obtained by the action of hydriodic acid on the alcoholic solution of the oxide (see below). The liquid yields by spontaneous evaporation, shining yellow needles of the iodide an inch long. They are not altered by contact with the air, but appear to decompose slowly by keeping (Baeyer). The same compound is produced by the action of 2 at. iodine on iodide of cacodyl, or of 3 at. iodine on free cacodyl, iodide of methyl being set free at the same time. (Cahours, Compt. rend. l. 1022):

$$AsMe^2I + I^2 = MeI + AsMeI^2$$
$$AsMe^2 + I^3 = MeI + AsMeI^2$$

It melts at 25° C., and often remains liquid for a long time after cooling. It is colourless and volatile without decomposition above 200° C. It is but slightly soluble in water, but dissolves readily in alcohol, ether, and sulphide of carbon; less readily, however, in presence of free hydriodic acid. Hydrochloric acid converts it into chloride, and hydrosulphuric acid into sulphide of arsenmethyl. (Baeyer.) Distilled with 2 at. iodine, it yields iodide of methyl, and triiodide of arsenic, AsI^3. (Cahours.)

Oxide of Arsenmethyl, $As(CH^3)O$, is produced by the action of potash on the dichloride:

$$AsMeCl^2 + 2KHO = AsMeO + 2KCl + H^2O;$$

but on distilling the product with excess of potash, complete decomposition takes place and oxide of cacodyl is obtained, instead of oxide of arsenmethyl (see below).

A better result is obtained by saturating the dichloride with carbonate of potassium, then adding an excess of the latter, extracting with absolute alcohol, distilling off the alcohol in a stream of carbonic acid, digesting the residue in sulphide of carbon, which leaves chloride of potassium and other impurities undissolved, and leaving the clear solution to evaporate. Oxide of arsenmethyl is then obtained in large cubical crystals (not regular, however), which soon become dull, and assume the aspect of white porcelain; sometimes, however, crystals are obtained which retain their transparency, but they are then very imperfectly developed. The oxide is very heavy, permanent in the air, and has a strong odour like that of asafœtida. It dissolves slowly but abundantly in cold water, readily in hot water, also in alcohol, ether, and sulphide of carbon. It melts at 95° C., and remains liquid for a considerable time after cooling. It is decomposed by distillation, and the evolved vapours explode when mixed with air. A portion volatilises, however, with the vapour of water or alcohol. By distillation with hydrate of potassium, it is resolved into arsenious oxide and oxide of cacodyl:

$$4As(CH^3)O = As^2O^3 + As^2(CH^3)^4O.$$

The oxide appears to possess rather basic than acid properties, as it does not unite with baryta, but dissolves readily in acids; its aqueous solution is neutral to vegetable colours. *Hydrochloric acid* added to the concentrated aqueous solution throws down the chloride of arsenmethyl in oily drops; *hydrobromic acid* acts in like manner; *hydriodic acid* produces a yellow precipitate of the iodide; and *hydrosulphuric acid* a white precipitate of the sulphide. The oxide is not acted upon by hydrocyanic acid, but is easily raised to a higher stage of oxidation by *nitric acid*, *mercuric oxide*, or *silver-oxide*. *Chlorine*, *bromine*, and *iodine* added to its solution in sulphide of carbon, form precipitates which soon decompose. Corrosive sublimate does not appear to unite with it.

Arsenmethylic acid. $As(CH^3)H^2O^3$.—The barium-salt of this acid is obtained by decomposing the dichloride of arsenmethyl with a slight excess of silver-oxide; filtering from chloride of silver; treating the filtrate with excess of baryta-water; removing that excess by carbonic acid; evaporating the filtered liquid to dryness over the water-bath; dissolving the residue in a small quantity of water; and precipitating by alcohol. The same salt may be obtained by decomposing the aqueous solution of oxide of arsenmethyl with mercuric oxide (for which purpose the alcoholic distillate obtained in the preparation of the oxide, *vid. sup.* may be used), decomposing the resulting mercurous salt with baryta, and proceeding as before.

By carefully decomposing the barium-salt with sulphuric acid and evaporating the filtrate over the water-bath, arsenmethylic acid is obtained in the form of a laminated mass, resembling precipitated nitrate of urea. It is purified by solution in hot alcohol, and crystallises, on cooling, in large spear-shaped laminæ, composed of small needles, united in arborescent groups, permanent in the air, and not containing any water of crystallisation. It is a strong acid, having a pure, sour, agreeable, taste, and capable of decomposing carbonates. It is very soluble in water, and dissolves in alcohol more readily than cacodylic acid. All its salts either crystallise or form precipitates. It is a dibasic acid, the formula of its normal salts being $As(CH^3)O^3M^2$. The *barium-salt*, prepared as above, crystallises in colourless needles, containing 10 at. of water, which it gives up at 100° C. The anhydrous salt separates as a white powder composed of rhombic crystals, when the concentrated aqueous solution is evaporated or mixed with alcohol. On examining with the microscope the precipitate produced by alcohol, the rhombic crystals are seen to change in a few minutes into the long needles of the hydrated salt. The salt is quite insoluble in alcohol, and may thus be easily separated from cacodylate of barium, which is soluble in that liquid. *Arsenmethylate* of silver, $As(CH^3)O^3Ag^2$, is precipitated in small crystals, having a strong nacreous lustre, on mixing the neutral solution of the barium-salt with nitrate of silver. It is anhydrous, is but little altered by exposure to air and light, does not decompose at 100° C., but explodes at higher temperatures, with rather strong detonation.

Sulphide of Arsenmethyl, $As(CH^3)S$.—Obtained by passing sulphuretted hydrogen into water in which dichloride of arsenmethyl is immersed:

$$As(CH^3)Cl^2 + H^2S = As(CH^3)S + 2HCl.$$

The chloride is then converted into a white mass of the sulphide, without the slightest separation of sulphur. The product is dissolved in a mixture of alcohol and sulphide of carbon, from which it crystallises by rapid evaporation in shining laminæ, or by slow evaporation in small prisms. It is insoluble in water, moderately soluble in alcohol and ether, very soluble in sulphide of carbon. In the crystallised state, it melts at about 100° C., but often remains fluid for a long time after cooling. It is decomposed by heat, with separation of sulphide of arsenic. It is permanent in the air, and has a faint odour like that of asafœtida. The alcoholic solution decomposes the salts of silver, copper, lead, platinum, and mercurosum, with formation of metallic sulphides, and produces a white cloud with mercuric chloride.

ARSENDIMETHYL OR CACODYL. $As(CH^3)^2 = Kd$.—(**Cadet**, Crell. N. Chem. Arch. i. 212; **Bunsen**, Pogg. Ann. xl. 219; xlii. 145; Ann. Ch. Pharm. xxxvii. 6; xlii. 19; **Baeyer**, Ann. Ch. Pharm. cvii. 257.—**Gm.** ix. 316; **Gerh.** i. 626.)—This body, together with the products of its oxidation, constitutes the spontaneously inflammable liquid, known as *Cadet's fuming liquid* or *alkarsin.** To prepare this liquid, a mixture of equal parts of acetate of potassium and arsenious oxide is distilled in a retort provided with a receiver, from which a long tube passes into the chimney, to carry away the poisonous gases evolved during the process. The retort is placed in a sand-bath and gradually heated till it is red-hot at the bottom. A brown oleaginous liquid consisting of impure cacodyl is then found in the receiver, together with metallic arsenic, and a mixture of water, acetone, and acetic acid, which floats on the top. The reaction is very complicated, considerable quantities of carbonic anhydride and hydride of methyl (marsh-gas) being given off, together with other gases in smaller quantity; but the formation of cacodyl is evidently connected with the splitting up of acetic acid at a red heat into carbonic anhydride and hydride of methyl (p. 12). The oily liquid, which is very inflammable, is decanted by means of a syphon, the longer arm of which dips under water. It is then washed with boiled water and distilled over hydrate of potassium in a current of hydrogen.

Pure cacodyl is obtained by decomposing the chloride with metallic zinc, dissolving out the chloride of zinc by water, and dehydrating the oily liquid, which sinks to the bottom, by distillation from chloride of calcium. The strong tendency of cacodyl to take fire in the air and the extremely poisonous quality of its vapour, render it necessary to perform all the distillations in sealed vessels, filled with dry carbonic acid gas. Bunsen's method is as follows:

1. Chloride of cacodyl is prepared perfectly free from oxide, by distilling alkarsin with strong hydrochloric acid, till the resulting chloride no longer emits the slightest fume on exposure to the air; or better, by mixing the dilute alcoholic solutions of alkarsin and mercuric chloride, and distilling the resulting precipitate of *chloromercurate of cacodyl* ($Kd^2O.4HgCl$) with very strong hydrochloric acid. To free the distillate obtained by either of these methods from water and hydrochloric acid, it is digested for several days with a mixture of chloride of calcium and quick lime, contained in the bulb-apparatus A (*fig.* 74). The air is first expelled from this apparatus by a stream of dry carbonic acid gas; the lower extremity *a* is then dipped into the chloride of cacodyl below the hydrochloric acid; the chloride of cacodyl is drawn into the bulb by means of a hand-syringe attached by a caoutchouc tube to the upper end *b*; and lastly the apparatus is sealed at both ends and set aside for several days.

2. The decomposition of the chloride of cacodyl is effected in a second apparatus *B*, represented in *fig.* 75. A moderately strong and rather wide gas-delivery tube is blown out to a bulb in two places *a*, *b*, about six inches apart; the lower extremity is then drawn out and twice bent, as shown at *c*, *d*: the upper bulb *a* is partly filled through the wide open end of the tube with small cuttings of pure zinc-foil; the upper end of the tube is then drawn out and bent, as shown in the figure, and the whole apparatus is filled with perfectly dry carbonic acid gas. To introduce the purified chloride of cacodyl into the bulb *a*, the tube of apparatus *A* is cut off at *c*, just above the bulb; the upper extremity *f* of the apparatus *B*, is then introduced into bulb *A*; and a quantity of the liquid, sufficient to half fill it, is drawn in by means of a hand-syringe connected with the lower end *e*, after which the lower end of the tube is sealed by the blowpipe at *e*, and the upper end sealed and melted off at *g*, close to the bulb *a*. The apparatus is now inverted, and the bulb *a* immersed in water at 100° C. The reduction then takes place without evolution with gas, and after some hours, the contents of the bulb *a* are converted into a white saline mass, which appears to be a compound of cacodyl with chloride of zinc, and melts to an oily liquid at 110°—120° C. To separate the cacodyl from the chloride of zinc, the

---

* This liquid was supposed by Bunsen to be the oxide of cacodyl, $(AsC^2H^6)^2O$. It does not appear, however, to be definite in constitution. Bunsen's analyses of it vary from 29·9 to 22·4 per cent. in the carbon, and from 65·4 to 66·2 in the arsenic. Dumas (Ann. Ch. Phys. [3] viii. 362) found 22·0 and 23·2 per cent. carbon, and from 68·9 to 69·3 per cent. arsenic. Now the formula of oxide of cacodyl requires 21·2 carbon, and 66·4 arsenic, while that of cacodyl itself requires 22·9 carbon, and 71·4 arsenic. These results are quite in accordance with the supposition that Cadet's liquid is a variable mixture of cacodyl and its oxide; the spontaneous inflammability of the liquid likewise indicates the presence of free cacodyl. The true oxide of cacodyl (Bunsen's *paracacodylic oxide*, p. 407, supposed by him to be isomeric with alkarsin), produced by slow oxidation of cacodyl or of alkarsin itself, is not spontaneously inflammable. (**Gerhardt.**)

end *e* of the apparatus is broken off under water which has been thoroughly freed from air by boiling; the whole apparatus is heated to expel the carbonic anhydride, and then left to cool, till the bulb *b* is nearly filled with water; the end *e* is again sealed; the apparatus inclined so that the water may flow into the bulb *a*; and this bulb is gently heated. The chloride of zinc then dissolves, and the cacodyl sinks to the bottom as a heavy oily liquid.

Fig. 74.

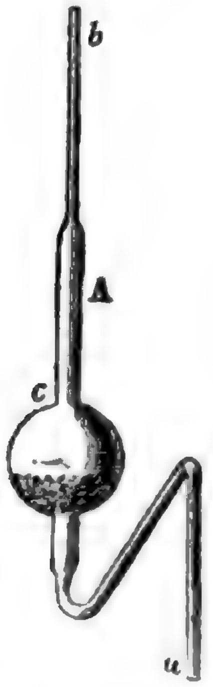


Fig. 75.

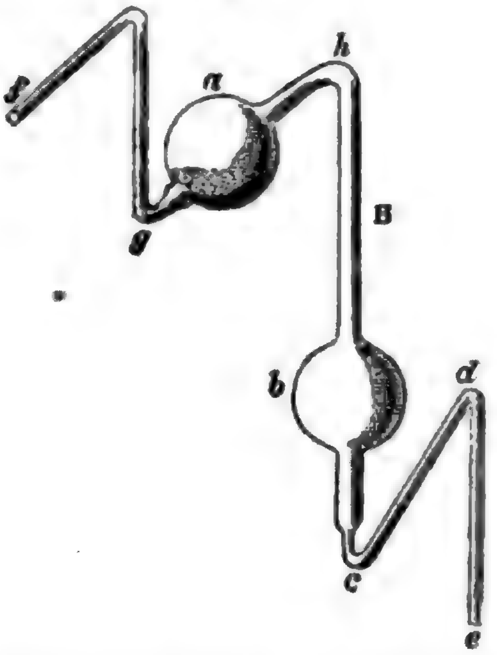

To dehydrate the cacodyl and purify it further, it is next transferred, with the same precautions as before, into another apparatus *A* (*fig.* 74), the bulb of which contains dry chloride of calcium: for this purpose, the bulb *a* of apparatus *B* is cut off at *h*, and the apparatus *A* having been filled with dry carbonic acid gas, its lower extremity *a* is introduced into the bulb *a*, and made to dip into the cacodyl below the watery liquid; the cacodyl is then drawn by suction with the syringe into the bulb of apparatus *A*, which is then sealed at both ends, and set aside for some time. The dehydrated cacodyl is next transferred into a second apparatus B, filled with dry carbonic acid gas, and having some zinc-cuttings in the bulb *a*, and the two arms of the tubes are then sealed and melted off just below the bulbs *a*, *b*. The bulb *b* is then immersed in cold water; the cacodyl distilled into it by gently heating the bulb *a* with a spirit-lamp, and then poured back; and the rectification is repeated in this manner two or three times. Lastly, the bulb *b* is cooled in a freezing mixture to −6° C., and left there till about ⅔ of the liquid has crystallised, and the still liquid portion is poured back: that which then remains in the solid state is pure cacodyl.

Cacodyl may also be prepared by heating the sulphide with mercury.

Properties.—Cacodyl is at ordinary temperatures a transparent colourless, strongly refracting liquid, heavier than water. It boils near 170° C. Its vapour-density (referred to air as unity) is by experiment 7·101, which shows that the formula of cacodyl in the free state is $As^2C^4H^{12} = As^2Me^4 = KdKd$. For the atomic weight represented by this formula is 210 ($= 2 . 75 + 4 . 12 + 12 . 1$), and if this represents 2 vols. of vapour, the weight of one vol. of vapour, that is to say, the specific gravity referred to hydrogen as unity, is 105; and multiplying this by 0·0693, the specific gravity of hydrogen referred to air, we obtain for the specific gravity of cacodyl-vapour referred to air as unity, the number 7·2755, which is very near the number determined by experiment. Cacodyl has a disgusting odour, somewhat like that of arsenetted hydrogen, and its vapour is very poisonous. It solidifies at 6° C. in square-based prisms. It is sparingly soluble in water, very soluble in alcohol and in ether. When heated in a close vessel to about 400° C. it is resolved, without deposition of carbon, into metallic arsenic, and a mixture of 2 vol. marsh gas and 1 vol. olefiant gas:

$$As^2C^4H^{12} = 2CH^4 + C^2H^4 + As^2.$$

Cacodyl takes fire in the air, at ordinary temperatures, even more readily than crude alkarsin, yielding carbonic anhydride, water, and arsenious oxide, but if the quantity of air present is not sufficient for complete combustion, a red compound, Bunsen's *erythrarsin*, is formed at the same time. This red substance is also produced when cacodyl is passed through red-hot tubes; also by the action of protochloride of tin, or phosphorous acid on cacodyl. It appears to contain $C^4H^{12}As^4O^3$. Cacodyl exposed to the gradual action of *oxygen*, as when air is passed into it in successive bubbles, is converted first into oxide of cacodyl, and afterwards into cacodylic acid. It takes fire in *chlorine gas*, and is converted by chlorine-water into chloride of cacodyl. It dissolves *sulphur*, forming a protosulphide or trisulphide of cacodyl, according to the quantity. *Fuming sulphuric acid* dissolves it without blackening: the solution gives off, even in the cold, a considerable quantity of sulphurous acid, and yields by distillation a product having an agreeable ethereal odour. It dissolves in *nitric acid*, and the solution yields with *nitrate of silver* a crystalline precipitate of nitrate of silver and cacodyl.

Bromide of Cacodyl, $As(CH^3)^2Br = KdBr$, is obtained by distilling the chloromercurate, $As^2C^4H^{12}O.4HgCl$, with concentrated hydrobromic acid, and is purified like the chloride. It is a yellow liquid, which does not fume in the air, and closely resembles the chloride. When heated over mercury to a temperature between 200° and 300° C. it is decomposed, yielding free cacodyl and mercurous bromide. Heated with water it forms an *oxybromide*.

Chloride of Cacodyl, $As(CH^3)^2Cl = KdCl$.—Prepared by distilling the chloromercurate with very strong hydrochloric acid, and purified from water and adhering hydrochloric acid by placing it in contact with chloride of calcium and quick lime, and distilling it in the hermetically sealed apparatus (*fig.* 74) filled with dry carbonic anhydride. It is also produced by the action of chlorine-water on cacodyl. It is a very mobile liquid, heavier than water, which does not solidify even at $-45°$ C. It boils a little above 100° C., forming a colourless vapour of specific gravity 4·56 (by calculation 4·85). It does not fume in the air, but emits a very pungent intoxicating odour. The vapour mixed with air produces, when inhaled in rather large quantity, swelling of the mucous membrane of the nose and extravasation of blood in the eyes. The vapour evolved from the boiling liquid takes fire spontaneously in the air, and explodes violently when heated with oxygen gas.

Chloride of cacodyl is insoluble in *water* and *ether*, but soluble in all proportions in *alcohol*. *Sulphuric* and *phosphoric acids* decompose it, eliminating hydrochloric acid. Strong *nitric acid* sets it on fire. It burns in *chlorine* gas, with copious deposition of charcoal. *Zinc*, *tin*, and *iron* decompose it, setting the cacodyl free. With *alcoholic potash* it yields chloride of potassium, and an ethereal liquid having a disagreeable odour, and miscible in all proportions with water and alcohol. Mixed with solution of *nitrate of silver*, it gives up the whole of its chlorine, forming a precipitate of chloride of silver.

A *subchloride* or *oxychloride of cacodyl*, $KdCl.xKd^2O$, is obtained by the action of water on the chloride, also by distilling alkarsin with dilute hydrochloric acid, rectifying the product over a mixture of chalk and water, and redistilling in an atmosphere of carbonic anhydride. It is a liquid which resembles the chloride, has a very offensive odour, and boils at 109° C., giving off a vapour of specific gravity 5·46.

Chlorocuprite of Cacodyl, $KdCl.Cu^2Cl$, is obtained as a bulky white precipitate, on mixing an alcoholic solution of chloride of cacodyl with a solution of cuprous chloride in hydrochloric acid. In contact with the air, it turns green, and gives off very fetid arsenical vapours. It is decomposed by heat into its component chlorides.

Chloroplatinate of Cacodyl.—An alcoholic solution of chloride of cacodyl mixed with dichloride of platinum, yields a red-brown precipitate, probably consisting of $AsC^2H^6Cl.PtCl^2$; but on boiling this product with water, a yellow solution is obtained, which on cooling, deposits crystals of a new compound, viz.:

Chloride of Cacoplatyl, $AsC^2H^4PtCl.H^2O$, or rather $AsC^2H^4pt^2Cl.H^2O$, that is to say, the chloride of a radicle, cacoplatyl, formed from cacodyl by the substitution of 2 at. platinicum (pt. = 49·9) for 2 at. hydrogen. It appears to be formed from chloroplatinate of cacodyl, by abstraction of 2HCl. This salt forms needle-shaped crystals, which are inodorous, have a nauseous taste, and are soluble in hot water and alcohol. Ammonia dissolves it in all proportions, and the solution when evaporated yields indistinct crystals insoluble in alcohol. Chloride of cacoplatyl sustains a temperature of 164° C. without decomposing, merely giving off 4 per cent. of water, which it takes up again when boiled with water. At higher temperatures, it turns brown, and then burns away, giving off arsenical vapours and leaving arsenide of platinum. Chloride of cacoplatyl is not attacked by hydrochloric acid; sulphuric acid colours it yellow. With iodide and bromide of potassium, it forms yellow, precipitates of *iodide* and *bromide of cacoplatyl*, precisely similar in composition to the chloride. With nitrate of silver, it forms a precipitate of chloride of silver, the liquid remaining neutral. Boiled with sulphate of silver, it also forms chloride of silver, and the filtered solution evaporated in vacuo yields white crystalline grains of *sulphate of cacoplatyl*, $(AsC^2H^4pt^2)^2.SO^4$. (Gerh. i. 642.)

Trichloride of Cacodyl, $As(CH^3)^2Cl^3$.—Produced: 1. By the action of perchloride of phosphorus on cacodylic acid:

$$KdO^2H + 2PCl^5 = KdCl^3 + 2PCl^3O + HCl.$$

The chloride of phosphorus must be immersed in anhydrous ether, the cacodylic acid in powder added by small portions at a time, and the action moderated by external cooling.—2. By the action of chlorine on the monochloride. The latter compound, when brought directly in contact with chlorine gas, takes fire and undergoes complete decomposition; but if chlorine be led on to the surface of a solution of the monochloride in sulphide of carbon externally cooled, the trichloride is formed in crystalline laminæ, which may be purified by washing with sulphide of carbon.

The trichloride, prepared by the first method, forms beautiful large prismatic crystals, which, however, are very unstable, being instantly decomposed, at temperatures between 40° and 50° C., into chloride of methyl and dichloride of arsen-monomethyl:

$$As(CH^3)^2.Cl^3 = As(CH^3)Cl^2 + CH^3Cl.$$

The decomposition takes place spontaneously in the course of a day at ordinary temperatures, even when the compound is enclosed in sealed tubes. The crystals obtained by the second method are much more stable.

Trichloride of cacodyl dissolves without decomposition in anhydrous ether, and separates by quick cooling of a warm saturated solution, in laminæ, by slow cooling, or spontaneous evaporation, in transparent colourless prisms, which, however, become dull even in a vacuum. It dissolves less freely in sulphide of carbon, from which it separates in large laminæ. Anhydrous alcohol decomposes it, forming a syrup, which, by slow evaporation, yields crystals of basic perchloride of cacodyl, or hydrochlorate of cacodylic acid:

$$As(CH^3)^2Cl^3 + 2(C^2H^5.H.O) = \underbrace{As(CH^3)^2O^2H^2Cl}_{\text{Basic perchloride of cacodyl.}} + \underbrace{2C^2H^5Cl.}_{\text{Chloride of ethyl.}}$$

The alcoholic solution, left to evaporate, gives off a substance, probably *dichloride of arsen-monomethyl* (p. 401), which acts intensely on the mucous membranes. The trichloride fumes in moist air, giving off hydrochloric acid, and forming basic perchloride of cacodyl. The same decomposition takes place in the ethereal solution when exposed to the air, the basic perchloride separating in long needles, the formation of which may be accelerated by the addition of water or alcohol. The trichloride dissolves in water, with considerable rise of temperature, forming a solution of cacodylic acid and hydrochloric acid:

$$As(CH^3)^2Cl^3 + 2H^2O = As(CH^3)^2O^2H + 3HCl.$$

The decomposition is exactly similar to the preceding, the basic perchloride containing indeed the elements of cacodylic and hydrochloric acid:

$$As(CH^3)^2O^2H^2Cl = As(CH^3)^2O^2H + HCl.$$

The ethereal solution of the trichloride does not attack *mercuric oxide;* but on adding alcohol, a brisk action takes place, and an oil separates which contains chlorine and mercury, is soluble in alcohol, and precipitated by ether. On further addition of mercuric oxide, the whole solidifies to a mass of corrosive sublimate, and the compound of that substance with cacodylic acid (p. 408). Oxide of silver is also without action on the ethereal solution. (Baeyer.)

Dibromochloride of Cacodyl, $As(CH^3)^2ClBr^2$.—Bromine acts upon monochloride of cacodyl in the same manner as chlorine. On adding bromine to a mixture of the monochloride and sulphide of carbon, the dibromochloride is precipitated in the form of a yellow crystalline body, which is even more unstable than the trichloride, being quickly resolved into gaseous bromide of methyl, and a liquid which appears to be chlorobromide of arsen-monomethyl, $As(CH^3)^2.ClBr$, but is very unstable. (Baeyer).

Cyanide of Cacodyl, $As(CH^3)^2.CN = KdCy$, is obtained by distilling alkarsin (Cadet's liquor) with strong hydrocyanic acid, or better with a concentrated solution of cyanide of mercury; metallic mercury then separates, and cyanide of cacodyl collects under the water in the receiver, in the form of a yellowish oil, which soon solidifies in fine prismatic crystals. The liquid is decanted, and the crystals are dried by pressure between bibulous paper. The crystals are oblique prisms, truncated on the acute edges, and terminated by dihedral summits. It melts at 33° C., forming a colourless ethereal, strongly refracting liquid, which solidifies again on cooling. It boils at 140° C., yielding a vapour of specific gravity 4·63. It dissolves sparingly in water, much more readily in alcohol and ether. It is intensely poisonous, more so than any other cacodyl-compound. A few grains of it diffused in vapour through the air of a room, are sufficient to excite giddiness, delirium, numbness of the hands and feet, and even loss of consciousness; these attacks, however, are of short duration, provided the person affected make his escape in time. Cyanide of cacodyl is not decomposed by dilute alkalis, but *concentrated acids* decompose it, with evolution of hydrocyanic acid. With *silver-solutions* it forms a precipitate of cyanide of silver. It reduces *mercurous nitrate*, but does not act on mercuric nitrate. With *mercuric chloride*, it forms a white precipitate of chloromercurate of cacodyl.

Fluoride of Cacodyl, $As(CH^3)^2F = KdF$.—Produced by distilling the chloromercurate with hydrofluoric acid. It is a colourless liquid, which has an offensive odour, and attacks glass.

Iodide of Cacodyl, $As(CH^3)^2I = KdI$.—When alkarsin is distilled with concentrated hydriodic acid, an oily liquid passes over, which on cooling deposits transparent rhomboïdal tables, consisting of *oxyiodide of cacodyl*. To complete the separation, the liquid is immersed in a freezing mixture, then decanted from the crystals, and afterwards dried and rectified in the manner described for the chloride, the distillation being, however, discontinued when two-thirds of the liquid have passed over. Iodide of cacodyl thus prepared is a yellowish, slightly syrupy liquid, having a strong repulsive odour. It is heavier than melted chloride of calcium. It remains liquid at −10° C., and boils at a temperature above 100° C.; nevertheless it distils with the vapour of water. It does not fume when exposed to the air, but gradually oxidises and deposits fine prismatic crystals of cacodylic acid. It is soluble in *alcohol* and *ether*, but insoluble in water. *Nitric* and *sulphuric acids* decompose it, setting iodine free. When heated in the air it burns with a dazzling flame, giving off vapours of iodine.

Oxide of Cacodyl, $As^2C^4H^{12}O = Kd^2O$. (Bunsen's *Paracacodylic Oxide*, see p. 403.)—This compound is formed by the slow oxidation of cacodyl; also by the action of reducing agents, such as hydriodic, hydrobromic, sulphydric, or phosphorous acid, protochloride of tin, &c., on cacodylic acid. When air is made to bubble slowly through alkarsin, that liquid is gradually converted into a syrup filled with crystals of cacodylic acid; and on dissolving in water the mass thus obtained, and distilling, water having the odour of cacodyl passes over at first, and afterwards between 120° and 130° C., an oily liquid, which when dried over caustic baryta, and rectified out of contact of air, yields pure oxide of cacodyl, in the form of a limpid oil, having a pungent odour, sparingly soluble in water, and boiling at 120° C. When exposed to the air, it oxidises very slowly, without fuming or rise of temperature, and is converted into cacodylic acid. Air mixed with its vapour between 50° and 70° C. detonates violently on the approach of a burning body. Oxide of cacodyl dissolves in hydrochloric, hydriodic, and hydrobromic acids, forming the chloride, bromide, and iodide of cacodyl.

Oxide of cacodyl forms with *mercuric chloride*, a white precipitate, which is a compound of the two substances $Kd^2O.4HgCl$. This compound, called chloromercurate of cacodyl, is also produced by mixing a dilute alcoholic solution of alkarsin with a dilute solution of mercuric chloride, the latter not being in excess. After several crystallisations from boiling water, it forms silky tufts, and by slow cooling of the solution, may be obtained in small rhombic tables; 100 pts. of boiling water dissolve 3·47 pts. of the compound: it is also soluble in alcohol, especially at the boiling heat. It is inodorous, but has a disagreeable metallic taste, and is very poisonous. When heated in contact with the air, it decomposes without leaving any residue. With hydrochloric, hydriodic, and hydrobromic acids, it forms chloride, iodide, and bromide of cacodyl.

Oxide of cacodyl forms with *mercuric bromide*, a compound similar in composition and properties to that just described, viz. the bromomercurate of cacodyl, $Kd^2O.4HgBr$. With *nitrate of silver*, it forms the compound $3Kd^2O.2NO^3Ag$, which separates in the form of a heavy, white, crystalline powder, on pouring a solution of nitrate of silver into a cold solution of alkarsin in dilute nitric acid. This compound sustains a temperature of 90° C. without decomposing, but explodes at 100° C., giving off fetid arsenical products. With *dichloride of platinum*, oxide of cacodyl forms a red-brown precipitate, and with *cyanide of mercury* a brown pulverulent precipitate, resembling paracyanogen and smelling like dried nightshade berries.

Dioxide of Cacodyl, $AsC^2H^6O = KdO$, or *Cacodylate of Cacodyl*, $\left.\begin{matrix}Kd\\Kd\end{matrix}\right\}O^2$—This is the thick syrupy liquid which is produced by the slow oxidation of cacodyl or alkarsin, and gradually becomes filled with crystals of cacodylic acid. It is decomposed by water, and the liquid then yields a distillate of oxide of cacodyl, and leaves a residue of cacodylic acid:

$$4KdO + H^2O = Kd^2O + 2KdO^2H.$$

Cacodylic Acid, $AsC^2H^7O^2 = KdO^2.H$, or $Kd^2O^3.H^2O$.—This compound may be prepared by passing oxygen gas for several days through alkarsin; the greater part of the liquid is then converted into crystals of cacodylic acid, which may be purified by pressure between paper and recrystallisation. This mode of preparation, however, is disagreeable and dangerous, on account of the inflammability and poisonous character of the cacodyl. A safer and more expeditious method is to oxidise alkarsin with mercuric oxide. The two substances are placed together under water, in a vessel externally cooled; mercury is thereby reduced, and cacodylate of mercury formed:

$$Kd + 2Hg^2O = 3Hg + KdO^2Hg.$$

More alkarsin is then added, drop by drop, till mercury no longer separates on heating the mixture, and a faint odour of cacodyl becomes perceptible; after which the liquid is evaporated, the residue dissolved in alcohol, and the cacodylic acid which crystallises from the solution is purified by recrystallisation from alcohol. It is then obtained in large oblique rhomboidal prisms, transparent and colourless. It is inodorous and not at all poisonous, although it contains 54·35 per cent. of arsenic. It dissolves in water in all proportions, somewhat less freely in alcohol, and is insoluble in ether. It is permanent in dry air, but damp air decomposes it. It is altogether a very stable compound, sustaining a heat of 200° C. without decomposition; at higher temperatures however, it decomposes, yielding arsenious oxide and other arsenical products having a very fetid odour. It is not attacked by fuming nitric acid, or by a mixture of sulphuric acid and chromate of potassium, even at the boiling heat. It is not deoxidised by sulphurous acid, oxalic acid, ferrous sulphate, or hydrogen gas; but when heated with *phosphorous acid*, it gives off vapours of cacodyl. It is also reduced when its aqueous solution is boiled with *zinc*. An acid solution of *protochloride of tin* converts it into chloride of cacodyl. Dry *hydriodic acid* gas, passed over dry cacodylic acid, forms iodide of cacodyl, water, and free iodine:

$$KdO^2H + 3HI = KdI + 2H^2O + 2I.$$

Dry *hydrobromic acid* gas acts in a similar manner. With dry *hydrochloric acid*, on the contrary, or with the concentrated aqueous acid, cacodylic acid unites directly, forming the compound $KdO^2H.ClH$. But by exposing cacodylic acid for some time to a stream of hydrochloric acid gas, *dichloride of arsenmonomethyl* is obtained, together with water and chloride of methyl. (Baeyer):

$$As(CH^3)^2O^2H + 3HCl = AsCH^3Cl^2 + 2H^2O + CH^3Cl.$$

Sulphydric acid, either dry or in aqueous solution, decomposes cacodylic acid, with rise of temperature, forming disulphide of cacodyl, water, and sulphur:

$$2KdO^2H + 3H^2S = 2KdS + 4H^2O + S;$$

but if the cacodylic acid is dissolved in weak alcohol, a considerable quantity of protosulphide is formed as well as disulphide:

$$2KdO^2H + 3H^2S = Kd^2S + 4H^2O + 2S.$$

Cacodylates.—Cacodylic acid dissolves metallic oxides, and decomposes carbonates with effervescence. Most of its salts are gummy, but few being capable of crystallising. The general formula of the normal cacodylates is $AsC^2H^6MO^2 = KdO^2M$. They require a higher temperature to decompose them than the acid, and give off stinking products, leaving a residue of carbonate or arsenate. They dissolve in water and in alcohol. Sulphydric acid converts them into the corresponding *sulpho-cacodylates* KdS^2M. With *silver*, cacodylic acid forms a normal salt, KdO^4Ag, and an acid salt, $KdO^2Ag.2KdO^2H$, both of which crystallise in needles.

Cacodylic acid also combines with certain *acids*.

Hydrochlorate of cacodylic acid, $KdO^2H.ClH$, called by Bunsen, *basic perchloride of cacodyl*, is obtained by dissolving cacodylic acid in concentrated hydrochloric acid, and evaporating in vacuo. It then solidifies in a mass of beautiful lamellated crystals, inodorous, but having a strong acid taste (Bunsen). It is also produced by the action of water or alcohol on trichloride of cacodyl (Baeyer, p. 406). The compound is decomposed by water into hydrochloric and cacodylic acids, and when heated to 200° C. gives off monochlorinated hydride of methyl, water, hydrochloric acid, and an oily liquid, leaving a residue of arsenious acid.

On mixing the alcoholic solutions of cacodylic acid and mercuric chloride, a *cacodylate of mercuric chloride*, $Kd^2O^4.2HgCl$, is precipitated in white shining scales, which change after a while to slender needles.

Hydrofluoric acid forms with cacodylic acid a similar compound, $KdO^2H.FH$, which crystallises in fine prisms. *Hydrobromic acid* also unites directly with cacodylic acid, but the compound is a syrupy liquid which does not crystallise.

Selenide of Cacodyl, is obtained by distilling chloride of cacodyl two or three times with aqueous selenide of sodium. It passes over with the vapour of water, in the form of a heavy yellow oil, having an extremely offensive odour. It is insoluble in water, but soluble in alcohol and ether. It has a very high boiling point. It forms black precipitates with *lead* and *silver* salts, and with *mercuric chloride*, it yields first a black precipitate of sulphide of mercury, and afterwards, on further addition of the mercury-salt, a copious precipitate of chloromercurate of cacodyl.

Sulphide of Cacodyl, $As^2C^4H^{12}S = Kd^2S$, may be prepared by adding a solution of sulphide of barium to the crude liquid obtained by distilling acetate of potassium with arsenious oxide, or by distilling sulphydrate of barium with chloride of cacodyl. It is purified by means of carbonate of lead and chloride of calcium. It is a transparent, colourless, extremely fetid liquid, which retains its fluidity at 40° C., and boils at a temperature considerably above 100°, yielding a vapour of specific gravity 7·72. It is nearly insoluble in water, but mixes in all proportions with alcohol and ether. It does not fume in the air, but rapidly absorbs oxygen, being converted into dioxide and disulphide of cacodyl:

$$Kd^2S + O = KdO + KdS.$$

Hydrochloric acid converts it into chloride of cacodyl, with evolution of sulphydric acid.

Disulphide of Cacodyl, KdS, or *Sulphocacodylate of cacodyl*, $\left.\begin{matrix}Kd\\Kd\end{matrix}\right\}S^2$.—Obtained by the action of sulphur on cacodyl, or on the monosulphides, or by treating cacodylic acid with sulphuretted hydrogen in a vessel externally cooled. Disulphide of cacodyl then separates, mixed with excess of sulphur, from which it may be separated by solution in boiling alcohol. The solution, if slowly cooled, deposits the disulphide in large rhombic tables, but if quickly cooled, in small prisms, soft and greasy to the touch. The compound has a pungent odour, like that of asafœtida, is permanent in the air, and melts at 50° C., forming a colourless liquid, which solidifies in a crystalline mass on cooling. It is insoluble in water, but dissolves readily in alcohol, very sparingly in ether. It dissolves in hydrochloric acid without alteration; in strong sulphuric acid, with evolution of sulphurous acid and separation of sulphur. Nitric acid and peroxide of lead convert it into cacodylic acid. Mercury decomposes it, forming protosulphide of cacodyl, and sulphide of mercury.

Sulphocacodylic acid, $AsC^2H^6S^2 = KdS^2H$.—This acid has not been obtained in the free state, but its salts, KdS^2M, are obtained by precipitating the alcoholic solution of the disulphide with alcoholic solutions of certain metallic salts, or by decomposing the cacodylates with sulphydric acid. The *lead-salt*, KdS^2Pb, forms small white pearly scales, which are indorous, permanent in the air, not affected by sulphydric acid, insoluble in water, nearly insoluble in alcohol. The *cuprous salt*, KdS^2Ccu, [$Ccu = Cu^2$], is obtained by adding an alcoholic solution of cupric nitrate to a large excess of alcoholic disulphide of cacodyl, cacodylic acid and nitrate of cacodyl being formed at the same time:

$$4KdS + 2NO^3Cu + 2H^2O = 2KdS^2Cu + KdO^2H + NO^3Kd + NO^3H.$$

It is a soft, loose, egg-yellow powder, which is decomposed by heat, and is insoluble in water, aqueous acids, alcohol, and ether. The *antimony-salt*, Kd^3S^6Sb (Sb being equivalent to H^3), crystallises in short light yellow needles, difficult to purify. The *bismuth-salt*, Kd^3S^6Bi, forms delicate, golden-yellow, inodorous scales, which are permanent in the air, sustain a heat of 100° C. without decomposition, and are not affected by sulphydric acid. They are insoluble in water, and nearly insoluble in alcohol and ether. The *gold-salt*, KdS^2Au, is obtained by mixing the alcoholic solutions of disulphide of cacodyl and trichloride of gold, cacodylic acid being formed at the same time, as a soft, yellowish white, tasteless, inodorous powder, which is set on fire by strong nitric acid, with separation of sulphur and gold. It is decomposed by caustic potash, but not by sulphydric acid. Insoluble in water, hydrochloric acid, alcohol and ether.

ARSENTRIMETHYL $As(CH^3)^3$ and **ARSENMETHYLIUM** $As(CH^3)^4$. (**Cahours** and **Riche**, Compt. rend. xxxix. 541.)—When iodide of methyl is dropped by small portions into a small flask filled with carbonic anhydride and containing pulverised arsenide of sodium, a considerable degree of heat is developed; and if the additions of iodide of methyl be repeated till no further rise of temperature is produced, and the mixture be then distilled in a current of carbonic anhydride, four products are obtained, viz. unaltered iodide of methyl, a white crystalline body, and a heavy liquid composed of two distinct compounds, one of which boils at 120° C., the other between 165 and 170°. The former is arsentrimethyl; the latter arsendimethyl or cacodyl. The quantity of these liquids obtained is but small, even when the matter operated upon amounts to 100 grammes.

Arsentrimethyl is obtained pure by the decomposition of iodide of arsenmethylium, *e.g.* by treating the compound of iodide of arsenmethylium and iodide of arsenic (*vid. inf.*) with boiling potash-ley, evaporating to dryness, and distilling in an atmosphere of carbonic anhydride. It is a colourless mobile liquid, boiling below 100° C. It is diatomic. The *oxide*, $AsMe^3O$, is crystallisable but deliquescent. The *sulphide*, $AsMe^3S$ crystallises from aqueous or alcoholic solution by slow evaporation in colourless prisms. It unites already with iodine and bromine, forming the compounds $AsMe^3I^2$ and $AsMe^3Br^2$. (Cahours, Compt. rend. xlix 87; Jahresber. d. Chem. 1859, 431.)

Iodide of Arsenmethylium.—This is the crystallised body just mentioned, which is in fact the chief product of the reaction. It may also be obtained by the action of iodide of methyl upon cacodyl. On mixing these two liquids in a tube, a violent action takes place, and a yellowish white mass of crystals of iodide of arsenmethylium is obtained, impregnated with an oily matter of the same colour, consisting of iodide of cacodyl:

$$2CH^3I + 2As(CH^3)^2 = As(C^2H^3)^4I + AsC^2H^6.I.$$

The crystals, freed from the oil by draining and pressure between bibulous paper, and then dissolved in iodide of methyl mixed with alcohol, separate from the solution in the form of beautiful colourless tables having a high lustre.

Iodide of arsenmethylium boiled with recently precipitated oxide of silver, yields a strongly alkaline liquid, which, when evaporated in vacuo, yields very deliquescent crystalline laminæ consisting of the *hydrated oxide of arsenmethylium;* and its solution mixed with sulphate or nitrate of silver, yields iodide of silver, and *sulphate* of arsenmethylium, $SO^4(AsMe^4)^2$, or the *nitrate*, NO^3AsMe^4. These salts are very soluble, highly deliquescent, and separate from their solutions by evaporation in vacuo, in the form of beautiful crystals.

Iodide of Arsenmethylium with Tri-iodide of Arsènic $As(CH^3)^4I.AsI^3$.—When iodide of methyl is heated to 200° C., in contact with metallic arsenic, the latter disappears, and a large quantity of orange-red tabular crystals are obtained, moistened with a brownish liquid.

The crystals are decomposed by distillation, yielding an oil which has a penetrating odour and excites tears. This oil is a mixture of several substances, the least volatile of which boils at 170° C., has the composition of iodide of cacodyl, and yields cacodyl when distilled with amalgam of zinc; the more volatile portion deposits long white very beautiful needles, isomeric with iodide of cacodyl.

Iodide of Arsenmethylium and Zinc, $As(CH^3)^4I.ZnI$, is obtained in colourless crystals by heating iodide of methyl with arsenide of zinc. It is decomposed by boiling with potash-ley, a heavy oil separating, which solidifies on cooling, and if this mass be exposed to the air till the free potash is converted into carbonate, then exhausted with absolute alcohol, and the alcohol left to evaporate, iodide of arsenmethylium crystallises out in prisms. (Cahours, Compt. rend. xlix. 87.)

Iodide of Arsenmethylium and Cadmium, $As(CH^3)^4I.CdI$, is obtained in like manner and exhibits similar properties. (Cahours.)

Tri-iodide of Arsenmethylium, $As(CH^3)^4I^3$.—Analogous to tri-iodide of tetrethylium. (Cahours.)

Bromide of Arsenmethylium.—Bromide of methyl acts energetically on cacodyl, yielding bromide of arsenmethylium in beautiful, very deliquescent crystals, and liquid bromide of cacodyl. (Cahours and Riche.)

ARSENDIMETHYL-DIETHYLIUM. $As(CH^3)^2(C^2H^5)^2 = AsMe^2E^2$.—(Cahours and Riche, Compt. rend xxxix. 544.)

This radicle, like the preceding, has not been obtained in the free state, but the sulphide, iodide, bromide, and chloride are formed, together with the corresponding compounds of cacodyl, by the action of sulphide, iodide, &c., of ethyl on cacodyl.

Iodide. $As(CH^3)^2(C^2H^5)^2I$.—When iodide of ethyl is mixed with cacodyl, no apparent change takes place at first; but the mixture, when left to itself, gradually deposits magnificent crystals of iodide of arsendimethyldiethylium, and likewise yields an oil consisting of iodide of cacodyl:

$$2EI + 2AsMe^2 = AsMe^2E^2I + AsMe^2I.$$

Bromide and *Chloride of ethyl* act in a similar manner, but more slowly. To obtain *chloride of arsenmethethylium*, the mixture must be heated in sealed tubes to 180° or 200° C.; it then deposits an oil containing needle-shaped crystals of the chloride. On distilling the oil and leaving the distillate to cool, these crystals separate in large quantity. Chloride of arsendimethyldiethylium forms crystalline compounds with chloride of mercury, trichloride of gold, and dichloride of platinum.

The *Hydrate* is formed by treating a solution of the iodide with oxide of silver; a strongly alkaline liquid is then obtained, which, when evaporated, deposits the oxide in very deliquescent crystalline scales.

Sulphide.—Sulphide of ethyl acts very slowly on cacodyl, and only when heated, forming crystalline sulphide of arsendimethyldiethylium and a yellowish oil, consisting of sulphide of cacodyl.

The *Sulphate* and *Nitrate* are obtained in the form of very deliquescent crystals, by treating the solution of the iodide with sulphate or nitrate of silver.

ARSENTRIMETHYL-ETHYLIUM, $AsMe^3EI$, and ARSENMETHYL-TRIETHYLIUM, $AsMeE^3$.—The iodides of these radicles are obtained by treating arsentrimethyl with iodide of ethyl, and arsentriethyl with iodide of methyl respectively. Both are isomorphous with the iodides of arsentetramethylium and arsentetrethylium.

ARSENDIMETHYL-DIAMYLIUM, $As(C^2H^3)^2(C^5H^{11})^2 = AsMe^2Am^2$.—The iodide of this radicle is produced, together with iodide of cacodyl, by heating cacodyl with iodide of amyl to 180° C. for two or three days. It crystallises either in nacreous needles, or in thin plates. Treated with oxide, nitrate, and sulphate of silver, it yields the *oxide*, *nitrate*, and *sulphate* of arsendimethyldiamylium. (Cahours and Riche.)

The arsenides of methyl and their compounds are related to one another by the following law. If we arrange them in two groups, the one formed on the type of chloride of ammonium, NH^4Cl, the other on that of ammonia, NH^3, as in the following tables, we find that each member of the second column may be derived from the one next above it in the first, by abstraction of chloride of methyl; and each member in the first column except the highest, may be formed from the one next above it in the second, by addition of 2 atoms of chlorine, the series extending from chloride of arsentetramethylium to trichloride of arsenic:

Type NH^4Cl.	*Type* NH^3.
As Me Me Me Me Cl	
	As Me Me Me
As Me Me Me Cl Cl	
	As Me Me Cl
As Me Me Cl Cl Cl	
	As Me Cl Cl
As Me Cl Cl Cl Cl	
	As Cl Cl Cl

All the reactions indicated in this table have been actually observed, excepting the resolution of $AsMe^4Cl$ into $AsMe^3$ and $MeCl$, and that of $AsMe^3Cl^2$ into $AsMe^2Cl$ and $MeCl$; but a decomposition analogous to the former of these, appears to take place in the preparation of the iodides of the arsenmethyls and arsenethyls, the iodide of arsenmethylium or arsenethylium being formed at first, and then resolved by distillation into iodide of methyl or ethyl, and arsentrimethyl or arsentriethyl, just as iodide of tetrethylium, $N(C^2H^5)^4I$, is resolved under similar circumstances into iodide of ethyl and triethylamine.

There is also another relation to be observed between these compounds, viz. that each of them may be derived from the one immediately above it in the same column, by substitution of chlorine for methyl; and hence it appears that $AsMe^4$ is monatomic; $AsMe^3$ diatomic; $AsMe^2$ either monatomic or triatomic; and $AsMe$ either diatomic or tetratomic; just as in chloride of propyl, C^3H^7Cl, the radicle C^3H^7 replaces 1 at. hydrogen, whereas in chloride of propylene, $C^3H^6Cl^2$, derived from the former by substitution of 1Cl for 1H, the radicle C^3H^6 takes the place of 2 atoms of hydrogen; and in trichlorhydrin, $C^3H^5Cl^3$, the next term in the same series, C^3H^5 (glyceryl), takes the place of 3 at. H. Moreover, just as the group C^3H^5 is monatomic in the allyl-compounds, and triatomic in the glyceryl-compounds, so likewise $As(CH^3)^2$ is sometimes monatomic and sometimes triatomic. The analogy between the two series of compounds will be more clearly seen from the following tabular view:

$As(\overset{\prime}{C}H^3)^2 \ . \ Cl$	$\overset{\prime}{C^3}H^7 \ . \ Cl$
$As(\overset{\prime\prime}{C}H^3)^3 \ . \ Cl^2$	$\overset{\prime\prime}{C^3}H^6 \ . \ Cl^2$
$As(\overset{\prime\prime\prime}{C}H^3)^2 \ . \ Cl^3$	$\overset{\prime\prime\prime}{C^3}H^5 \ . \ Cl^3$
$As(\overset{\prime}{C}H^3)^2 \quad Cl.$	$\overset{\prime}{C^3}H^5 \ . \ Cl.$

Similar analogies may be traced in the compounds of arsenic and ethyl, and likewise, though not yet quite so clearly, in the compounds of antimony, bismuth, and phosphorus, with the alcohol-radicles. (Baeyer.)—In fact, the compounds of these metalloïdal radicles may, in almost all cases, be reduced to the general types MR^3 M^2R^3, MR^5, M^2R^5, where M stands for P, As, Sb, or Bi; and the 3 or 5 at. R are made up, partly by an alcohol-radicle, partly by an equivalent quantity of chlorine, iodine, oxygen, sulphur, &c. (See ORGANO-METALLIC BODIES.)

Arsenide of Tetryl. *Tetryl- or Butyl-cacodyl. Cacodyl of Valeric Acid.*—When valerate of potassium is distilled with an equal weight of arsenious oxide, a heavy yellowish oil passes over, which has a penetrating alliaceous odour, fumes copiously in the air, but does not take fire spontaneously. It is soluble in water, forms a thick white precipitate with mercuric chloride, and appears to reduce mercuric oxide to the metallic state. When left for some time in a loosely closed vessel, it changes entirely into a mass of large, hard, shining, nearly colourless, prisms, which, after drying between filtering paper, are destitute of odour. They have an acid reaction, dissolve in water, and are completely decomposed by nitrate of silver. (Gibbs, Sill. Am. J. [2] xv. 118.)

Arsenide of Trityl. *Trityl- or Propyl-cacodyl. Cacodyl of Butyric Acid.*—By distilling equal weights of butyrate of calcium and arsenious oxide, shaking up the distillate with magnesia and water, and rectifying, a heavy colourless oily liquid is obtained, which has a disgusting cacodyl-odour, does not fume in the air, but burns when set on fire with a white flame and arsenical smoke. The watery liquid which passes over with the oil, appears to contain a considerable quantity of it, and gives a white precipitate with mercuric chloride, the cacodyl-odour being at the same time destroyed. The precipitate dissolves on heating the liquid, but reappears in small crystals on cooling. On mixing the solution and the crystals with hydrochloric acid and zinc, the odour of cacodyl reappears, the evolved hydrogen gives off thick white fumes in the air, and deposits an orange-coloured substance on cold bodies. The mixture when heated yields a colourless fœtid oil, which fumes in the air, but is not spontaneously inflammable. (Wöhler, Ann. Ch. Pharm. lxviii. 127.)

ARSENIOSIDERITE. *Arsenocrocite.* A hydrated ferrico-calcite arsenate, occurring at Romanèche, near Macon, in spherical masses of fibrous texture and yellow colour. Its exact composition has not been determined.

ARSENITE or **ARSENOLITE.** *Arsenic bloom. Native Arsenious Oxide.*—A rare mineral, generally occurring in needle-shaped or capillary crystals, also massive, with spherical and botryoïdal surface; very rarely in regular octahedrons. Specific gravity = 3·69 to 3·71. Hardness = 1·5. It consists of arsenious oxide more or less pure, has a white to greyish-white colour, occasionally yellow, red, or green; sometimes covered with a blackish crust (? suboxide or a mixture of arsenious oxide with metallic arsenic). It is translucent, with vitreous to silky lustre. It is found, accompanying ores of silver, lead, arsenical iron, cobalt, nickel, &c., at Andreasburg in the Harz; also at Joachimsthal in Bohemia, Kapnik in Hungary, and in the old mines of Biber in Hanau. (Dana, ii. 139.)

ARSENOMELANE. See BINNITE.

ARSENOPYRITE. Syn. with MISPICKEL.

ARSENOSIDERITE. Native diarsenide of iron. (See IRON, ARSENIDES OF.)

ARSENPHYLLITE. Breithaupt's name for a mineral which, according to him, has the composition of arsenious oxide, but crystallises in forms of the trimetric system, isomorphous with valentinite. The trioxides of arsenic and antimony are therefore isodimorphous.

ARSIDOGEN. The name given by L. Gmelin (Handb. ix. 315), to the hypothetical compound AsH^2 (= Ar), analogous to amidogen, NH^2, formerly supposed by Laurent, Gerhardt, and Dumas, to exist in cacodyl and its derivatives. According to this view, cacodyl was supposed to be the hydride of a compound, C^4ArH^3, analogous to ethylene, viz. $C^4ArH^3.H$; oxide of cacodyl = $C^4ArH^3.HO$; the protosulphide = $C^4ArH^3.HS$, &c.

ARTHANITIN, or **CYCLAMIN,** a crystalline substance extracted by Saladin (J. Chim. méd. vi. 417), from the roots of *Cyclamen Europæum* (*Arthanita officinalis*).—It is said also to exist in small quantity in the roots of the cowslip (*Primula veris*), of *Anagallis arvensis*, and *Limosella aquatica*.—It is prepared by digesting the fresh roots of cyclamen with alcohol, evaporating the extract, and treating the residue, first with ether, then with cold water: the insoluble part constitutes arthanitin. It is purified by recrystallisation from alcohol, with the aid of animal charcoal. It crystallises in fine colourless needles, which are inodorous, but have a strongly acrid and styptic taste. It is neutral to vegetable colours, dissolves in 500 pts. of water, readily in alcohol. It is altered at the temperature of boiling water, becoming less soluble in alcohol. Nitric acid transforms it into oxalic acid. Sulphuric acid communicates to it a violet-red tint. Taken internally, arthanitin acts like a purgative, and produces vomiting.

ARTICHOKE. According to Verdeil (Compt. rend. xli. 588), the green colouring matter of the artichoke (*Cynara scolymus*) and other composite plants, is a substance distinct from chlorophyll, and is formed by the action of the air, water, and ammonia, on the comminuted parts of the plants. The liquid, which has a fine green colour, forms with acetic acid a bulky green precipitate, which resembles indigo when dry, but when treated with aqueous alkalis, again forms solutions of a beautiful green colour.

The artichoke yields, according to Richardson (Ann. Ch. Pharm. lxvii. Table), in the fresh state, 1·17 per cent. of ash; in the dry state, 6·2 per cent. In the roots, stems, and leaves of the Jerusalem artichoke (*Helianthus tuberosus*) Way and Ogston (Journ. of Agric. Soc. vii. [2] 593) found in the fresh state, 1·79, 1·94, and 15·00 per cent. of ash; in the same parts when dried, 12·2, 4·4, and 28·3 per cent. The constituents of the ash are given in the following table:

	Artichoke.	Jerusalem Artichoke.		
		Root.	Stem.	Leaves.
Potash	24·0	55·9	38·4	6·8
Soda	5·5		0·7	3·7
Lime	9·6	3·3	20·3	40·1
Magnesia	4·1	1·3	1·9	2·0
Sulphuric acid (SO^3)	5·2	3·8	3·2	2·0
Carbonic acid (CO^2)		11·8	25·4	24·3
Phosphoric acid (P^2O^5)	36 2	16·7	3 0	0·6
Silica	7·0	1·5	1·5	17·5
Sesquioxide of iron		0 5	0·9	1·1
Chloride of potassium		5·0		
Chloride of sodium	3·6		4·7	1·8
Sesquiphosphate of iron	4·8			

ARTOCARPUS INCISA. The fruit of this tree, the bread-fruit tree, which grows in the islands of the East Indian Archipelago, contains 14 per cent. of starch, 3 per cent. albumin, 19 gluten and woody fibre, and 63 water.

ARUM ESCULENTUM. The fresh tubers of this plant yield, according to T. J. Herapath (Chem. Soc. Qu. J. iii. 193), 1·65 per cent. ash, containing in 100 pts.: 61·7 pts. soluble in water, and consisting of 45·1 K^2O; 8·1 NaCl; 3·8 SO^3; 4·7 P^2O^5; and 38·7 pts. insoluble in water, consisting of 18·3 K^2O; 1·1 Fe^4O^3; 11·4 P^2O^5, 6·1 SiO^2.

ARUM MACULATUM. The fresh plant contains a sharp milky juice, which produces inflammation of the skin, but is so volatile and unstable that it is no longer present in the dried root. The dry root is said to contain 71 per cent. starch, together with 23 per cent. gum and vegetable mucus.

ARUNDO PHRAGMITES. The dry plant yields 4·7 per cent. of ash, which according to Schulz-Fleeth (Pogg. Ann. lxxxiv. 80), contains in 100 pts.: 8·6 K^2O; 5·9 Ca^2O; 1·2 Mg^2O; 0·2 Fe^4O^3; 2·8 SO^3; 71·5 SiO^2; 6·6 CO^2; 2·0 P^2O^5; 0·4 NaCl.

ASA DULCIS. See Benzoin.

ASAFŒTIDA. *Gummi Asæ fœtidæ, Stinkasant, Teufelsdreck.*—A gum-resin extracted from the root of the *Ferula Asafœtida*, an umbelliferous plant growing in Persia. The root, which is black on the outer surface, resembles a large parsnep. On cutting it transversely, the asafœtida exudes in the form of a white juice, like cream, but on exposure to the air, it gradually becomes yellow and at last dark brown. It is very apt to run into decomposition; hence, those who collect it carefully defend it from the sun. The fresh juice has an excessively strong smell, which grows weaker and weaker upon keeping; a single dram of the fresh fluid smells more than a hundred pounds of the dry asafœtida brought to us. The Persians are commonly obliged to hire ships on purpose for its carriage, as scarcely any one will receive it along with other commodities, its stench infecting everything that comes near it.

Asafœtida is met with, sometimes in small drops or tears, but more frequently in reddish masses with white streaks. Specific gravity 1·327. Its recently fractured surface has but little colour, but quickly reddens on exposure to the air. It is friable at very low temperatures, but softens at the heat of the hand. It dissolves in alcohol much more readily than in water. It has an extremely disagreeable alliaceous odour, and a sharp biting taste. It contains in 100 pts., according to Pelletier (Bull. Pharm. iii. 556), 65·0 of resin, 19·4 soluble gum, 11·2 bassorin, 3·6 volatile oil, and 0·3 of malate of calcium. According to Johnston (Phil. Mag. Dec. 1838) the resin of asafœtida, which may be extracted by alcohol, is of a light yellow colour, when pure, but becomes purple on exposure to the sun. It contains about 70·2 per cent. of carbon, 7·6 of hydrogen, and 22·2 of oxygen; no sulphur. Asafœtida is used as a remedy in nervous and hysteric affections, as a deobstruent, and sometimes as an anthelmintic. It is said to be used also by some Asiatic tribes as a condiment.

Oil of Asafœtida.—Asafœtida distilled with water yields about 3 per cent. of a sulphuretted essential oil, to which its odour is due. This oil is neutral, begins to boil between 135° and 140° C., and when left at rest, gives off a considerable quantity of sulphydric acid. Hlasiwetz (Ann. Ch. Pharm. lxxi. 23) obtained from it by analysis, from 64·2 to 69·3 per cent. carbon, from 9·1 to 10·5 per cent. hydrogen, and 20·2 to 25·5 per cent. sulphur, its composition varying with the time elapsed since its preparation. Hlasiwetz regards it as a variable mixture of the two compounds $C^{12}H^{22}S^4$ and $C^{12}H^{22}S$. When it is treated with oxide of silver, sulphide of silver is formed, and the liquid, if afterwards rectified, contains 65·6 per cent. C, 13·1 H, and 24·8 S. On agitating it with strong solution of potash and hydrate of lead, and then rectifying, an oil is obtained having an odour of lavender or rosemary, and containing about 60·7 per cent. C, 9·5 N, and 29·85 S. An oil having the same composition is obtained by passing sulphurous acid gas through the crude oil.

The alcoholic solution of oil of asafœtida forms with dichloride of platinum, yellow or brown precipitates varying in composition, according to the strength of the solutions and the duration of the action, but all containing the same proportions of carbon and hydrogen as the oil itself, viz. C^6H^{11}.

On mixing concentrated alcoholic solutions of oil of asafœtida and chloride of mercury a white precipitate is formed, which is partly dissolved by boiling alcohol; and the solution on cooling yields microscopic crystals containing $2C^6H^{11}S.5Hg^2S + 2C^6H^{11}Cl^2.HgCl$. The portion of the precipitate insoluble in alcohol, blackens when treated with potash, a proof that it contains mercurous chloride: it was found to contain $C^6H^{11}S^4.Hg^2S.4Hg^2Cl.4Hg^2SCl$. Both these mercury-compounds, when treated with sulphocyanate of potassium, yield a volatile oil smelling like oil of mustard, and like that oil, forming a crystalline compound with ammonia: it does not however contain allyl, but probably the homologous radicle, C^6H^{11} (Hlasiwetz, Hand. d. Chem. 2^{te} Aufl. ii. 339.)

ASARIN or **ASARONE**, $C^{20}H^{26}O^5$.—This substance is contained in the root of asarabacca (*Asarum europæum*) and passes over in the crystalline form when the dry root is distilled with water. The crystals belong to the monoclinic or oblique prismatic system, and resemble camphor in taste and odour. Asarone melts at 40° C., begins to boil at 280°, and may be sublimed in small quantity between two watch-glasses. It is insoluble in water, but dissolves readily in alcohol, ether, and essential oils. When it is boiled for some time with alcohol, the solution gradually turns red, and a portion of the asarone is converted into an uncrystallisable, resinous, isomeric modfication, which does not distil with vapour of water, and decomposes at 300° C. Nitric acid converts asarone into oxalic acid. It is dissolved with red colour by strong sulphuric acid, and reprecipitated by water. It is strongly attacked by chlorine, giving off hydrochloric acid, and yielding a thick oil whose composition approximates to the formula $C^{20}H^{22}Cl^4O^5$. (Goertz, Pfaff's System d. Materia Medica, iv. 229; Blanchet and Sell, Ann. Ch. Pharm. vi. 296; Schmidt, *ibid.* liii. 156.)

ASARITE. A camphor-like substance found, together with asarone, in the root of *Asarum europuæm*, and resembling that substance in many respects, but differing from it in appearance, in not decomposing so readily when sublimed, but chiefly in its melting point which is 70° C. whereas that of asarone is 40°. It is obtained by dissolving in alcohol the impure crystals of asarone as they are obtained by distilling the root with water, precipitating by alcohol, and collecting the small silky crystals which float about in the liquid. Gräger, who obtained this substance at first, regarded it as a distinct body, but was afterwards disposed to regard it as identical with asarone: the difference in the melting point is, however, too great to be accounted for by error of observation. Blanchet and Sell suppose it to be the solid part of asurum-oil, and asarone a product of the decomposition of that oil.

ASARUM-OIL. A volatile oil existing in small quantity (about $\frac{1}{180}$) in the root of *Asarum europæum*, and passing over, together with asarone, when the root is distilled with water. It may be separated from the asarone by treating the oily portion of the distillate with a small quantity of alcohol. Two layers then form, the upper being an alcoholic solution of asarone, containing a little of the oil; the lower, a solution of small quantities of asarone and alcohol in the oil. On distilling this lower liquid over hydrate of lime, and leaving the distillate to stand for some time, the asarone separates out, and the remaining oil may be dehydrated by chloride of calcium. The oil is yellowish and viscid, smells like valerian oil, has a sharp burning taste, is lighter than water, sparingly soluble in water, but easily soluble in alcohol, ether, and in oils both fat and volatile. Blanchet and Sell (Ann. Ch. Pharm. vi. 296) deduce from their analysis (74·4 C, and 9·7 H) the formula C^8H^9O, which does not agree very well with it: the formula $C^{10}H^{15}O^2$, is more in accordance with the analysis. As, however, the oil doubtless still contained asarone, it is useless to attempt to determine its formula exactly till further experiments are made. It appears, however, to contain more carbon and hydrogen than asarone, which therefore may have been formed from it by oxidation.

ASBESTOS, or **ASBESTUS.** (ἄσβεστος, indestructible.)—A mineralogical term used rather to denote a peculiar form assumed by several minerals, than to designate any particular species. It is, in fact, applied to several varieties of amphibolic and augitic minerals, such as *actinolite*, *tremolite*, *anthophyllite*, &c. which occur in long capillary crystals, placed side by side in a parallel position, thus producing a fibrous mass. These conditions may be fulfilled in various degeees, and there are accordingly various kinds of asbestos. Those varieties whose fibres are very delicately and regularly arranged, are called *flexible asbestos*, or *amianth* (a Greek term, signifying *unpolluted*); the individual crystals are easily separated from each other, are very flexible and elastic, and have a white or greenish colour, with a fine silky lustre. A single fibre of this mineral fuses readily into a white enamel; but in the mass, it is capable of resisting ordinary flame, so that when woven it produces a fire-proof cloth. The most beautiful specimens are found in the Tarantaise in Savoy, and in Corsica, where it occurs very abundantly. It is also found near Barège in the Pyrenees, in Dauphiny, and on the St. Gothard; at St. Neverne in Cornwall; at Portsoy in Scotland; in mica slate at Glenelg, Inverness-shire; and near Durham. Those varieties in which the crystals are coarser, with scarcely any flexibility, are called *common asbestos*. There are also three other varieties, called *mountain leather*, *mountain cork*, and *mountain wood*, which differ from common asbestos by the fibres interlacing each other.

Common asbestos occurs in masses of fibres of a dull greenish colour, and of a somewhat pearly lustre. Fragments splintery. It is scarcely flexible, and much denser than amianthus. It is slightly unctuous to the touch. Specific gravity 2·7. Fuses with difficulty into a greyish-black scoria. It is more abundant than amianthus, and is found usually in serpentine, as at Portsoy in the Isle of Anglesea, and at the Lizard in Cornwall. It was found in the limestone of Glentilt, by Dr. M'Culloch, in a pasty state, but soon hardened by exposure to air.

Mountain Leather consists, not of parallel fibres like the preceding, but interwoven and interlaced so as to become tough. When in very thin pieces, it is called *mountain paper*. Its colour is yellowish-white, and its touch meagre. It is found at Wanlockhead, in Lanarkshire. Its specific gravity is uncertain.

Mountain Cork, or *Elastic Asbestos*, is, like the preceding, of an interlaced fibrous texture; opaque; has a meagre feel and appearance, not unlike common cork, and like that substance is somewhat elastic. It floats on water. Its colours are, white, grey, and yellowish-brown. It takes an impression from the nail; is very tough; cracks when handled, and melts with difficulty before the blowpipe. Specific gravity from 0·68 to 0·99.

Mountain Wood.—Ligniform asbestos is usually massive, of a brown colour, and has the aspect of wood. Internal lustre glimmering. Soft, sectile, and tough; opaque; feels meagre; melts to a black slag. Specific gravity 2·0. It is found in the Tyrol; Dauphiny; and in Scotland, at Glentilt, Portsoy, and Kildrumie.

The ancients manufactured cloth out of the fibres of flexible asbestos, for the purpose, it is supposed, of wrapping up the bodies of the dead when exposed on the funeral pile. This cloth has also been made in modern times, the chief artifice seeming to consist in the admixture of flax and a liberal use of oil, both which substances are afterwards consumed by exposing the cloth for a certain time to a red heat. Gloves are made of it for holding red-hot crucibles, &c. The cloth of asbestos, when soiled, is restored to its primitive whiteness by heating in the fire. Ignition impairs the flexibility of asbestos in a slight degree.—U.

ASBOLAN. See COBALT, EARTHY.

ASBOLINE. A nitrogenous substance contained, according to Braconnot (Ann. Ch. Phys. [2] xxxi. 37), in soot (ἀσβολη). It is extracted by boiling the soot with water, evaporating, redissolving in water, adding hydrochloric acid to the solution, washing the pitchy precipitate with cold water, then boiling it with water, filtering after cooling, evaporating again, and treating with boiling water till no deposit forms on cooling. The liquid then yields by evaporation a kind of varnish, partially soluble in alcohol; and on treating the residue with ether and evaporating, asboline remains in the form of a yellow, very acrid, bitter, volatile oil, which is lighter than water, burns with flame, and yields an ammoniacal product by distillation. Asboline dissolves in nitric acid, yielding picric and oxalic acids. Its aqueous solution is coloured deep red by alkalis, forms an orange-coloured precipitate with acetate of lead, reduces nitrate of silver, and is precipitated by infusion of galls.

ASCLEPIADIN. A bitter emetic principle, contained in the *Asclepias vincetoxicum.* It is insoluble in water, alcohol, and alcoholic ether. It appears not to contain nitrogen. (Fenelle, J. Pharm. [2] xi. 565.)

ASCLEPIONE. $C^{20}H^{34}O^3$.—When the white milky juice of *Asclepias syriaca* is heated, the albumin contained in it coagulates, and on treating the coagulum with ether, and evaporating, asclepione is deposited in finely radiated or cauliflower-like groups of crystals. It is tasteless, inodorous, quite insoluble in water and alcohol, but dissolves readily in ether, less easily in oil of turpentine, naphtha, and strong acetic acid. It melts at 104° C., and then remains amorphous. At a higher temperature, it decomposes, giving off the odour of burnt caoutchouc. It is not attacked by strong boiling potash. (List, Ann. Ch. Pharm. lxix. 125.)

ASH OF ORGANIC BODIES. When any part of an organised body, vegetable or animal, is burnt with free access of air, part of it is resolved into volatile compounds, chiefly water, carbonic anhydride, and free nitrogen, while the other, and generally the smaller portion, is left as incombustible residue or **ash.** This residue may contain the following elements: —

Basic.	*Acid.*
Potassium	Chlorine
Sodium	Bromine
Calcium	Iodine
Barium	Phosphorus (as phosphoric acid)
Iron	Sulphur (chiefly as sulphuric acid)
Magnesium	Silicon (as silicic acid)
Manganese	Carbon (as carbonic acid, and occasionally as cyanogen).
Aluminium	
Copper	
Zinc	
(Lead, nickel, cobalt, tin)?	

These substances are the so-called inorganic or mineral constituents of the vegetable or animal structure; they are essential to its existence, and are associated with the organic matter in certain definite forms, not necessarily the same as those which they assume in the ash. It must be remembered, however, that the distinction between the organic and inorganic elements of an organised body is by no means absolute: for the carbon and oxygen, which are never absent from the ash, belong essentially to the organic structure of the body. Perhaps the best distinction between the organic and inorganic constituents of a plant or animal body is, that the former, viz. the carbon, hydrogen, oxygen, and nitrogen, are derived, in great part at least, from the air, whereas the latter are derived exclusively from the soil.

The inorganic constituents above enumerated are not all of equal importance to the existence of organised structures, or of equally frequent occurrence. Potassium, sodium, calcium, magnesium, and iron, associated with phosphoric acid, sulphuric acid, carbonic acid, silicic acid, and chlorine, are almost always present, in greater or lesser quantity, in the ashes of organised bodies, whether vegetable or animal; fluoride of calcium, in very small quantity, appears also to be an almost invariable constituent; and manganese, also in small quantity, is of frequent occurrence; the other elements are of rare or doubtful occurrence.

The mineral constituents of plants and animals vary greatly in amount, as well as in composition. In *bone*, the inorganic matter constitutes from ½ to ¾ of the entire mass, the amount in individual cases depending upon the age and species of the animal; in the higher classes of animals, the bone-ash consists mainly of phosphate of calcium, with a smaller quantity of carbonate; in the lower classes, the proportions of these constituents are reversed. Phosphate of calcium occurs also in the ashes of the *albuminous principles*, both of plants and animals, and is especially abundant in the *seeds* of cereal and leguminous plants; phosphate of magnesium is abundant in the ash of wheat-grain. The alkaline chlorides are very widely diffused throughout the bodies of plants and animals; chloride of sodium is invariably present in the fluids of the animal body and in the juices of plants. Alkaline carbonates are always present in the *blood*, and appear to be essential to the solution of the albuminous principles. Carbonate of potassium forms the greater part of *wood-ash*. **Silica** is scarcely ever absent from the ashes of organised bodies. The ashes of *equisetaceous plants* contain 97 per cent. of silica. The hard external sheathing of the stems of *grasses* consists of silicate of potassium. The shields of the lowest classes of animals, *infusoria*, &c., consist mainly of silica, which is so thickly deposited in their organs, that neither decomposition nor incineration can destroy their form: hence it is that deposits of infusoria are so often discovered. In the tissues and juices of the higher classes of animals, silica occurs only as an incidental constituent, though it is seldom altogether absent. According to Gorup-Besanez (Ann. Ch. Pharm. lxvi. 342), it forms an integral constituent of *feathers* and of *hair*.

Sulphur occurs to the amount of about 1 per cent. in all the albuminoïdal substances, and is converted during incineration into sulphuric acid, which is found in the ash as alkaline sulphate, sometimes however more or less reduced to sulphide by the action of the carbon at a high temperature. The juices of the animal body and of plants also contain small quantities of alkaline sulphates and sulphate of calcium.

Iron is always present in vegetable and animal tissues and fluids, and is found in the ash as sesquioxide, either free or as basic phosphate.

Alumina has been found in considerable quantity in the juice of plants which exhibit an acid reaction, *e. g.* in *Lycopodium chamæcyparissus*, *L. clavatum*, and *L. denticulatum* (Salm-Horstmar, J. pr. Chem. xl. 302; Aderholdt, Ann. Ch. Pharm. lxxxii. 111; Solms-Laubach, *ibid.* c. 297). In most other plants, alumina is altogether absent, any small quantities that may be found in the ash, generally arising from impurity in the reagents, especially in the caustic potash or soda, or from want of due care in cleansing the leaves, roots, or other parts under examination, from adhering particles of soil.

The other metals above-mentioned as occasional constituents of ashes, occur only in very small quantity, their presence being mostly, perhaps, due to some peculiarity in the nutrition of the plant or animal in which they are found. A peculiar kind of violet (*Viola calaminaris*) with yellow flowers, was found by A. Braun (Pogg. Ann. xcii. 175) to contain **zinc**, which metal was likewise found in the soil, its presence doubtless determining the production of the peculiar variety of the plant. The ash of the blue blood of *Limulus cyclops* was found by Genth (Pogg. Ann. xcv. 60) to contain 0·08 to 0·33 per cent. of **oxide of copper**. The occurrence of **titanic acid** in plant-ashes is mentioned by Städeler (Wöhler's prakt. Chem. Uebungen, 1853 p. 173), of **baryta** by Scheele (in 1788), and more recently by Eckard (Ann. Ch. Pharm. c. 294), and by Forchhammer (Pogg. Ann. xcv. 60; Jahresber d. Chem. 1859, p. 987). On the occurrence of copper and other metals in plant-ashes, see also Jahresber. 1847—8, p. 874; 1849, p. 430; 1852, p. 702; 1853, p. 604.

As the mineral constituents of plants are all derived from the soil and vary greatly both in amount and in composition, it will be easily understood that the examination of plant-ashes is of great importance with reference to agriculture. A plant will not grow on soil deficient in the mineral substances which it requires; if phosphoric acid is deficient, wheat and other cereal grasses cannot form their seed in its normal amount; if there is a deficiency of silica, the straw will be weak. Some plants require abundance of alkali, others of lime, &c. The examination of the ash shows what particular mineral substances the plant requires, and consequently what substances must be supplied to it artificially in the form of manure, if they are not already contained in the soil.

We now proceed to describe the preparation and analysis of ashes.

Preparation of the Ash.—The substance to be incinerated must in the first place be carefully freed from extraneous matter. Herbs, roots, and barks, which are especially liable to be contaminated with adhering mould, clay, or sand, must first be cleaned from the grosser impurities by scraping, or otherwise, and then washed with a slightly moistened sponge to remove the fine dust; washing with large quantities of water is objectionable, as it may remove some of the soluble salts. Seeds are best cleaned by pouring distilled water upon them in a glass jar, stirring for a little while with a rod, and then pouring the whole on a coarse sieve, which allows the fine dust to run through, but retains the seeds. After repeating this treatment two or three times, the seeds may be further cleansed by rubbing them between a linen cloth. Animal substances are less liable to contamination with mechanical impurities: their incineration is often facilitated by exhausting them with water, and incinerating separately the aqueous extract and the residue. The quantity of material incinerated should be such as to yield from 4 to 6 grammes of ash. Of seeds, roots, barks, and leaves, which are for the most part rich in mineral constituents, from 100 to 200 grammes of the dried substance is generally sufficient; of wood, two or three times that quantity must be taken; of animal substances containing a large amount of water, it is often necessary to incinerate a much larger quantity. The substance should, previous to incineration, be carefully dried and somewhat comminuted; seeds, however, if not very large, are best incinerated without comminution.

The incineration must be conducted with great care, as the constitution of the ash is often materially affected by the manner in which it is performed. The chlorides of potassium and sodium, though fixed at comparatively low degrees of heat, volatilise perceptibly at the high temperature sometimes attained during the incineration, especially in a current of air; this is still further the case with iodides. Moreover, by the joint action of silica and charcoal, phosphates may be decomposed and phosphorus volatilised; sulphates also reduced to sulphides, or sulphuric acid driven off. And even when no actual loss takes place, different modes of incineration may give rise to considerable differences in the composition of the ash. Carbonates in an ash generally result from the combustion of salts of organic acids existing in the substance burned; they may, however, be introduced in other ways. If tribasic phosphate of sodium be ignited in presence of a large quantity of organic matter, sugar, for example, till the organic matter is charred, and the mass be then lixiviated with water, a solution of carbonate of sodium is obtained, and the residue, after the charcoal has been completely burned away, consists of pyrophosphate of sodium, the carbonic acid produced by the combustion of the organic matter having decomposed the tribasic phosphate, taken away 1 at. of the base, and converted it into carbonate. If, on the other hand, the mass be at once completely incinerated without lixiviation of the charcoal, nothing but tribasic phosphate will be obtained. In all cases then, in which the arrangement of the mineral constituents of an organised structure is to be inferred from the composition of the ash, great care must be taken to guard against or allow for any such modifications as that just noticed. In the examination of plant-ashes for agricultural purposes, such questions are indeed of minor importance, the chief object of the investigation being to determine the ultimate constituents of the ash; but in physiological inquiries, the actual arrangement of the mineral constituents in the living structure is often a point of great importance.

The difficulty of incinerating an organic substance is greatly increased when the ash is easily fusible, the decompositions just considered being then most likely to occur. Leaves, herbaceous stems, roots, bark, &c., which chiefly contain infusible salts of the alkaline earths, are comparatively easy to burn; but seeds, and many animal substances, such as dried blood, which contain large quantities of alkaline salts, are very troublesome, and require great care in regulating the temperature.

The method of incineration originally practised, especially for the preparation of plant-ashes, consisted in burning the dried substance in a Cornish or Hessian crucible, laid obliquely in the fire, and kept at a moderate red heat. The carbon then burns away with greater facility, the looser the texture of the charred mass, and the less its position and form are altered by movement and stirring. The objections to this method are that it often gives incorrect results regarding the amount of phosphoric acid, carbonic acid, and chlorine, inasmuch as chlorides are decomposed by the action of acid phosphates in presence of water, and at very high temperatures, phosphorus may be volatilised by the action of charcoal on acid phosphates. Extraneous matters may also be introduced into the ash by the action of phosphates in a state of fusion on the crucible.

A much better method is that recommended by **Erdmann**, which consists in incinerating the plant or animal substance in a muffle built into the mouth of a furnace in such a manner that the heat may play upon it chiefly from the top. The incineration goes on most favourably at a distance of 3 or 4 inches from the front aperture of the muffle, and at a low red heat not visible by daylight. At this temperature, there is no danger either of the volatilisation of chlorides or of the fusion of phosphates. If the muffle be kept loosely closed by a clay stopper, sufficient air will enter to produce, in the course of twelve hours, a quantity of ash free from charcoal sufficient for an analysis. A convenient mode of proceeding is first to char the substance in a platinum or porcelain dish, and then heat the charred residue in the muffle in the manner just described; the charcoal then burns away with slight incandescence. The ash may afterwards be weighed in the dish.

Messrs. **Lawes** and **Gilbert** use cast-iron muffles 18 inches long, 3½ inches high, and 5 inches wide at the bottom. The muffle, which has a flange at the fore part, fits exactly into an orifice in a cast-iron furnace front; and a 1½ inch pipe proceeding from the farther end of the muffle, passes through the cast-iron furnace back, and serves to carry away the evolved gases. The muffle rests on a brick in the furnace, to lessen bottom heat and thus prevent fusion, the fuel being heaped up at the sides and top, chiefly the latter. The substance is burnt in large platinum sheets or dishes, the latter 10 inches long, 4 to 5 inches wide, and 1½ inch deep. By this arrangement, the access of ash from the fire is entirely avoided; the ash is burnt by surface, not by bottom heat; the draught of air is free; and the incineration may be accomplished at a very low temperature.*

This is by far the best mode of incineration yet devised; nevertheless it is occasionally attended with slight loss of sulphur, phosphorus, chlorine, iodine, &c. To obviate these losses, it has been proposed to mix the substance to be incinerated with lime, baryta, or other strong bases capable of retaining the acids. Wackenroder adds for this purpose, acetate or carbonate of calcium, or quick lime; Strecker proposes to moisten the dried and charred substance with such a quantity of baryta-water, that the ash, after incineration, may contain about half its weight of baryta. The moistened charcoal is then dried and burnt in the muffle at as low a temperature as possible. To substances which produce ashes containing much carbonic and silicic acids, Way and Ogston, add for the same purpose, nitrate of barium; Slater adds peroxide of barium; Verdeil, nitrate of ammonium; and Will, mercuric oxide; but all these admixtures are attended with peculiar inconveniences, which stand in the way of their general application.

H. Rose adds a weighed quantity of carbonate of sodium, chars the substance in a crucible, and burns away the charcoal by directing a stream of oxygen upon it through an aperture in the lid. This method effects a complete and rapid combustion of the charcoal, but the high temperature produced often causes the ash to fuse, and then the crucible is attacked. Crucibles of stone-ware (*Steingut*) withstand the action better than those of porcelain.

[For the methods of Mitscherlich and Hlasiwetz, see Handw. d. Chem. 2te Aufl. ii. 352; for the latter also, Ann. Ch. Pharm. xcvii. 244.]

Analysis of the Ash.—Of the various methods which have been given for the analysis of ashes, the simplest and most generally applicable is that of Professor Will (Handw. d. Chem. 2te Aufl. ii. 361; Conington's Handbook of Chemical Analysis, p. 226). The ash prepared in the muffle at the lowest possible temperature, is triturated to a uniform powder, and preserved in a stoppered bottle. One portion of it is used to determine the carbonic acid by one of the methods given under ALKALIMETRY, p. 119. A second is treated with dilute nitric acid, and the filtrate is used for determining the chlorine by precipitation with nitrate of silver; while a third portion (4 or 5 grammes) is used for determining the silica and the other constituents. For this last purpose, the ash is treated with hydrochloric acid; the silica separated by complete evaporation to dryness, and digestion of the residue with water containing hydrochloric acid (see SILICA); and the quantity of the filtrate, together with the washings, is determined, either by weight or by measure.

In one portion of this filtrate, of known weight or volume, the sulphuric acid is determined by precipitation with chloride of barium; in a second, the lime, magnesia, sesquioxide of iron (alumina, if present), and the phosphoric acid; in a third, the alkalis.

Lime, Magnesia, Ferric Oxide, Phosphoric Acid.—If, as in the ashes of seeds and of many animal substances, all the bases, or the greater part of them, are present as phosphates, the liquid is first supersaturated with ammonia (or mixed with acetate of sodium), then with acetic acid, and the undissolved ferric phosphate, $Fe^4O^6.cP^2O^5$, is collected and weighed (together with phosphate of aluminium, if present, which may afterwards be separated by potash). The lime is next precipitated by oxalic acid, then part of the phosphoric acid and all the magnesia by ammonia, and the rest of the phosphoric acid by a magnesium-salt. In ashes containing a smaller proportion of phosphoric acid, part or the whole of the magnesia remains in solution after this treatment. This portion is determined by precipitation with phosphate of sodium, or (if the filtrate is to be afterwards used for the determination of the alkalis) with phosphate of ammonium. If manganese is likewise present (as a manganous salt), the ferric phosphate is first precipitated as above; the liquid filtered from the precipitate is mixed with a known volume of a standard solution of ferric chloride made as neutral as possible; the whole is heated to boiling; the precipitate thoroughly washed with hot water and dried; and from its weight, that of the (anhydrous) phosphoric acid is found by deducting the weight of the ferric oxide added†; to this quantity of phosphoric acid, must be added that which was previously determined as ferric phosphate (and phosphate of aluminum). In the filtrate, which contains manganese, calcium, and magnesium, these metals are determined by the usual methods, the manganese being precipitated as peroxide by hypochlorite of sodium, the precipitate collected after twenty-four hours, then ignited or weighed as manganoso-manganic oxide (Mn^3O^4).

Alkalis.—The ash, dissolved in hydrochloric acid, not in great excess, is mixed with

---

* For the above description, the Editor is indebted to the kindness of Dr. Gilbert.

† The amount of phosphoric acid in this precipitate might be determined directly by dissolving in hydrochloric acid, adding sufficient tartaric acid to prevent precipitation of iron and alumina by alkalis, then adding excess of ammonia, and precipitating by a magnesium-salt.

oxalic acid, then with excess of ammonia, and if magnesia is still in solution with phosphate of ammonium.* The precipitate is washed with ammoniacal water; the filtrate is evaporated a little to expel the excess of ammonia, and mixed while still hot with acetate of lead; the liquid is again filtered, and the excess of lead removed by ammonia and carbonate of ammonium; the filtrate from this precipitate, together with wash-water, is evaporated, with addition of sal-ammoniac; and the ammoniacal salts are expelled by gentle ignition. The residue, which contains nothing but the chlorides of potassium and sodium, is then weighed, and the relative quantities of the two chlorides are determined, either by precipitating the potassium with dichloride of platinum, or determining the amount of chlorine by precipitation with nitrate of silver. (See ANALYSIS, INDIRECT, p. 220.)

Knop and Arendt (Chem. Centralbl. 1857, 169), determine the phosphoric acid in ashes by adding *uranic acetate* to the solution, acidulated with acetic acid as above, whereby a precipitate of ammonio-uranic phosphate is produced, which, when ignited with addition of a few drops of nitric acid, leaves uranic phosphate, containing $2Ur^4O^3.P^2O^5$. (For the details of the method, see PHOSPHORIC ACID, under PHOSPHORUS.)

For other methods of ash-analysis, see Fresenius and Will, Ann. Ch. Pharm. l. 363; Erdmann, J. pr. Chem. xxxviii. 20; H. Rose, Pogg. Ann. lxxx. 94, and Handb. d. Analyt. Chem. ii. 766; Mitscherlich, J. pr. Chem. xxxv. 231; Wackenroder, Arch. Pharm. [2] liii. 1; Städeler, Prakt. Uebungen in der Chem. Anal. von Wöhler, 1853, 172; Wittstein, Pharm. Centralbl. 1853, 761. Also for a description of all these methods, Handw. d. Chem. 2te Aufl. ii. 353.

For the composition of the ash of individual plants, see the names of the plants in this dictionary. Extensive tables of the composition of plant-ashes are given in the first five volumes of Liebig and Kopp's *Jahresbericht für Chemie*, 1847 to 1852. The new edition of Ure's *Dictionary of Arts, Manufactures, and Mines* (i. 212), also contains a table showing the average composition of the ash of some of the most useful agricultural plants.

ASH, VOLCANIC. This name is applied to the pulverulent portion of the matter thrown out by volcanos. The ash emitted by different volcanos, by the same volcano at different times, and even at different stages of the same eruption, exhibits great differences of structure and composition. It is sometimes dark-coloured or even black, and composed of earthy or soft particles, sometimes grey or white, and finely divided. In the eruption of Vesuvius, A.D. 79, which overwhelmed Pompeii and Herculaneum, the ash was so fine and dry that it took exact casts of objects buried in it. It is this finely divided matter to which the term ash is especially applied, the coarser varieties being generally denominated volcanic sand; it sometimes rises to considerable heights, and is then carried by the wind to great distances. In the eruption of Coseguina, on the Bay of Conchagua, in Guatemala (1835), some of the ash fell at Kingston in Jamaica, at a distance of 700 miles.

Volcanic ash, when examined by the microscope, appears to be composed of fragments of lava, slag, mica, felspar, magnetic iron ore, augite, pumice, olivine, &c. It is therefore a mechanical mixture of minerals and rocks abraded by trituration against each other. In the ash thrown out by Vesuvius on the 22nd of October 1822, Vauquelin found 28 pts. silica, 8·0 alumina, 18 gypsum, 20·88 iron pyrites, 2·6 lime, and 1 carbon, together with 41·42 pts. sulphate of copper, sulphate of ammonium, chlorides, and sulphur. In the ash emitted from the crater of the Soufrière in Guadaloupe, in 1797, Dufrénoy (Ann. Ch. Phys. [2] lxvii. 251) found 2 per cent. of alum, potash, and gypsum, 8·84 water, 32·61 pts. of matter attacked by acids (which he regarded as labrador), and 56·23 pts. not attacked by acids (regarded as glassy felspar). In the ash thrown out by the same crater in the year 1836, Dufrénoy found 50·88 pts. of matter insoluble in acids, 33·72 pts. soluble in acids, 6·93 water and 0·62 sulphur (loss 1·85 per cent.)

The following table contains the results of a few more recent analyses: *a*, *b*, ash from the above-mentioned eruption of Coseguina (Dufrénoy and Élie de Beaumont, Ann. Ch. Phys. [2] lxviii. 266); this ash contained 18 pts. of matter decomposible by hydrochloric acid (*a*), and 82 pts. unattacked by that acid (*b*). *c*, Ash from Gunnung-Gurtur, in Java; eruption of January 4th, 1843 (Mayer, Leonhard and Bronn's Jahrb. d. Miner. 1853, 463). *d*, Ash from the same volcano; eruption of November 25th, 1843. Of this ash, water dissolved 0·3 per cent. consisting of lime and magnesia-salts (Schweitzer, J. pr. Chem. lxv. 194). *e*. So-called *ferric* ashes, and *f*, so-called *ferrous* ashes from Etna (Sartorius von Waltershausen, "Vulcanishe Gesteine," Göttingen, 1853, 172). *g*. Ash from the eruption of Hecla in 1846 (Genth, *ibid.* 176).

ASPARAGINE. $C^4H^8N^2O^3$, or $C^8H^8N^2O^6$. *Altheine, Asparamide.* (Gm. x. 239.)—This substance was discovered in 1805 by Vauquelin and Robiquet (Ann. Chim. lvii. 88). It exists ready formed in many plants, viz. in common asparagus (*Asparagus officinalis*), in the marsh-mallow (*Althaea off.*), in comfrey (*Symphytum off.*), in potatoes, in chestnuts, in the leaves of the deadly nightshade (*Atropa Belladonna*), in liquorice-root, in the root of *Robinia pseudacacia*, in *Convallaria majalis*, and *C. multiflora*, in the milky juice of the lettuce, in the tubers of the dahlia, and in the young shoots of vetches, peas, beans, and several other leguminous plants grown in the dark. According to Piria (Ann. Ch. Phys. [3] xxii. 160), the young shoots of these plants, when formed in the light, contain just as much asparagine as when they are grown in the dark; but the asparagine disappears as the plant arrives at the flowering stage. On the other hand, Dessaignes and Chautard (J. Pharm. [3] xiii. 245), and likewise Pasteur (Ann. Ch. Phys. [3], lxxxi. 70), find that vetches growing in light are free from asparagine.

Preparation.—The juice obtained from the young shoots of *asparagus*, filtered and evaporated to a syrup, deposits after standing for some days, crystals of asparagine, which may be purified by recrystallisation from water. As the mucus of the plant impedes the crystallisation, it is best to leave the shoots to ferment for a few days in a warm place, and then bruise and press them, with addition of water; by this treatment the mucus is decomposed. In a similar manner, asparagine may be obtained from marsh-mallow roots, and from the young shoots of vetches, &c. grown in the dark. To obtain asparagine from liquorice-root, the root is cut into pieces and exhausted with water; the liquid boiled to precipitate the albumin, then mixed with acetic acid to separate the glycyrrhizin contained in the root, and afterwards with acetate of lead, which throws down phosphate and malate of lead, together with brown colouring matter; and the excess of lead is removed by sulphydric acid. The filtered liquid evaporated to a small bulk, deposits crystals of asparagine after a few days.

Asparagine forms hard brittle crystals, $C^4H^8N^2O^3.H^2O$, belonging to the trimetric system. The ordinary form is a right rhombic prism, $\infty P\ .\ oP\ .\ m\breve{P}\infty\ .\ \infty\bar{P}\infty$, with the hemihedral faces $\frac{P}{2}$. Inclination of the faces, $\infty P : \infty P = 129° 37'$; $\frac{P}{2} : oP = 116°\text{-}57'$; $m\breve{P}\infty : oP = 120° 46'$. Specific gravity 1·519 at 14° C. The crystals are inodorous, have but a slight taste, and are permanent in the air. They give off water of crystallisation at 100° C. They dissolve in 11 pts. of cold, and 4·44 pts. of boiling water; the solution has a slight acid reaction. Asparagine dissolves also in acids and in alkalis. It is insoluble in cold absolute alcohol, and nearly insoluble in that liquid at higher temperatures; insoluble also in ether and in oils, whether fat or volatile.

Asparagine dissolved in water and in alkalis, deflects the plane of polarisation of a ray of light to the left; but when dissolved in acids, it deflects the plane of polarisation to the right. The specific rotatory power of an acid solution is + 35°, and of an ammoniacal solution, − 11° 18'..

Asparagine heated with strong acids or alkalis, is resolved into aspartic acid and ammonia:

$$C^4H^8N^2O^3 + H^2O = C^4H^7NO^4 + NH^3.$$

The crystals subjected to dry distillation also give off ammonia, and leave aspartic acid. Asparagine dissolved in cold nitric acid, yields aspartic acid and nitrate of ammonium, but when subjected to the action of nitrous acid, as when nitric oxide gas is passed through a solution of asparagine in pure and moderately strong nitric acid, it is converted into malic acid, with evolution of nitrogen:

$$C^4H^8N^2O^3 + N^2O^3 = C^4H^6O^5 + N^4 + H^2O$$

The solution of pure asparagine-crystals may be kept unaltered; but if the crystals are coloured, their solution soon passes into a state of fermentation, and the whole of the asparagine is converted into succinate of ammonium:

$$C^4H^8N^2O^3 + H^2O + H^2 = C^4H^4(NH^4)^2O^4.$$

The hydrogen is derived from the fermenting matter. A solution of perfectly pure asparagine experiences the same change when mixed with a small quantity of the juice expressed from the young shoots of vetches (Piria). Asparagine ferments also under the influence of casein, and is converted first into aspartate of ammonium, afterwards into succinate.

Asparagine forms definite compounds with acids. The *hydrochlorate*, $C^4H^8N^2O^3.HCl$, is obtained in large crystals either by dissolving 1 at. asparagine in 1 at. hydrochloric acid, evaporating at a gentle heat, and adding alcohol; or by passing dry hydrochloric acid gas over finely pounded crystals of asparagine, exposing the resulting compound to the air till it no longer gives off acid vapours, then dissolving in hot water, and leaving the solution to cool.

Asparagine also forms salts in which 1 at. of its hydrogen is replaced by a metal; thus the *copper-salt* is $C^4H^7CuN^2O^3$. These salts are obtained by mixing a solution of asparagine with the corresponding oxides. Asparagine also unites with chloride of mercury and nitrate of silver.

Asparagine has the same composition as malamide, $N^2(H^4.C^4\overset{''}{H}{}^4O^3)$, and its conversion into malic acid by the action of nitrous acid, suggests the idea that it may be really the amide of that acid. According to Demondesir, however (Compt. rend. xxxiii. 227), and Pasteur (Ann. Ch. Phys. [3] xxxviii. 437) the amide obtained by the action of ammonia on malic ether, differs from asparagine in crystalline form and in other properties.

ASPARAGOLITE. An old name of the variety of apatite which has the green colour of asparagus.

ASPARAGUS OFFICINALIS. The ashes of wild and cultivated asparagus, and of the young heads of the cultivated plant, have been analysed by T. J. Herapath (Chem. Soc. Qu. J. ii. 9). 100 parts of the fresh wild plant yielded 2·42 pts. of ash; 100 pts. of same dried, 6·07 per cent. ash. The cultivated plant yielded in the fresh state 1·53, and in the dry state 6·07 per cent. ash. The young heads in a state fit for the table gave 0·81 per cent. and 11·24 per cent. ash. The constituents of the several ashes are as follows:—

Soluble in water:		Wild.	Cultivated.	Young Heads.

ASPARAMIDE. Syn. with ASPARAGINE.

ASPARAMIC ACID. Syn. with ASPARTIC ACID.

ASPARTIC ACID. $C^4H^7NO^4$, or $C^8H^7NO^8$. (Plisson, Ann. Ch. Phys. xxxv. 175, xl. 303.—Plisson and O. Henry, *ibid.* xlv. 315.—Boutron-Chautard and Pelouze, *ibid.* lii. 90.—Liebig, Pogg. xxxi. 232, Ann. Ch. Pharm. xxvi. 125, 161.—Piria, Ann. Ch. Phys. [3] xxii. 160.—Dessaignes, Compt. rend. xxx. 329; xxxi. 342; Ann. Ch. Pharm. lxxxiii. 83.—Pasteur, Ann. Ch. Phys. [3] xxxiv. 30; Ann. Ch.

Pharm. lxxxii. 324.—Gm. x. 230; Gerh. i. 812.)—This acid, which is isomeric, if not identical with malamic acid, $O\left\{\begin{matrix}N.(H^2.C^4H^4O^3)\\H\end{matrix}\right.$, is obtained either by the decomposition of asparagine, chiefly under the influence of acids or alkalis, or by the action of heat on the acid malate, maleate, or fumarate of ammonium. The acids obtained by these two processes are identical in composition, but differ in their relations to polarised light, the former being optically active, the latter inactive.

To prepare *active aspartic acid*, asparagine is boiled: 1. With water and oxide of lead, as long as ammonia continues to escape, the water being replaced as it evaporates: the resulting aspartate of lead, after being purified by boiling with water and alcohol, is decomposed by sulphydric acid, and the filtered solution is evaporated till it crystallises (Plisson).—2. With baryta-water, the aspartate of barium being decomposed by sulphuric acid (Boutron and Pelouze).—3. With potash, the liquid being afterwards evaporated to dryness with excess of hydrochloric acid, and the chloride of potassium dissolved out by water, which leaves the aspartic acid undissolved and perfectly free from potash (Liebig).—4. With hydrochloric acid, for three hours, the solution being then evaporated to dryness, and the residual chloride of ammonium and hydochlorate of aspartic acid dissolved in a small quantity of water and half neutralised with ammonia; the liquid on cooling deposits a considerable quantity of aspartic acid. (Dessaignes.)

Active aspartic acid crystallises in very small thin, shining, rectangular plates, truncated at the angles; they belong to the trimetric system. Specific gravity 1·6613 at 12·5° C. It is much less soluble in water than asparagine, 1 pt. of it requiring 364 pts. of cold water to dissolve it. In boiling water it dissolves more readily, but is nearly insoluble in alcohol. It dissolves readily in alkalis, and the solutions turn the plane of polarisation of a luminous ray to the left. It is also easily soluble in the stronger acids, and the solutions thus formed turn the plane of polarisation to the right. The specific rotatory power of the solution in hydrochloric acid is + 27° 86′. (Pasteur.)

Inactive Aspartic Acid is obtained by heating acid malate of ammonium to 200° C.; boiling the residue for some hours with hydrochloric acid; dissolving the hydrochlorate of aspartic acid, which crystallises from the liquid on cooling, in hot water, and half saturating the solution with ammonia. Inactive aspartic acid then separates in small crystals, belonging to the monoclinic system. Ordinary combination $\infty P . oP . [P\infty]$. Inclination of the faces, $\infty P : \infty P$ in the plane of the oblique diagonal and the principal axis = 128° 28′; $oP : \infty P = 91° 30′$; $[P\infty] : oP = 131° 25′$. The crystals are grouped in stars, and sometimes take a lenticular form. Specific gravity 1·6632 at 12′ 5° C. The inactive acid is more soluble in water than the active acid, 1 part of it dissolving in 208 pts. of water at 13·5° C. It dissolves very easily in hydrochloric and in nitric acid. The solutions have no action on polarised light. (Dessaignes, Pasteur.)

Aspartic acid is decomposed by heat, giving off ammonia and a faint empyreumatic odour, like that evolved in the destructive distillation of animal substances. It is not acted upon by boiling with hydrochloric acid or with dilute sulphuric acid, but when heated with strong sulphuric acid, it decomposes, and sulphurous acid is given off. It is not decomposed by pure nitric acid, but if nitrous acid is also present, as when nitric oxide gas is passed through a solution of aspartic acid or nitric acid, the aspartic acid is converted into malic acid, with evolution of nitrogen gas:

$$\underbrace{2C^4H^7NO^4}_{\substack{\text{Aspartic}\\\text{acid.}}} + N^2O^3 = \underbrace{2C^4H^6O^5}_{\substack{\text{Malic}\\\text{acid.}}} + N^4 + H^2O$$

Compounds of Aspartic Acid with Acids.—Both the active and inactive varieties of aspartic acid dissolve in the stronger acids, forming definite compounds, which by evaporation over the water-bath, or better by spontaneous evaporation, are obtained in crystals. The compounds are active or inactive to polarised light, according as they are obtained from the active or inactive acid.

The *active hydrochlorate*, $C^4N^7NO^4.ClH$, forms crystals belonging to the trimetric system; they are prisms with angles of about 90°, very much truncated on two opposite lateral edges, and terminated by faces inclined at an angle of about 115°, and belonging to an irregular tetrahedron. The crystals deliquesce in the air, the aspartic acid being set free. They are decomposed by solution in water, but the addition of a few drops of hydrochloric acid prevents the decomposition. Specific rotatory power of the solution + 24·4°. The crystals are decomposed by heat, giving off water and hydrochloric acid, and leaving fumarimide. The crystals of the *inactive hydrochlorate* belong to the monoclinic system, and differ altogether in appearance from those of the active compound. Ordinary combination ∞P . ∞P∞ . −P . oP . +mP∞. Inclination of the faces oP : ∞P∞ = 119° 45′; ∞P∞ : ∞P = 123°. The crystals are nearly unalterable in the air, only in summer losing their lustre and transparency, and becoming milk-white on the surface. They decompose when dissolved in water, but the inactive acid being more soluble than the active acid, is not precipitated; if, however, alcohol be added, an abundant precipitation takes place. The inactive hydrochlorate is decomposed by heat like the active salt.

The *sulphate*, $C^4H^7NO^4.SO^4H^2$, is obtained by gradually adding aspartic acid to strong sulphuric acid heated to 50° or 60° C. in a wide glass tube, and leaving the tube closed for a few days; it then separates in large agglomerated prisms, which are lighter than the mother-liquor (Dessaignes). The *nitrate* is obtained, like the hydrochlorate, in beautiful crystals.

Aspartates.—Aspartic acid is monobasic, the formula of its normal salts being $C^4H^6MNO^4$. It likewise forms basic salts, the composition of which is not very clearly made out. The aspartates of the alkali-metals are soluble, and taste like broth. The active and inactive aspartates agree in composition, and in most of their properties, differing only in solubility, crystalline form, and relation to polarised light.

The *ammonium* and *potassium* salts are very soluble and difficult to crystallise.

The *sodium-salts*, $C^4H^7NaNO^4.H^2O$, are obtained by neutralising the acid with caustic soda or its carbonate, and leaving the solutions to evaporate slowly; they are perfectly neutral. The *active salt* crystallises in prismatic needles belonging to the right prismatic system, and terminated by faces of a tetrahedron inclined to one another at about 106°. The four faces of this tetrahedron are either present alone, or are much more developed than those of the opposite tetrahedron, which, if equally developed with the former, would constitute a rhombic pyramid; 1 part of this salt dissolves in 1·12 pts. of water at 12·2 C. The specific rotatory power of the solution is −2° 23′. The salt gives off its water of crystallisation at 160° C., turns yellow and gives off ammonia at 170°, and froths up considerably at higher temperatures. The *inactive sodium-salt* crystallises in the monoclinic system, the ordinary combination being ∞P . ∞P∞ . oP . +P. Inclination of the faces, oP : ∞P∞ = 144° 46′; ∞P : ∞P, in the plane and of the oblique diagonal and principal axis = 51° 38′; +P : +P = 112° 53′. The salt often forms twin-crystals, with the face of junction ∞P∞. One pt. of the salt dissolves in 1·19 pts. of water at 12·5° C.

Normal barium-salt, $C^4H^6BaNO^4.2H^2O$.—The active salt crystallises in very slender silky needles soluble in water, and giving off 14·4 per cent. water at 120° C. (Dessaignes). The *inactive normal salt* forms an uncrystallisable gummy mass (Wolff). The *basic* barium-salt is obtained by gradually adding hydrate of barium to a hot and rather strong solution of the normal salt. The liquid solidifies on cooling in a crystalline mass, but by recrystallisation from boiling water in a vessel protected from the carbonic acid of the air, this salt may be obtained in rather large shining prisms containing $2C^4H^6BaNO^4.Ba^2O + 5H^2O$. In vacuo, the crystals give off 3 at. water; when heated to 160° C. they lose 16·4 per cent., and the residual salt contains, according to Dessaignes, 57·05 per cent. Ba^2O, agreeing nearly with the formula $C^4H^5Ba^2NO^4$, which requires 57·55 per cent. This is the formula of the normal salt of a dibasic acid; but since aspartic acid is in all probability an amidogen-acid, and such acids are always monobasic, it is rather to be supposed that the true formula of the salt dried at 160° C. is $2C^4H^6BaNO^4.Ba^2O$. This formula requires only 55·0 per cent. Ba^2O; the greater proportion obtained by Dessaignes may have been due to the presence of carbonate of barium. (Gerhardt, Traité, i. 818.)

The *normal calcium-salt* is gummy, and tastes like the sodium-salt. The *basic* salt frequently forms prismatic crystals containing $2C^4H^6CaNO^4.Ca^2O + 7H^2O$; according to Dessaignes, it gives off 8 atoms of water at 160° C., and is then reduced to $C^4H^5Ca^2NO^4$.

Magnesium-salts.—The normal salt forms crystalline crusts, soluble in about 16 pts. of boiling water, insoluble in absolute alcohol. The basic salt obtained by dissolving magnesia in the normal salt is a gummy mass.

Aspartate of Zinc is a white non-deliquescent salt. *Aspartate of nickel* is obtained by evaporation in a green fissured mass. An aspartate of *iron* is precipitated on adding a solution of basic aspartate of magnesium to sesquichloride of iron.

Aspartates of Copper.—The normal salt of the active acid exists only in solution. A basic salt is obtained by adding a solution of the normal barium-salt to a hot solution of sulphate of copper. The liquid on cooling deposits pale blue, very light crystals which, according to Dessaignes, contain $C^4H^5Cu^2NO^4.5H^2O$ (or rather, perhaps, $2C^4H^6CuNO^4.Cu^2O + 9H^2O$), and give off their water at 160° C., leaving the anhydrous salt $C^4H^5Cu^2NO^4$. Inactive aspartate of ammonium forms a bluish precipitate with copper-salts. (Wolff.)

Aspartates of Lead.—The normal lead-salt, $C^4H^6PbNO^4$, is obtained by precipitating a solution of acetate of lead with aspartate of potassium or basic aspartate of calcium. On mixing an ammoniacal solution of normal acetate of lead with inactive aspartate of sodium, a curdy precipitate is formed, and the filtered liquid, if diluted with a considerable quantity of water, deposits, after two or three days, nacreous crystals united in very hard spherical masses. These crystals are anhydrous, and contain 63·88 per cent. of lead-oxide, agreeing with the formula $2C^4H^6PbNO^4.Pb^2O$, which requires 64·5 per cent. Pb^2O. The formula $C^4H^5Pb^2O^4$, analogous to that of the basic aspartates examined by Dessaignes, would require 66·1 per cent. of lead-oxide (Pasteur). The sodium-salt of active aspartic acid also forms a precipitate with ammoniacal acetate of lead, and the liquid afterwards deposits hard radiated nodules containing 65 per cent. lead-oxide; these, however, are nothing but a basic acetate of lead. (Pasteur.)

Aspartate of Mercury.—Mercuric oxide, boiled with aspartic acid, forms a white powder, containing, when dried at 100°, $2C^4H^6HgNO^4.Hg^2O$, a composition analogous to that of Pasteur's basic lead-salt. (Dessaignes.)

Aspartates of Silver.—When nitrate of silver is added to a slightly alkaline solution of aspartate of ammonium, a precipitate is formed, which disappears on stirring, and the liquid, after 24 hours, yields white, heavy, entangled crystals of a basic salt. The mother-liquor, left to crystallise, deposits yellowish crystals of the normal salt, $C^4H^6AgNO^4$. The basic salt appears to be $C^4H^5Ag^2O^4$. This formula requires 66·86 per cent. oxide of silver, and the mean of several analyses made by different chemists, and not differing by more than 0·2 per cent., gives 66·7 per cent. This salt appears then to be really a dibasic aspartate. Pasteur finds, however, that the same salt, when merely pressed between paper, and then dried for 24 hours at the ordinary temperature, agrees in composition with the basic lead- and mercury-salts, its formula being $2C^4H^6AgNO^4.Ag^2O$. The active and inactive acids yield silver-salts identical in composition. (Pasteur.)

Aspartate (?) *of Ethyl.*—When malate of ethyl is saturated with dry ammonia-gas, the liquid becomes heated, and in a few days solidifies to a radiated crystalline mass, which, after being drained, and then washed with ether, consists of pure malamate (or aspartate) of ethyl, $\left.\begin{matrix} N(H^2.C^4H^4O^3) \\ C^2H^5 \end{matrix}\right\} O$. By further treatment with ammonia, it is converted into malamide [? asparagine]. (Pasteur.)

ASPASIOLITE. A variety of *cordierite* [$3(Mg^2O.SiO^2) + Fe^2O.SiO^2 + 2(2Al^4O^3.3SiO^2)$], in which the magnesia is partly replaced by water. The two minerals crystallise in the same form, and crystals are found consisting partly of cordierite, partly of aspasiolite, the most complete transitions from one to the other occurring in the same specimen. Moreover, both minerals contain the same proportions of silica and alumina; but aspasiolite contains less magnesia and more water than cordierite, the difference being that 1 at. of magnesium in the latter is replaced by 3 at. of hydrogen in the former (or 1 at. of magnesia by 3 at. of water). Similarly it is found that 1 at. of iron or manganese may be replaced by 3 at. H without alteration of crystalline form. This kind of isomorphism, called *polymeric* isomorphism, was discovered by Scherer; it was first noticed in the minerals cordierite and aspasiolite. (Pogg. Ann. lxviii. 319.)

ASPERTANNIC ACID. A variety of tannic acid obtained by Schwartz (Ann. Ch. Pharm. lxxx. 333) to be contained in woodruff (*Asperula adorata*). Schwarz assigns to it the formula $C^{14}H^8O^8$, but it does not appear to have been obtained in a state of purity. (See also Rochleder, Ann. Ch. Pharm. lxxxiii. 64.)
